BACKGROUND: Human insulin (Regular, Neutral Protamine Hagedorn (NPH), 70/30 Regular/NPH mix), is available over-the-counter at a relatively low cost. Recent reports in the news media have indicated that some patients with limited to no insurance coverage rely on human insulins for treatment. Such patients are also at risk for poor diabetes outcomes. Using a nationally representative, publicly available data set, we sought to examine whether there were sociodemographic differences in patients who use human insulin versus insulin analogues and whether the type of insulin used was associated with differences in glycemic control or hospitalization.

METHODS: This study was a cross-sectional analysis of the National Health and Nutrition Examination Survey (NHANES), a publicly available data set compiled and maintained by the Center Disease Control and Prevention's (CDC) National Center for Health Statistics (NCHS). Data was selected from four survey cycles (2007-2014) for participants who had interview and examination data, were 21 years and older, and reported current use of insulin. Participants were divided into three groups based on insulin formulation (human only, analogue only, and combination human/analogue insulins). Outcomes of interest were HbA1C and self-reported hospital utilization in the past 12 months. With insulin type as a predictor of interest, we controlled for potential confounders that were associated with our outcomes of interest.

RESULTS: Out of 802 respondents who report current insulin use, 698 reported the type of insulin used (human only n=162; analogue only n=500; and human/analogue combination n=36). In our bivariate analysis we found that respondents who used human insulin were more likely to identify as non-Hispanic African American than non-Hispanic White (38.9% vs 28.8%, p=0.002) and were less likely to be college graduates (9.9% vs 14.6% p=0.024). Although not statistically significant, respondents who reported an insurance lapse in the past year and those with marginal food security were more likely to report use of human insulin compared to analogue insulin (8.5% vs 3.8% p=0.087; 14.9% vs 11.8% p=0.236). There was no significant association between insulin type and glycemic control as measured by HbA1c. After multivariate adjustment, use of human insulin was not associated with differences in HbA1c or rate of hospitalization.

CONCLUSIONS: In a nationally representative sample of patients with diabetes who use insulin, we found that use of human insulin was more common among patients who had characteristics associated with low socio-economic status, such as minority race, lower education, unstable insurance and food insecurity. However, we did not observe differences in outcomes. Our findings suggest that human insulins may offer similar glycemic control, potentially at lower cost. However, further research should be conducted to understand outcomes for specific populations of patients of low socioeconomic status who appear to use human insulins at higher rates.

SOLO SE VIVE UNA VEZ (YOU ONLY LIVE ONCE): A CAMPAIGN TO IMPROVE HIV TESTING AMONG LATINX IN BALTIMORE

Harita Shah; Suzanne M. Grieb; Alejandra Flores-Miller; Kathleen Page. Johns Hopkins University, Baltimore, MD. (Control ID #3162751)

BACKGROUND: Of the 263,000 Latinx with HIV in the US, one fifth are unaware of their infection. Consistent with national trends, Baltimore City Health Department (BCHD) data show that HIV-infected Latinx in Baltimore are more likely to be diagnosed late than any other racial/ethnic groups. In prior studies, we demonstrated prominent barriers to HIV screening among Latinx in Baltimore include HIV stigma, cultural/linguistic discordance, lack of insurance, and fear of deportation. Interventions that include complementary individual and community components have been shown to improve HIV testing rates; thus, we partnered with BCHD to create the Solo Se Vive Una Vez campaign to increase HIV screening rates among Latinx in Baltimore. The present study assessed reach of the campaign and its impact on people's decision to get tested.

METHODS: From July to December 2018, we implemented the Solo Se

Vive Una Vez campaign across Baltimore. On an individual level, the campaign centers on a website (solovive.org) addressing barriers to testing and offering rapid HIV testing with bilingual outreach workers. On a community level, the campaign was advertised through social media, dating apps, community events, buses, billboards, and radio. We conducted cross sectional surveys of Latinx adults obtaining HIV testing at the BCHD clinic and outreach before (n=78) and after (n=315) the campaign launch. Surveys assessed demographics, HIV testing history, exposure to the campaign, and influence of the campaign on the decision to get tested. Sexual risk behaviors and PrEP information were obtained from BCHD medical records by trained research assistants. Characteristics of the population exposed to the campaign versus not exposed were compared using t-test and chi squared analyses.

RESULTS: 34% (106) of respondents surveyed after the campaign launch reported exposure to the Solo Se Vive Una Vez campaign, compared to 0% in the baseline surveys. Of those exposed to the campaign, 86% reported that it positively influenced their decision to get tested. Respondents who had campaign exposure had significantly higher numbers of sexual partners and rates of paying drugs/money for sex (p<0.05). The most common channels for exposure included Facebook, the website, and community events. 9,790 unique users have visited the website to date, and 127 unique users requested HIV testing through the website. 89% of Latinx surveyed had never heard of PrEP and were provided PrEP information.

CONCLUSIONS: Solo Se Vive Una Vez is Baltimore's first Spanish-language public health campaign promoting HIV screening among Latinx. It achieved comparable rates of exposure to other campaigns addressing HIV testing in Latinx. The campaign positively influenced the majority of testers exposed to it to get tested, including Latinx with high risk sexual behaviors. Based on the survey cohort, an estimated 29% got tested due to the campaign; BCHD surveillance data is currently being tabulated to measure effect on testing rates for Latinx in Baltimore.

SOURCE OF DIABETES KNOWLEDGE INFORMATION AND ITS IMPACT ON SELF-MANAGEMENT BEHAVIOR AMONG OLDER US ADULTS

Jennifer A. Campbell¹; Emma Garacci²; Leonard E. Egede¹. ¹Medical College of Wisconsin, Milwaukee, WI, ²Meidcal College of Wisconsin, Milwaukee, WI. (Control ID #3177601)

BACKGROUND: Diabetes Self-Management (DSM) is a key part of diabetes care and critical to maintaining optimal outcomes. Effective DSM requires knowledge, skills, and understanding of lifestyle changes to address modifiable risk factors that lead to diabetes complications. Diabetes knowledge information can be accessed from a number of sources outside of the diabetes care team including internet, magazines, television, and friends. Understanding how these sources of knowledge for diabetes may impact DSM behaviors has important implications for diabetes care and DSM Education practice.

METHODS: Data from 1,901 adults from the Health and Retirement Survey (HRS) 2003 diabetes cohort was used. The outcome, DSM behaviors included medication adherence, diet, and blood sugar testing. The primary independent variable was source of diabetes information. This included patients reporting how often they received diabetes information from the following: television, internet, newspaper or magazines, books, and friends. Survey logistic regression models tested the likelihood of performing recommended DSM behaviors, and whether source of information was associated with DSM behaviors. The model controlled for age, gender, race, education, and marital status.

RESULTS: The mean age of the population was 70 years. The majority of the population were non-Hispanic White (76%), and 44% of participants had at least a high school diploma. Patients reporting the internet as a source of diabetes information was significantly related to lower odds of medication adherence for taking recommended medication (OR 0.37; CI 0.21-0.65), as well as taking recommended dose (OR 0.43; CI 0.24-0.76). Patients reporting television (OR .68; CI 0.51-0.91), newspapers/magazines (OR

0.55; CI 0.42-0.73), and friends (OR 0.62; CI 0.47-0.82) as a source of diabetes information was related to lower odds of following a recommended healthful eating plan compared to those not using these sources for diabetes information. Conversely, reporting books as a source of diabetes knowledge was related to 74% higher odds of eating 5 or more servings of fruits/vegetables (OR 1.74; CI 1.22-2.49), 53% higher odds of testing blood sugar as recommended (OR 1.53; CI 1.04-2.25), and 35% higher odds of following a healthful eating plan (OR 1.35; CI 1.05-1.73).

CONCLUSIONS: Overall, sources of diabetes information had a differential relationship with DSM behaviors. Patients reporting the use of books as a source of diabetes information had significantly higher likelihood of following a healthful eating plan, following recommended diet for fruits/vegetables, and were more likely to test their blood sugar as recommended by their physician. Taken together, these results provide new information on the impact that sources of diabetes information may have on DSM behavior. Incorporating effective sources of information into the DSM Education and care plan may improve DSM, specifically for blood sugar monitoring.

SPENDING AND COST-SHARING ON OUT-OF-NETWORK CARE IN THE UNITED STATES, 2008-2016

Zirui Song^{1, 2}; Jacob Wallace³. ¹Harvard Medical School, Boston, MA; ²Massachusetts General Hospital, Boston, MA; ³Yale School of Public Health, New Haven, CT. (Control ID #3186093)

BACKGROUND: Out-of-network medical care has garnered increasing attention. While patients are becoming more aware of the costs associated with out-of-network care, little is known about how spending on out-of-network care has evolved over time in the United States. This study analyzes trends in in-network and out-of-network spending and cost-sharing in the largest segment of the United States—people with employer-sponsored health insurance.

METHODS: We analyzed in-network and out-of-network spending and cost-sharing for a large nationwide cohort of employers that continuously contributed data to the Truven database from 2008-2016. All individuals were enrolled for at least 1 year. Main outcomes were in-network and out-of-network medical spending and cost-sharing, as well as the percent of spending and cost-sharing out-of-network. We estimated changes in the share of spending that was out-of-network using an ordinary least squares model adjusted for age, sex, risk, insurance plan, and region. We conducted subgroup analyses by provider specialty and category of service.

RESULTS: Our population comprised 27,833,040 individuals nationwide, averaging 33.8 years of age, 52% female, and a DxCG risk score of 0.9. The unadjusted share of medical spending that was out-of-network was 7.0% in 2008-2010 and 6.1% in 2014-2016, a decline of 0.10 percentage-points per year over the study period ($p=0.02$). Among outpatient services, the share of spending out-of-network was stable or declined for all categories except laboratory services, where it increased from 5.2% in 2008-2010 to 11.5% in 2014-2016 (0.80 percentage-point increase per year, $p<0.001$). Among professional services, the share of spending out-of-network was stable or declined among all specialties except hospitalists and pathologists, in which it rose by 0.54 ($p=0.01$) and 0.31 percentage-points per year ($p<0.001$), respectively. Both prices and cost sharing were substantially higher when a service was provided out-of-network than in-network.

CONCLUSIONS: Contrary to some of the public discourse, the share of spending out-of-network has been relatively stable for the past decade in the employer-sponsored population (half of the United States population). However, some areas of medical care, particularly laboratory services, have seen a sharp rise in out-of-network spending and cost-sharing. These results are consistent with qualitative evidence that laboratory services may be increasingly contracted to large regional or national suppliers which are out-of-network for many insurers. To our knowledge, this is the first national evidence of these

troubling upward trends in the share of laboratory spending out-of-network. Extending consumer protections to these settings is one policy solution. Alternative proposals such as capping out-of-network prices at a percentage of in-network prices, reference pricing, or protecting patients from balance-billing also warrant consideration as patients and employers struggle with out-of-network bills.

SPENDING AND QUALITY AFTER 3 YEARS OF MEDICARE'S VOLUNTARY BUNDLED PAYMENTS FOR JOINT REPLACEMENT SURGERY

Amol S. Navathe^{1, 2}; Ezekiel J. Emanuel^{1, 1}; Athendar Venkataramani^{1, 1}; Qian Huang¹; Atul Gupta^{3, 1}; Claire T. Dinh¹; Eric Z. Shan¹; Dylan Small^{1, 1}; Norma B. Coe^{1, 1}; Erkuan Wang¹; Xinshuo Ma¹; Jingsan Zhu¹; Deborah Cousins¹; Joshua M. Liao^{4, 1, 1}. ¹University of Pennsylvania, Philadelphia, PA; ²CMC VA Medical Center, Philadelphia, PA; ³The Wharton School, University of Pennsylvania, Philadelphia, PA; ⁴University of Washington, Seattle, WA. (Control ID #3179521)

BACKGROUND: Based on early savings from the Bundled Payments for Care Improvement (BPCI) program, Medicare has continued to scale bundled payments for lower extremity joint replacement (LEJR) episodes nationwide through new voluntary programs such as BPCI-Advanced. However, despite growing participation in voluntary LEJR bundles, there is a paucity of evidence about their long-term impact on spending and quality.

METHODS: We used 2011-2016 Medicare claims to identify a sample of 205,655 Medicare beneficiaries undergoing LEJR at 244 BPCI hospitals operating in 123 markets and 53,711 fee-for-service Medicare beneficiaries undergoing LEJR at 244 propensity-matched Non-BPCI hospitals operating in 98 markets. We used a difference-in-differences method with propensity matching of hospitals not participating to those participating in BPCI, and hierarchical multivariable generalized linear models with quarter and hospital fixed-effects, to evaluate the association between hospital participation in LEJR bundles under BPCI and changes in spending and quality over a three-year period. This approach also used an instrumental variable (IV) that used historical hospital referral patterns to instrument for observed hospitalization at a hospital participating versus not participating in BPCI. This IV mitigated confounding from changes in unobservable patient characteristics after hospitals started in BPCI. We also evaluated associations by program period and participant wave. Parallel trends were confirmed. Analyses were performed using SAS, version 9.4. Statistical tests were 2-tailed and significant at $=0.05$.

RESULTS: Over 3 years, BPCI participation was associated with a 1.5% decrease in average episode spending (95% CI -2.1% to -0.9%, $p<0.001$), with reductions occurring in the early (1.8% decrease in average episode spending, 95% CI -2.5% to -1.1%, $p<0.001$) but not late program period (1.0% decrease, 95% CI -2.6% to 0.5%, $p=0.19$). Savings were driven by performance of first wave (differential change of -2.0%, 95% CI -2.6% to -1.3%, $p<0.001$) but not second wave participants (differential change of -0.02%, 95% CI -1.7% to 1.7%, $p=0.98$). Savings were 30% lower than naïve regressions without the IV. BPCI participation was not associated with changes in 4 quality measures.

CONCLUSIONS: Participation in LEJR Bundles under BPCI was associated with sustained episode savings accounted for by early participants but not associated with changes in quality. These findings support Medicare's decision to continue scaling up bundled payments via voluntary participation through BPCI-Advanced, while also suggesting tempered expectations for participants in its second wave. Our findings also quantify the effect of unobserved patient selection in voluntary LEJR bundles - a major policy concern - but corroborate true associated savings in spite of such selection.

SPILLOVER EFFECTS OF PROGRAM IMPLEMENTATION TRAINING ON HEALTH CENTER STAFF KNOWLEDGE

AND ATTITUDES ABOUT HEALTH EQUITY

Arshiya A. Baig¹; Erin M. Staab¹; Jefferine Li¹; Wen Wan¹; Scott Cook⁴; Joel Jackson¹; Amanda Campbell³; Cynthia T. Schaefer²; Michael T. Quinn¹. ¹University of Chicago, Chicago, IL; ²University of Evansville, Evansville, IN; ³Midwest Clinicians' Network, East Lansing, MI; ⁴The University of Chicago, Chicago, IL. (Control ID #3185297)

BACKGROUND: Little is known about the spillover effect of quality improvement training on staff knowledge and attitudes about health equity.

METHODS: As part of a 5-year cluster randomized trial to assess the effect of diabetes group visits on patient glycemic control, we trained 26 providers and staff from 7 health center sites across 6 Midwestern states. The 2-day in-person training was led by a team of academic and health center staff and focused mainly on how to implement group visits for adults with diabetes. The training included a video clip on National Standards for Culturally and Linguistically Appropriate Services in Health and Health Care (CLAS Standards), a presentation on trends in disparities in healthcare quality and an overview of healthcare care disparity interventions, and one presentation on understanding stereotypes and bias. Participants were surveyed before and after the training and answered questions on a 5-point Likert-type scale ranging from "strongly disagree" to "strongly agree." We used descriptive statistics to summarize responses and paired t-tests to determine change from pre-to post-training. We used 2-sample t-tests to examine differences in responses between those with and without prior cultural competency training and the diversity of patient population served at their site.

RESULTS: From pre to post training, participants had improvements in perceived benefits of the group visit model of care ($p=0.001$), knowledge of potential barriers to implementing diabetes group visits ($p=0.03$), and confidence in implementing diabetes group visits at their site ($p=0.04$). Staff reported an increase in the potential of group visits to reduce racial/ethnic disparities in diabetes outcomes ($p=0.03$) from pre to post training. Staff were also more familiar with the CLAS Standards ($p<0.0001$), better able to describe racial/ethnic disparities in diabetes prevalence and outcomes ($p=0.002$) and reported knowing steps their center could take to address racial/ethnic health disparities ($p=0.04$). Changes in knowledge of CLAS or health disparities or perceptions of the impact of group visits on disparities did not differ significantly between those who participated in cultural competency regularly during the past 10 years vs. those who participated less or not at all. There was a greater increase in knowledge of steps to take to address racial/ethnic health disparities for staff at health centers with fewer racial/ethnic minority patients.

CONCLUSIONS: Health center staff demonstrated improvements in knowledge and confidence in implementing diabetes group visits. Staff also noted that group visits had the potential to improve racial/ethnic disparities in diabetes outcomes in their patient population and learned steps that their health centers could take to address disparities. Future studies need to assess the impact of staff QI training on racial disparities on patient health outcomes.

SPILOVER EFFECTS OF THE MEDICARE BUNDLED PAYMENTS FOR CARE IMPROVEMENT PROGRAM AMONG NON-MEDICARE PATIENTS

Joshua M. Liao^{3, 1}; Ezekiel J. Emanuel^{1, 1}; Akriti Mishra¹; Jingsan Zhu¹; Claire T. Dinh¹; Deborah Cousins¹; Xinshuo Ma¹; Joshua Rolnick¹; Amol S. Navathe^{1, 2}. ¹University of Pennsylvania, Philadelphia, PA; ²CMC VA Medical Center, Philadelphia, PA; ³University of Washington, Seattle, WA. (Control ID #3179513)

BACKGROUND: Early evidence suggests that voluntary bundled payments for joint replacement surgery under the Bundled Payment for Care Improvement (BPCI) program were associated with episode savings without decrements in quality. Practice redesign in response to BPCI may benefit all patients, not just Medicare fee-for-service beneficiaries. Understanding the presence and magnitude of such "spillover effects" is

critical to understanding bundled payment as a mechanism for improving value. Therefore, we examined the impact of hospital BPCI participation on episode quality and costs for commercially insured patients, including those in Medicare Advantage, receiving joint replacement surgery.

METHODS: We used data from Medicare to identify hospitals participating in BPCI for joint replacement surgery (BPCI hospitals) from 2013 Quarter 3 to 2016 Quarter 4 and associated data from the Health Care Cost Institute (full claims activity of 25% of all insured US individuals younger than 65), to construct care episodes for commercially insured patients encompassing hospitalization and 90-days of post-discharge care. Our sample consisted of 21,470 commercially insured patients undergoing joint replacement surgery during hospital BPCI participation and 266,916 commercially insured patients undergoing joint replacement surgery outside of hospital BPCI participation. There were 287 BPCI hospitals and 2,044 non-BPCI hospitals. After confirming parallel trends, we used a difference-in-differences (D-in-D) method and hierarchical multivariable generalized linear models to evaluate changes in hospital length of stay (LOS), 90-day readmissions rate, and episode spending at BPCI hospitals before and after participation, versus changes at non-BPCI hospitals. Covariates adjusted for age, gender, Elixhauser risk score, dual eligibility status, and insurance product, and including quarter and hospital fixed-effects and a time-varying indicator of BPCI participation. Analyses were performed using SAS, version 9.4. Statistical tests were 2-tailed and significant at $=0.05$.

RESULTS: Several characteristics, including case-mix, age distribution, and dual-eligibility status, varied between patients cared for at BPCI versus non-BPCI hospitals. Over a 3-year period, hospital participation in BPCI was associated with a 2.8% decrease in average episode spending (95% CI -3.5% to -2.2%, $p<0.001$). Hospital BPCI participation was also associated with decrease in 90-day readmissions (D-in-D -1.3%, 95% CI -1.9% to -0.8%) and hospital LOS (D-in-D -8.8%, 95% CI -9.9% to -7.8%,) ($p<0.001$ for both).

CONCLUSIONS: Hospital participation in the Medicare BPCI program was associated with decreases in episode spending, hospital LOS and 90-day readmissions for commercially insured patients receiving joint replacement surgery. Our findings suggest that hospitals may implement broad care redesign that benefits all patients regardless of insurance coverage and reimbursement through bundled payments.

SPINA BIFIDA ACTION RESEARCH: ASSESSING THE NEEDS OF INDIVIDUALS WITH SPINA BIFIDA TRANSITIONING TO ADULT-ORIENTED CARE

Ashley Jenkins^{1, 2}; Diane Burns³; Rhonda Morrison³; Brittany Spicer²; Lisa Vaughn^{2, 4}; Jason Woodward^{2, 1}. ¹University of Cincinnati Medical Center, Cincinnati, OH; ²Cincinnati Children's Medical Center, Cincinnati, OH; ³Spina Bifida Coalition of Cincinnati, Cincinnati, OH; ⁴University of Cincinnati, Cincinnati, OH. (Control ID #3179146)

BACKGROUND: Individuals with spina bifida (SB) experience gaps in care when transitioning from pediatric- to adult-oriented care. Our objective was to identify facilitators and barriers of successful transition to adult-oriented care for individuals with SB.

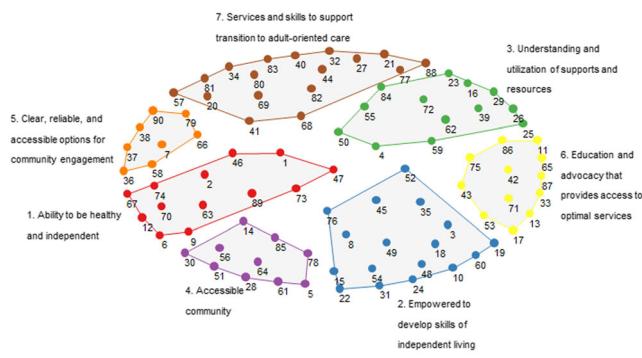

METHODS: We utilized concept mapping, a participatory research method that involves structured steps including: 1) community definition and prompt development, 2) idea generation, 3) sorting ideas, 4) visual representation of data, and 5) interpretation. We recruited from SB community stakeholder groups: individuals aged 12 years and older with SB, parents/caregivers, pediatric and adult healthcare providers, and community organizations. A purposeful sample of stakeholders generated ideas to three open-ended transition-related prompts (e.g. To be a healthy adult living with SB I think I need). We edited ideas to reduce redundancy and ensure clarity. A subset of stakeholders sorted responses into groups of similar ideas using a web-based platform. We used multidimensional scaling and hierarchical cluster analysis to generate a concept map based on the sorted data, reviewing to ascertain the appropriate number of

clusters and their meaning

RESULTS: We recruited 97 stakeholders (individuals with SB 32%, caregivers 21%, healthcare providers 29%, community organizations 18%). Idea generation, followed by editing, revealed 90 unique ideas. After stakeholder sorting, subsequent analysis revealed a seven-cluster concept map (Figure 1) showing how the arrangement (i.e. location and distance between) of the 90 ideas, illustrated by points, have meaning. Each of the seven clusters represents ideas sorted together due to conceptual similarity. Clusters emphasized two key conceptual domains: healthcare access (Clusters 3, 5, 6, and 7) and development of skills that foster empowerment and independence when living with SB (Clusters 1, 2, 4).

CONCLUSIONS: SB community stakeholders identified complex needs relevant to successful transition for individuals with SB from pediatric- to adult-oriented care. Concept map generation allows all SB stakeholders to easily interpret the relationship between ideas, as well as the perspectives of other community members. Both will inform future development of contextually relevant interventions.

Figure 1. Needs of Individuals with Spina Bifida Transitioning to Adult-Oriented Care Concept Map^a

SPIROMETRY UTILIZATION IN AN URBAN HEALTH CENTER

Prithwijit Roychowdhury¹; Amulya Amirneni²; Jasdeep Badwal^{4, 2}; Dilpreet Singh³; Alexander B. Knee²; Tara Lagu³. ¹University of Massachusetts Medical School, Sturbridge, MA; ²Baystate Medical Center, Springfield, MA; ³Baystate Medical Center, Florence, MA; ⁴Allergy & Immunology Associates of New England, Greenfield, MA; ⁵Arthritis Treatment Center, Springfield, MA. (Control ID #3184668)

BACKGROUND: Asthma affects an estimated 39.5 million people in the United States with a total cost of more than \$50 billion. Although experts recommend that spirometry is performed for all patients in whom the diagnosis of asthma is being considered and as follow-up at least once every two years after an initial diagnosis is made, the few studies on the subject suggest that spirometry is widely underutilized in the diagnosis of asthma. There have been no studies examining longitudinal use of spirometry in asthma care. We, therefore, examined use of spirometry for both diagnosis and follow up and identified predictors of spirometry in a cohort of primary care patients within one large health system.

METHODS: We conducted a retrospective study of adult patients who had a diagnosis of asthma and an appointment in the year of 2014. We used diagnosis codes to randomly identify 200 patients from community health centers and another 200 from private practices. We collected billing records and extracted charts to identify patient characteristics, asthma severity, and the presence or absence of spirometry. We attempted to characterize diagnostic vs follow-up spirometry, but we were unable to do so due to poor documentation in the medical record. We further examined the process of spirometry, including use of the methacholine challenge.

RESULTS: Among our sample of 400 randomly selected subjects, we excluded 6 because they did not have a diagnosis of asthma, resulting in a final analytic dataset of 394 patients. Mean (SD) age was 52 years (13) with a large proportion of the sample being white (61%; n=239) and female

(72%; n=284). A total of 75% (n=297) of patients had never had a prior visit with a pulmonologist or allergist. Of the 97 subjects who did see a specialist, 33 (34%) saw a pulmonologist and 74 (76%) saw an allergist. Of the 394 patients, 208 (53%) received spirometry at any time during the follow-up period, and 186 (47%) did not. For patients that received spirometry (n=208), 29.3% (n=61) received a methacholine challenge at any time and of these patients, 83.6% (n=51) showed a positive result, suggesting asthma/airway hyperreactivity. Seeing a specialist was the strongest predictor of whether a patient received spirometry or not: over 90% of those who had a specialist visit received spirometry, compared to 40% of those who did not have a specialist visit.

CONCLUSIONS: Despite the existence of guidelines set forth by experts, we found that spirometry is underused in both the diagnostic evaluation and subsequent monitoring of asthma. Among those who did receive spirometry, diagnostic tools such as the methacholine challenge were rarely used. The chance of receiving spirometry was strongly associated with seeing a specialist, which suggests a need to better incorporate spirometry into routine primary care for patients with asthma.

SPOKESPERSON-PATIENT CONCORDANCE IS STRONGLY ASSOCIATED WITH PATIENTS CHOOSING TO ACCEPT MEDICAL CARE NEAR THE END-OF-LIFE

Michael J. Green¹; Benjamin H. Levi¹; Lauren J. Van Scyoc¹; Ashley Bucher¹; Renee R. Stewart¹; Anne Dimmock¹; Erik B. Lehman²; Andrew J. Foy^{1, 2}. ¹Penn State College of Medicine, Hershey, PA; ²Pennsylvania State University, Hershey, PA. (Control ID #3185775)

BACKGROUND: A fundamental premise of surrogate decision-making in the context of serious illness is that spokespersons should accurately represent patients' wishes when patients cannot speak for themselves. Prior research using clinical vignettes showed that spokespersons' concordance with patient treatment preferences is imperfect (~50-70%) but factors associated with concordance are not well understood. We assessed whether spokesperson-patient concordance is associated with patient preference to accept vs decline medical interventions.

METHODS: This is a post-hoc analysis of a prospective trial of advance care planning (ACP) among adults with advanced, severe illness (class III/IV heart failure; stage III/IV COPD; stage 4/5 kidney disease; or advanced cancer). The study took place at two tertiary care centers (Hershey, PA and Boston, MA) and the main outcome was spokesperson's concordance with patient preferences. After completing an ACP intervention, participants were asked whether they would 'accept' or 'decline' potentially life-saving interventions by responding to 28 questions related to 6 clinical vignettes. Spokespersons were separately asked to indicate which treatments they thought the patient would want. For all questions, patients' responses were classified as choosing to 'accept' or 'decline' treatment, and agreement with spokesperson's response was assessed as a dichotomous variable (yes/no). Multivariable logistic regression was performed for each question to assess whether 'accepting treatment' was associated with agreement after adjusting for study site, diagnosis, and prior advance directive.

RESULTS: 267 spokesperson-patient dyads were included and 7294 paired-responses were analyzed. Patients' mean age was 64 and 46% were female; spokespersons' mean age was 56 and 75% were female. Spokesperson-patient concordance was greater when patients 'accepted' versus 'declined' treatment, with significant differences in 24 of 28 questions. The overall median concordance rate was 87% when patients 'accepted,' and 44% when patients 'declined' treatment, and the median difference was 46%. On multivariable testing, 'accepting' treatment was a significant, independent predictor of spokesperson-patient concordance for 24 of 28 questions. The overall median adjusted odds ratio was 10.9 when patients 'accepted' treatment. By contrast, no correlation was found with patients' or spokespersons' age, sex, race, ethnicity, religion, marital status, education, employment status, study site, prior experience with ACP, or patients' underlying medical condition.

CONCLUSIONS: Spokesperson-patient concordance is strongly

associated with patient preference to accept medical treatment. This finding suggests that spokespersons may have a bias toward action or treatment to prolong life. Such a bias could lead to overuse of medical treatments when patients desire less care near the end-of-life. Future studies may further examine biases of spokespersons.

SPREADING PRIMARY CARE 2.0: A QUALITATIVE EVALUATION OF READINESS FOR A TEAM-BASED CARE MODEL IN AN ACADEMIC MEDICAL SYSTEM

Nadia Safaeinil¹; Cati Brown-Johnson²; Jonathan G. Shaw³; Megan Mahoney⁴; Marcy Winget⁵. ¹Stanford University, Stanford, CA; ²Stanford School of Medicine, Stanford, CA; ³Stanford University School of Medicine, Stanford, CA; ⁴Stanford University, Palo Alto, CA; ⁵Stanford University Medical School, Stanford, CA. (Control ID #3185635)

BACKGROUND: In 2016, Stanford Healthcare developed a new model of primary care called Primary Care 2.0, which includes: 1) medical assistants (MAs) taking on advanced roles including scribing, population health management, and care-coordination; 2) team-based care, including an advanced practice provider and additional MA resources; and 3) an extended interdisciplinary care team (i.e. behavioral health, pharmacy, nutrition). The model has been implemented in one clinic with plans to spread to four additional primary care clinics. We conducted a qualitative assessment of perceived barriers and facilitators to implementation to inform the planned spread of the model.

METHODS: We collected data via semi-structured interviews with staff and providers (n=26) and day-long observations of clinic teams and workflows at five primary care clinics. Detailed field notes were taken. Interview audio, transcripts, and notes were analyzed and synthesized in a rapid qualitative approach, the Lightning Report. We used the Consolidated Framework for Implementation Research (CFIR) to structure the coding of the data and predictions about factors for successful implementation.

RESULTS: Providers and staff reported factors related to the CFIR construct *networks and communication* to be most supportive of spread, including: strong clinic management, medical assistant wellness, and open communication within teams. Interviewees also felt that an explicit commitment to open and nonjudgmental communication may be protective against change fatigue during spread. Regularly scheduled times for teams to debrief and surface concerns were described as essential. All levels of the team reported benefits when the forum for debriefs took place as interprofessional "case conferences", allowing all to ask questions and receive support. Finally, providers perceived medical assistant wellness as critical for implementing and spreading a successful team-based care model. Providers and staff anticipated barriers that mapped primarily to the CFIR constructs *available resources* and *access to knowledge and information*. Reported barriers to spread included perceived inequality of workload distribution among team members of the same level, lack of understanding of workflows and roles within the new model, and instability of staffing for medical assistants and clinic management. Additional barriers focused on: 1) operations, including space needed for a co-located team environment; 2) time available for regularly-scheduled case conferences; and 3) difficulty recruiting appropriate staff in a compressed timeframe.

CONCLUSIONS: Based on our analysis, we predict that the following CFIR constructs will be key factors in spread success: *networks and communication*, specifically practices around open interprofessional communication and support of medical assistant wellness; *access to knowledge and information* about spread workflow and role changes, and *available resources*.

STATINS FOR PRIMARY PREVENTION: WE'RE NOT DOING IT ALL THE TIME

Connie Park; Jeffrey Le; Rebecca Mazurkiewicz. Hofstra Northwell Lenox Hill Hospital, New York, NY. (Control ID #3185008)

BACKGROUND: Atherosclerotic Cardiovascular Disease

(ASCVD) is the leading cause of death worldwide and its complications remain expensive to treat. As per the 2013 American Heart Association and American College of Cardiology guidelines on the treatment of hypercholesterolemia to reduce ASCVD risk in adults, in patients without existing ASCVD, LDL cholesterol over 190, and diabetes, a moderate intensity statin is recommended if the 10-year ASCVD risk is 7.5% or greater using the ASCVD risk calculator. Given the complicated nature of this guideline, our hypothesis was that many of our patients are not appropriately on statins for primary prevention.

METHODS: This study consisted of chart review of patients seen by internal medicine residents from Lenox Hill Hospital from October 2017 to December 2017, aged 40-79 with a lipid panel resulted within the past year. We excluded patients with pre-existing ASCVD, LDL over 190, diabetes, documented statin allergy, AST or ALT three times upper limit of normal, HIV, end stage renal disease, and duplicate encounters within our date range. Variables collected included age, gender, race, lipid panel results, blood pressure reading on the date of lipid panel, current anti-hypertensive medications, smoking history, current statin therapy, and reasons documented in the visit note for why patient was not on a statin. In addition, Lenox Hill medicine categorical residents were surveyed anonymously and electronically, asking what they believed to be the barriers to prescribing statins. The answer choices were as follows: time constraints, knowledge that a statin was necessary, other, or patient refusal.

RESULTS: Of the 113 patients who met inclusion criteria and did not meet exclusion criteria, 31 (27.5%) were not on appropriate statin therapy for primary prevention of ASCVD. Of the 31 patients, 74% did not have a reason documented as to why they were not on appropriate statin therapy. For those who did have documentation, reasons included patient decision, conservative measures first for risk reduction, statin to be addressed at a follow up visit, and patient lost to follow-up. Twenty-three residents answered the survey. Residents most commonly cited time constraint (n=13, 56.5%) as the reason why they did not prescribe statins to patients. Others were patient refusal (n=5, 21.7%), knowledge that a statin was necessary (n=3, 13.0%), or other (n=2, 15.4%).

CONCLUSIONS: Our chart review confirmed that the main barrier at our clinical site to having patients on statin therapy for primary prevention appears to be from the clinician's side. This was confirmed by surveying a group of residents. This is in contrast to what is in the literature, which is a more patient-centered issue of compliance. We will explore possible interventions to increase the rates of statin therapy in the future. One idea would be to include documentation of ASCVD risk score for every patient aged 40 and 79 at every visit, with the corresponding statin recommendation.

STETHOSCOPE HYGIENE: USING CULTURES AND REAL-TIME FEEDBACK WITH RAPID BIOLUMINESCENCE SCORES TO CHANGE BEHAVIOR

Jurgen Holleck^{1, 2}; Sheldon Campbell^{1, 2}; Hedib Alrawili³; Cynthia Frank^{1, 2}; Naseema Merchant^{1, 2}; Benjamin Rodwin⁴; Shaili Gupta^{1, 2}; Daniel G. Federman^{1, 2}; John J. Chang^{1, 2}; Mario F. Perez⁵. ¹Yale University School of Medicine, Southbury, CT; ²VACT Healthcare System, West Haven, CT; ³Quinnipiac University, Hamden, CT; ⁴Yale School of Medicine, New Haven, CT; ⁵UConn Health, Farmington, CT. (Control ID #3149573)

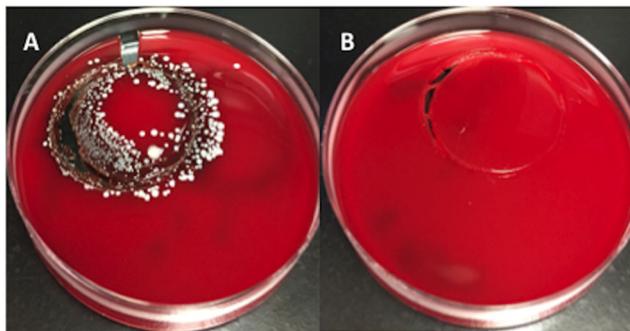

BACKGROUND: Stethoscope contamination is comparable to that of our hands. Guidelines recommend disinfection between patients, yet this is rarely done. Previously, an educational intervention at our institution did not improve low rates of disinfection. Therefore, we aimed to 1) gain a better understanding of beliefs and barriers to stethoscope hygiene and 2) determine whether showing providers what is growing on their stethoscopes via culture or bioluminescence technology alters perceptions and improves stethoscope hygiene.

METHODS: Our study utilized a pre/post intervention design involving

medical students, housestaff, and attendings between January and March 2018. Providers were given the opportunity to 1) culture their stethoscopes before and after disinfection with alcohol swabs, alcohol based hand rub (ABHR), or hydrogen peroxide wipes or 2) swab their stethoscopes for bioluminescence-based ATP testing before and after disinfection. Pre and post surveys were administered. Primary outcomes were observed stethoscope and hand hygiene rates. Secondary outcomes were survey responses exploring beliefs, barriers, and self-reported disinfection rates. Bacteria speciation, colony forming units (CFU), and bioluminescence scores pre and post disinfection were also tracked.

RESULTS: 1,245 observed hand hygiene opportunities found that compliance improved from 72.5% to 82.3% ($p<0.001$). 590 observed encounters revealed no significant change in stethoscope hygiene rates which were 10% at baseline and 5% post intervention ($p=0.08$). However, provider perceptions of the importance of stethoscope hygiene improved from 8.5 to 9.3/10 ($p=0.04$) and self-reported stethoscope hygiene rates trended up 56% to 67% ($p=0.06$). The impact of seeing bioluminescence scores on cleaning behavior rated equal to that of stethoscope cultures: 7.1 vs 7.2/10 ($p=0.89$). CFU reduction with alcohol swabs, ABHR, and hydrogen peroxide wipes was equivalent ($p=0.21$).

CONCLUSIONS: Showing providers what is growing on their stethoscopes via cultures and bioluminescence technology improved "buy in" regarding the importance of stethoscope hygiene. Although self-reported rates of stethoscope hygiene trended up, observed rates were lower and failed to show improvement, suggesting a gap between what providers think they are doing and what they actually are doing. Hand hygiene however, improved by 13.5% (9.8 percentage points).

Stethoscope culture before (A) and after (B) disinfection.

STRATEGIES FOR SHORT AND LONG-TERM PATIENT ENGAGEMENT AMONG HIGH-NEED PATIENTS: REFLECTIONS OF KEY STAKEHOLDERS IN VA'S PRIMARY CARE INTENSIVE MANAGEMENT (PIM) TEAMS

Alicia Bergman¹; Susan E. Stockdale²; Marian L. Katz³; Donna M. Zulman⁴; Evelyn T. Chang⁵. ¹VA Greater Los Angeles, North Hills, CA; ²Greater Los Angeles VA Healthcare System, Sepulveda, CA; ³Veterans Health Administration, North Hills, CA; ⁴Stanford University and VA Palo Alto, Stanford, CA; ⁵VA- Greater Los Angeles, Los Angeles, CA. (Control ID #3184414)

BACKGROUND: A recognized barrier to the success of intensive outpatient primary care programs for high-need patients is patient engagement, i.e., patients' active engagement in their own healthcare. However, research is lacking on how different strategies may be more conducive to different temporal phases of program involvement or lead to shorter or longer-term engagement. Our goal was to conduct a qualitative analysis of the Veterans Health Administration (VA) intensive primary care program (PIM) to learn about team members' successful patient engagement strategies, in order to describe the strategies by temporal phase of the patients' PIM program involvement, and by which strategies may facilitate shorter-term engagement versus longer-term self-sustaining patient engagement.

METHODS: Semi-structured interviews were conducted with twenty-

nine VA PIM team members (e.g., primary care providers, nurses, psychologists, social workers, dietitians) and primary care and program leaders. Interviews were recorded, transcribed, and analyzed to identify a novel organization of successful patient engagement strategies.

RESULTS: Some patient engagement strategies were particularly conducive to enabling immediate shorter-term engagement at the beginning phase of their program involvement, such as identifying with patients and general rapport-building, and setting guidelines/boundaries for what team member can and cannot do. During the ongoing phase of program involvement, other shorter-term "enabler" engagement strategies included scheduling appointments for patients, co-attending or connecting patients with primary care or specialty care appointments, assisting patients to get medication refills, providing or facilitating transportation to appointments, facilitating provider availability, and visiting patients when hospitalized. Other engagement strategies described by participants were potentially more conducive to longer-term and self-sustaining engagement; those employed at the beginning of patient program involvement included goal-setting, taking a whole-person health approach, conducting motivational interviewing, and educating patients on the wheel of health. Engagement strategies conducive to longer-term/self-sustaining patient engagement during the ongoing phase of program involvement included understanding psychiatric reasons that impede patient progress, medication management/education, encouraging patients to schedule/cancel appointments, coordinating/problem solving with the patient's caregiver/s or family, clinical dietitian advice, and collaborative decision-making.

CONCLUSIONS: Some engagement strategies were best employed at the beginning phase of patient program involvement while others fit well with ongoing involvement. Within both phases there were engagement strategies that seemed to facilitate either longer-term or shorter-term patient engagement. These findings can facilitate engaging primary care patients on a longer-term level, towards self-sustaining self-management.

STRATEGIES TO REDUCE ELECTRONIC HEALTH RECORD INBOX BURDEN: A MIXED METHODS STUDY

Daniel R. Murphy^{1, 2}; Tyler Satterly^{1, 2}; Traber Giardina^{2, 1}; Dean F. Sittig³; Hardeep Singh^{2, 1}. ¹Baylor College of Medicine, Houston, TX; ²Michael E. DeBakey VA Medical Center, Houston, TX; ³University of Texas, Houston, TX. (Control ID #3168054)

BACKGROUND: Electronic health record (EHR) inbox notification-related workload leads to information overload and is cited as a contributing factor for job dissatisfaction and physician burnout. Better understanding of physicians' inbox requirements and workflows could optimize inbox designs, enhance efficiency, and reduce safety risks from notification overload.

METHODS: We conducted a mixed-methods study to identify strategies to enhance EHR inbox design and workflow. First, two reviewers performed a secondary analysis of national survey data collected in 2010 of all Department of Veterans Affairs (VA) primary care practitioners (PCP) to identify major themes in responses to a free-text question soliciting suggestions to improve EHR inbox design and workflows. We then conducted expert interviews of clinicians at five health care systems to understand existing optimal strategies to improve efficiency and situational awareness related to EHR inbox use. Themes from survey data were cross-validated with interview findings.

RESULTS: We analyzed responses from 2104 PCPs who completed the free text inbox question (of 5001 PCPs who responded to survey) and used an inductive approach to identify five themes: (1) Inbox notification content should be actionable for patient care and relevant to recipient clinician, (2) Inboxes should reduce risk of losing messages (3) Inbox functionality should be optimized to improve efficiency of processing notifications, (4) Team support should be leveraged to help with EHR inbox notification burden, (5) Sufficient 'protected' time should be provided to all clinicians to process EHR inbox notifications. We subsequently interviewed 15 clinicians and identified 11 unique strategies

corresponding to each of these 5 themes, including disabling certain automated for-your-information messages, making use of future reminder features to prevent information loss, using data entry automation features in the EHR, delegation of tasks to non-provider team members, and processing messages in a distraction-free environment.

CONCLUSIONS: Feedback from practicing end-user clinicians provides robust evidence to improve EHR inbox content and designs and organizational workflows and policies. Given the emerging efficiency and safety risks related to the EHR inbox, both EHR developers and health systems should work together on high-priority strategies identified.

STRATIFICATION OF CHEST PAIN OBSERVATION PATIENTS USING THE HEART SCORE TO REDUCE UNNECESSARY CARDIAC TESTING

Shelly L. McGurk¹; Kevin Glenn¹; Ethan Kuperman². ¹University of Iowa Hospitals and Clinics, Iowa City, IA; ²University of Iowa Carver College of Medicine, Iowa City, IA. (Control ID #3185628)

BACKGROUND: Patients admitted to the observation unit with chest pain have a high utilization of cardiac diagnostic testing (e.g. stress testing). Current practice does not incorporate the consistent use of a risk-stratification tool. HEART score is a validated tool that accurately identified low-risk chest pain patients in the Emergency Room in past studies. The object of this study was to determine if the HEART score could identify patients on a medical observation unit who would not benefit from further cardiac testing.

METHODS: This was a retrospective, observational cohort study at a single academic medical center observation unit. Over a 12-month period, study data were collected and managed using REDCap. Data collection was done via manual chart review of patients with a chief complaint of chest pain. The HEART score was calculated using the history and physical, ED notes, EKG, and laboratory values. The endpoint was major adverse cardiac event (MACE), which was defined as acute myocardial infarction (AMI), percutaneous coronary intervention (PCI), surgical revascularization, or death within six weeks of the index visit. The type and results of cardiac diagnostic testing were also abstracted. Specificity, sensitivity, and frequency of cardiac testing were used for analysis.

RESULTS: There were 282 patients identified within the time period, 151 (54%) female and 131 (46%) male. The groups were dichotomized into low risk (HEART score 0-3) and elevated risk (HEART score >3). There were 115 (41%) patients in the low-risk group and 167 (59%) patients in the elevated-risk group. The MACE rate for the low-risk group was 2 (1.7%) and 17 (10.1%) for the elevated-risk group, ($p=0.005$). The two MACE events in the low-risk group were PCI and 17 MACE events in the elevated-risk group included 6 AMI, 11 PCI, 1 CABG, and 1 death. The death in the elevated-risk group was non-cardiac due to sepsis related to peritonitis/appendicitis. The HEART score sensitivity was 89% (95%CI: 66-98%) and specificity 43% (95%CI: 37-49%). Stress testing was performed 70/115 (60.9%) for the low-risk group and 102/167 (61%) for the elevated-risk group ($p=.89$). The low-risk group had 58/68 (85.3%) normal stress test results and 10/68 (14.7%) abnormal, 2 were not completed. The elevated-risk group had 67/102 (65.7%) normal stress test results and 35/102 (34.3%) abnormal results. There was a significant difference in the stress test results by group, ($p=0.005$).

CONCLUSIONS: The HEART score identified a patient population at low risk for adverse cardiac events who received diagnostic testing at a similar rate as the elevated risk group. Incorporation of the HEART score into the admission protocol will provide decision support for clinicians and help improve decision-making with regards to cardiac testing for chest pain. This could reduce unnecessary diagnostic testing and decrease wasteful spending.

STRENGTHENING THE FOUNDATION OF CLINICAL REASONING: A RESIDENT-LED INITIATIVE

Stephen G. Philip; Bruno Alvarez Concejo; Melanie Holtrop; Sarah Collins; Stephanie Brinker; Reeni A. Abraham. University of Texas Southwestern,

Dallas, TX. (Control ID #3175168)

BACKGROUND: Deficits in clinical reasoning skills have come into focus as a concern behind high rates of diagnostic medical errors in the United States. Since the foundation for a physician's diagnostic skill is laid in medical school, we sought to strengthen clinical reasoning by instituting a 4-week curriculum taught to medical students by internal medicine residents under faculty supervision. This study reports the initial effect of our curriculum on the students' subjective comfort with clinical reasoning.

METHODS: During the core internal medicine clinical rotation, students attended a 4-week course led voluntarily by a senior internal medicine resident. Each week, students analyzed a clinical case with guidance from the resident, and each session highlighted 1-2 concepts: illness scripts, problem representations, diagnostic schemas, likelihood ratios, semantic qualifiers, and awareness of bias. Cases became progressively more challenging to facilitate synthesis of earlier concepts. Simultaneously, the teaching skills of residents were observed and critiqued by internal medicine faculty using a rubric. Students completed a survey about their comfort level with and use of clinical reasoning both prior to and after the course.

RESULTS: 160 survey responses were received - 105 pre- and 55 post-course. Students had a median 6 months of clinical rotations prior to the concurrent internal medicine clerkship, and their median age was 24 years. Before the course, 53% of students felt either comfortable or very comfortable altering their diagnosis based on new information, increasing to 80% after the course. Before the course, 60% reported having a clinical reasoning framework, increasing to 96% after the course, the majority using illness scripts (50% pre vs. 69% post). Before the course, 5% of students felt comfortable or very comfortable using likelihood ratios, increasing to 58% after the course.

CONCLUSIONS: Our outcomes evaluation reflects an increase in medical students' confidence using key components of clinical reasoning, and a large increase in students reporting the use of a framework - the majority adopting illness scripts. This is significant as failed reasoning and the lack of a standardized approach to clinical problems account for a large percentage of diagnostic error. Our goal is to reinforce a method of reasoning that will be used by students in the future; however, the question whether our curriculum has an objective impact on clinical reasoning has yet to be answered with script concordance testing data. Finally, this data provides evidence that residents can be effective teachers of clinical reasoning to medical students. Since residents provide a large proportion of a student's clinical training, formal instruction in the diagnostic process so residents can teach others might have exponential benefits in reducing diagnostic error for any healthcare system.

STRIVES: ENGAGING MINORITY URBAN TEENS TO LEAD SOCIAL MEDIA CAMPAIGNS TO PROMOTE CLINICAL RESEARCH CAREERS IN THEIR COMMUNITIES

Christianah Ogunleye¹; Jeanne M. Farman²; Shannon K. Martin²; Audrey L. Tanksley³; Samantha Ngooi²; Laura Ruth Venable⁴; Samantha Anderson²; Jhonatan Marte¹; David Meltzer²; Vineet M. Arora⁵. ¹University of Chicago Pritzker School of Medicine, Chicago, IL; ²University of Chicago, Chicago, IL; ³Heartland Alliance Health, Chicago, IL; ⁴University of Chicago, Chicago, IL; ⁵University of Chicago Medical Center, Chicago, IL. (Control ID #3170345)

BACKGROUND: One driver of poor health equity is underrepresentation of certain minority groups as leaders of clinical research studies. A major problem is the lack of exposure minority communities have to clinical research careers. This study aimed to assess whether high achieving minority youth enrolled in a pipeline program could create a social media campaign to promote interest in clinical research in their communities.

METHODS: Spreading Teen Research Inspired Videos to Engage Schoolmates (STRIVES) aimed to engage teens in a pipeline program to develop a targeted social media marketing campaign to boost interest in clinical research careers. The pipeline students conducted focus groups of their communities to inform themes to best promote clinical research. The

students enrolled their friends to be study subjects. Friends were sent a survey to assess baseline interest in clinical research careers. The pipeline students scripted, storyboarded and filmed a short video to share on social media with a campaign hashtag. After the campaign launch, subjects were asked how they saw the video, their perceptions of the video and their post-interest in clinical research careers. Subjects who did not see the video through the online campaign were invited to watch as part of the study. Interest change scores were calculated using differences in Likert responses to "how interested are you in a career in clinical research?" An ordinal logistic regression model tested the association between watching a peer-shared video, perception of entertainment and interest change score controlling for underrepresented minorities in medicine (URM) status (Black, American Indian/Alaska Native, Native Hawaiian or Pacific Islander), gender and baseline interest in medical or clinical research careers.

RESULTS: From 2014-2017, 325 subjects were enrolled as part of 4 distinct campaigns: #WhereScienceMeetsReality, #RedefiningResearch, #DoYourResearch and #LifeWithoutResearch. Two-thirds [66% (214)] were female, 31% (101) were Hispanic, and 23% (75) were URM. Over half (180) of subjects watched the video via the campaign, 77% (n=227) found the video entertaining, and 28% (n=92) had baseline interest in clinical research. Interest change scores were approximately normally distributed with a median change score of 0. The ordinal logistic regression model found that subjects who viewed the video from a peer (OR 1.56, 95% CI 1.00-2.44, p=0.049) or found the video entertaining (OR 1.36, 95% CI 1.01-1.82, p=0.041) had greater odds of increasing interest in a clinical research career. Subjects with higher baseline interest in medicine (OR 1.55, 95% CI 1.28-1.87, p<0.001) also had greater odds of increasing interest in clinical research.

CONCLUSIONS: Authentic and relevant peer-created messages spread via video on social media can increase interest in clinical research careers among diverse youth. Peer-driven social media campaigns should be explored as a way to promote equity, engagement, and advocacy in minority communities.

STUDY HABITS AMONG RESIDENTS AND ATTENDINGS AT A SINGLE ACADEMIC MEDICAL CENTER

Casey N. McQuade¹; Michael G. Simonson¹; Kristen A. Ehrenberger²; Amar Kohli³. ¹University of Pittsburgh Medical Center, Pittsburgh, PA; ²UPMC, Pittsburgh, PA; ³UPMC, Mars, PA. (Control ID #3186176)

BACKGROUND: Modern physicians face increasing clinical demands, decreasing the time available to learn during and outside of work. We sought to characterize study patterns and the use of electronic study resources among residents and academic physician staff at an academic medical center. We hypothesized that residents would use electronic resources more frequently than attendings.

METHODS: Qualtrics surveys were emailed to 290 trainees and 165 faculty from the Departments of Medicine, Pediatrics, and Medicine-Pediatrics at UPMC. Survey participation was optional and not compensated. Questions covered demographic data, study time, resource usage, and time spent on social media. Means are reported \pm standard deviation for continuous variables. Relationships between variables were tested using non-parametric testing and regression analysis.

RESULTS: Responses were obtained from 118 trainees (41% response rate), ranging from PGY-1 to PGY-6, and 110 attending physicians (67%). Respondents were 60% female (n=131). The median age range was 25-34 years (IQR, 25-34 years to 45-54 years). Social media use was reported by 162 (86%). On average, participants studied for 15 min-1 hour/day (IQR, 5-15 min to 15 min-1 hour) on 4.0 \pm 1.8 days/week. Increased participant seniority was correlated with more studying time/day (p=0.0274) and more positive views on how essential studying was to learning (p=0.0002). The most popular study resources were websites (n=196), journal articles (n=180), and textbooks (n=143). Increased seniority was also correlated with more frequent use of textbooks (p=0.046), quick references (p=0.022), and websites like [Uptodate.com](#) (p=0.0001) but was inversely correlated with journal article use (p=0.012). Social media use was associated with

more frequent use of journal articles (OR 1.64, 95% CI 1.06-2.55).

CONCLUSIONS: Time spent studying between residents and faculty was not significantly different, although attendings more frequently used print or online reference materials for extracurricular studying while residents more frequently read journal articles. The correlation between journal articles and social media use may suggest that social media increases physician exposure to and uptake of primary literature. This cross-sectional analysis reveals previously undescribed trends in resident and faculty study habits including determinants of exposure to the primary literature. These results could be used to tailor future educational interventions to increase supplemental learning and use of evidence-based practices in academic practice settings.

SUBCLINICAL THYROID DYSFUNCTION AND DEPRESSIVE SYMPTOMS: AN INDIVIDUAL PARTICIPANT DATA ANALYSIS OF PROSPECTIVE COHORT STUDIES

Lea Wildisen²; Martin Feller^{2, 1}; Elisavet Moutzouri^{2, 1}; Shanthi Beglinger^{2, 1}; Cinzia Del Giovane²; Anne R. Cappola⁷; Bjørn O. Åsvold³; Stephan Bakker⁸; Graziano Ceresini¹²; Robin P. Dullaart⁸; Luigi Ferrucci⁹; Hans Grabe¹⁰; Matthias Nauck¹⁰; Stella Trompet⁵; Henry Völzke¹⁰; Rudi G. Westendorp⁴; Jacobijn Gussekloo^{5, 5}; Robin P. Peeters¹¹; Drahomir Aujesky¹; Douglas Bauer⁶; Nicolas Rodondi^{2, 1}. ¹Inselspital, Bern University Hospital, Bern, Switzerland; ²University of Bern, Bern, Switzerland; ³Norwegian University of Science and Technology, Trondheim, Norway; ⁴University of Copenhagen, Copenhagen, Denmark; ⁵Leiden University Medical Center, Leiden, Netherlands; ⁶University of California, San Francisco, CA; ⁷University of Pennsylvania School of Medicine, Philadelphia, PA; ⁸University of Groningen, Groningen, Netherlands; ⁹National Institute on Aging, Baltimore, MD; ¹⁰University Medicine Greifswald, Greifswald, Germany; ¹¹Erasmus Medical Center, Rotterdam, Netherlands; ¹²University Hospital of Parma, Parma, Italy. (Control ID #3182648)

BACKGROUND: Subclinical thyroid dysfunction may be associated with several negative health outcomes; including depressive symptoms. However, evidence for this association is conflicting across a large number of studies, in part due to inconsistencies in definitions and cut-offs. Analysis of individual participant data (IPD) is needed to understand the role of subclinical thyroid dysfunction in the development of depressive symptoms and to inform practice and guidelines.

METHODS: We conducted a systematic review of cohort studies to assess the association between subclinical hypothyroidism or subclinical hyperthyroidism and depressive symptoms. We requested individual participant data from cohorts identified through a search of EMBASE and MEDLINE databases (up to November 2018) and through the Thyroid Studies Collaboration ([www.thyroid-studies.org](#)). The outcome was depressive symptoms at first follow-up, measured on any validated depression scale. For better clinical interpretation we transformed all scores into the Beck Depression Inventory (BDI) scale (range: 0-63, higher numbers indicating more depressive symptoms, minimal clinically important difference: 5 points) by calculating conversion factors. Subclinical hypo- and hyperthyroidism were defined as elevated thyroid stimulating hormone (TSH) (> 4.5 mU/L) and reduced TSH (<0.45 mU/L) respectively, in combination with normal free thyroxine levels. We performed a two-stage IPD analysis. In each cohort, we estimated the mean difference (MD) in depressive symptoms scores between those with subclinical hypo- or hyperthyroidism and euthyroid controls adjusted for depressive symptoms at baseline. Further, we adjusted the multivariable linear regression analysis for age, sex and length of follow-up. We pooled the study effects estimates by using a random effects model. Heterogeneity was assessed by I^2 . The protocol is registered on PROSPERO (ID: CRD42018091627).

RESULTS: Among six cohorts, we analyzed data from 24,962 participants (65% female, mean age 61 \pm 13.3 years, subclinical hypothyroidism N=2,534, subclinical hyperthyroidism N=684, mean follow-up time 7.8 \pm 4.6 years). At baseline, there was no difference in BDI scores between subclinical hypothyroidism (10.67), subclinical hyperthyroidism (10.78) and controls (10.25). After a mean

follow-up time of 7.8 ± 4.6 years BDI scores did not differ between participants with subclinical hypothyroidism and controls (pooled MD 0.07, 95% CI -0.25 to 0.40, $I^2 = 0.0\%$) nor between participants with subclinical hyperthyroidism and controls (pooled MD -0.004, 95%CI -0.57 to 0.56, $I^2 = 2.5\%$). The results remained robust in sensitivity analyses, excluding participants taking thyroid medication ($N=23,602$).

CONCLUSIONS: In this large study of prospective cohorts, neither subclinical hypo- nor hyperthyroidism were associated with an increased development in depressive symptoms. Depressive symptoms seem not to be a good indication for thyroxine therapy if no overt thyroid dysfunction is present.

TAKING SOCIAL MEDICINE FROM FREE TIME TO PRIME TIME: SCREENING FOR SOCIAL DETERMINANTS OF HEALTH IN A LARGE URBAN PRIMARY CARE CLINIC

Daniel Gore¹; Emily B. Phelps¹; Zayd Hayami¹; Coralie Pardo¹; Leah Petrucelli¹; Shunei Asao¹; Adrienne Blackmon²; Eve Escalante²; Nousheen Meherally²; Christopher Nolan²; Charles F. Sweitzer²; Ritika Dhawan¹; Elizabeth S. Davis². ¹Rush University, Chicago, IL; ²Rush University Medical Center, Chicago, IL. (Control ID #3185815)

BACKGROUND: Patients at Rush University Internists (RUI) experience high rates of chronic diseases often influenced by social factors, but these social factors are infrequently discussed during appointments. This project aims to better identify, document, and address social determinants of health (SDoH) during medical appointments.

METHODS: Medical students piloted a SDoH screening protocol in RUI, a primary care practice in Chicago's West Side. The project assessed feasibility and optimization of student-led SDoH screening in primary care. This project was embedded in a larger institution-wide effort to increase SDoH screening. The SDoH questionnaire contains ten items addressing food security, housing, transportation, health insurance, and PCP access. When patients screen positive, resources are provided through a community resource database, NowPow, linked to the electronic medical record (Epic). NowPow identifies community resources close to where each patient lives. The protocol includes escalation to a licensed clinical social worker when needed. Screenings were assessed for average time spent, as well as number of patients screening positive for the various SDoH metrics. Domains of positive screens were characterized and analyzed, and patient feedback was elicited.

RESULTS: Between March and May of 2018, 43 patients were screened by six students, with the average screening time of five minutes. Fifty-six percent of patients (26) screened positive for one or more SDoH: food insecurity (17), utilities interruptions (14), transportation issues (9), insurance status (5), housing insecurity (2). Twelve patients were referred to social work. Overall, patients endorsed these efforts, as one stated "I'm glad you're asking these questions." Based on these experiences, the students involved in the pilot developed a student-run service learning program in which each year, a new interprofessional group of students is trained to screen for SDoH. In the 2018-19 school year, 30 students were trained and began screening patients in primary care. These students also partner with Rush-wide screening initiatives to screen patients in community outreach settings including health fairs.

CONCLUSIONS: SDoH screening in primary care is feasible, and rates of needs related to social determinants of health may exceed providers' expectations. Student screening offsets the workload of other staff. Institutional support of SDoH screening helps with stakeholder buy-in and accessing resources for patients. However, student schedules may limit screening large volumes of patients.

Further exploration is needed to determine the most sustainable way to screen and connect patients with resources.

TEACHING TRANSITIONS OF CARE: WHO OWNS IT?

Patrick Ryan^{1, 2}; Chi Zheng^{3, 2}; Alisha Skinner^{3, 2}. ¹Denver Health and Hospital Authority, Denver, CO; ²University of Colorado School of Medicine, Aurora, CO; ³Denver Health, Denver, CO. (Control ID #3184758)

BACKGROUND: Transitions of care are of increased focus and attention due to the financial impact of hospital readmissions on healthcare settings under the Hospital Readmission Reduction Program. However the amount of education dedicated towards transitions of care is not well quantified or described. In this study, we assessed what capacity and where residents receive transitions of care education.

METHODS: We developed a 21 question survey to assess where residents receive transitions of care teaching, the format of the instruction and their attitudes towards receiving further instruction in this arena. We distributed the survey to a single internal medicine residency program with 180 residents having tailored curriculums including a hospitalist track, primary track and categorical tracks.

RESULTS: A total of 64 residents (35%) respond to the survey with 92% reporting that they had rarely or never received transitions of care didactics during their inpatient rotations. Similarly, 89% of respondents reported rarely or never receiving such didactics during their outpatient rotations either. All respondents reported understanding transitions of care to be important to safe and high quality patient care and 98% reported resident education being important to very important in their residency education. Most respondents (57%) felt moderately confident in their transitions of care planning while 39% felt slightly confident. None of the respondents felt very confident in their transitions of care planning. 90% of respondents had some interest in learning more about transitions of care; however, only 57% of respondents stated they would be interested in a rotation dedicated to learning more about transitions of care. Those who anticipated careers as hospitalists were more likely to be interested in a rotation dedicated to transitions of care compared to those pursuing careers as specialists or PCPs, 76% vs 45% vs 50%, respectively ($p < 0.03$). Respondents described their future career paths as predominantly specialty bound (39%) compared to hospitalist (30%) and primary care (25%). The distribution of respondents was similar across years of training at 30% for interns, 38% for second years, and 32% for third year residents.

CONCLUSIONS: Although transitions of care and readmission reduction have become of increasing importance to institutions to provide higher quality patient care and reduce healthcare costs, it appears that there is not much attention paid to resident education of this critical arena. Even as residents identify transitions of care to be of importance to their education and patient care, only slightly more than half of responding residents are interested in taking a curriculum dedicated to this field. Further study is necessary in the most effective ways of teaching transitions of care to resident physicians.

TECHNOLOGY UTILIZATION IN PATIENTS WITH CIRRHOSIS AND PREFERRED FEATURES OF DIGITAL HEALTH MANAGEMENT TOOLS

Patricia Pringle; Thomas J. Wang; Bradley Green; Madeline Marx; Jasmine Ha; James M. Richter. Massachusetts General Hospital, Boston, MA. (Control ID #3154013)

BACKGROUND: Evidence-based guidelines have made important advances in cirrhosis care; however, many of these guidelines are not sustained in practice. Technology represents a promising tool to improve guideline compliance and health care delivery. We aimed to

assess cirrhotic patients' access to, utilization of, and comfort with technology, as well as the preferred features of a digital health tool.

METHODS: We performed a mixed-methods study of cirrhotic patients with high healthcare utilization, those readmitted within 90 days for a cirrhosis-related complication. Patients were identified from the inpatient hepatology consult census. We obtained disease data from chart review and performed an in-depth semi-structured interview. Two investigators iteratively read and coded interview transcripts for themes using NVivo 11.0.

RESULTS: Of 134 cirrhotic inpatients identified from June to November 2018, 40 patients met inclusion criteria and agreed to participate. Of the 40 participants, 26 (65%) were male, mean (SD) age was 58.4 years (11.7), with a mean (range) MELD of 22 (10-46). Thirty-one (78%) patients own a Smartphone and 25 (63%) patients have regular access to a computer. Smartphone apps are preferred by 23 (58%) patients, while computers are preferred by 3 (7.5%) patients. When asked if they would use a Smartphone app daily to manage their cirrhosis, 24 (60%) reported yes, 10 (25%) no, and 6 (15%) maybe. Patients are interested in a Smartphone app that could: communicate with their physician (32, 80.0%), send medication notifications (25, 63%), transmit diagnostic results and appointment reminders (30, 75%), educate about cirrhosis (31, 78%), and offer low salt diet recipes (25, 63%). Of 25 patients with prior hepatic encephalopathy, 21 (72%) would play a Smartphone game if it detected cognitive decline. Of 22 patients with volume overload, 19 (86%) would use a Smartphone app to transmit weight data to their doctor. Common themes from qualitative data include a willingness to learn more about digital tools, a desire to learn about liver disease and communicate with providers via digital tools, and an eagerness to utilize digital tools if it could improve health (see Table).

CONCLUSIONS: Among cirrhotic patients with an early readmission at our center, most have Smartphones and would be willing to use one to manage their disease. Future technology interventions should be tailored to the specific use patterns and preferences of this population.

TEMPORAL TRENDS IN DISCHARGE OPIOID PRESCRIBING FROM AN INPATIENT MEDICAL SERVICE

Nicholas Iverson; Nader Najafi; Yumiko Abe-Jones; Priya A. Prasad; Margaret Fang; Kirsten Kangelaris; Catherine Lau. UCSF, San Francisco, CA. (Control ID #3184800)

BACKGROUND: In March of 2016, the CDC released guidelines recommending shorter duration of opioid prescriptions. While these guidelines have the potential to influence hospitalist practice, it is not clear whether discharge prescribing patterns have changed. We examine changes in discharge opioid prescribing over time from an inpatient medical service at a single academic center.

METHODS: We used the electronic health record to identify all patients hospitalized on the acute care medical service at a 600-bed tertiary care hospital from 2012-2017, and stratified by whether they were on opioids at the time of admission according to provider medication reconciliation records. Patients were excluded if they had an ICD9 or 10 code for cancer-related pain or sickle cell disease, or who were on hospice or followed by the palliative care service. We calculated the number of opioid days supplied to the patient at discharge based on the discharge prescription signature and number of pills. All opioid prescriptions were standardized to morphine milligram equivalents (MMEs). We then calculated the median opioid days supplied at discharge by month, from 2012 to 2017. Multivariable Poisson regression analysis was used to assess temporal trends in likelihood of opiate prescription and median days supplied, with an interrupted time series approach to test for a significant change at the intervention point of March 2016.

RESULTS: We identified 19,759 medical inpatients who received opiates during their hospitalization, 23% of whom were not on opioids prior to admission. A total of 10,653 patients were discharged on opiates. The proportion of patients who were discharged with an opiate prescription declined over time (32.2% in 2012 to 25.6% in 2017, p<0.001; Figure 1).

The median number of opiate days prescribed also declined over time (8.3 in 2012 to 7.5 in 2017, p=0.02). The decline in median opioid days from 2016 to 2017 was statistically significant in patients taking opioids prior to admission (10 to 9.3 days, p=0.04). Though the median days prescribed on discharge in patients without baseline opiate use remained at 5 days from 2012 to 2017, there was a slight statistically significant decline in overall trend (p=0.02). After adjusting for patient level factors—age, sex, race, ethnicity, language, interpreter requirement, length of stay, ICU stay during admission, and van Walraven Comorbidity Index—we continued to find a significant decrease in opioid days supplied at discharge in all patients, with a significant decline post-March 2016 (rate ratio=0.93, p <0.001).

CONCLUSIONS: The percent of patients discharged on opioids from a hospital medicine service has declined over time, including a substantial drop after the release of the 2016 CDC guidelines. The median number of days among patients discharged on opioids has also declined over time. Patients on opioids at the time of admission are discharged with higher median days of opioids than those not previously on opioids - a trend that is ongoing.

TERMINAL DIGIT BIAS AND BLOOD PRESSURE CONTROL IN AN ACCOUNTABLE CARE ORGANIZATION

Kelsey B. Bryant¹; Siling Li¹; Yiyi Zhang¹; Siqin Ye¹; Brandon K. Bellows¹; Teryl K. Nuckols²; Marie Krousel-Wood³; Jonas Green²; Andrew E. Moran¹.

¹Columbia University Medical Center, New York, NY; ²Cedars-Sinai Medical Center, Los Angeles, CA; ³Tulane University, New Orleans, LA. (Control ID #3178947)

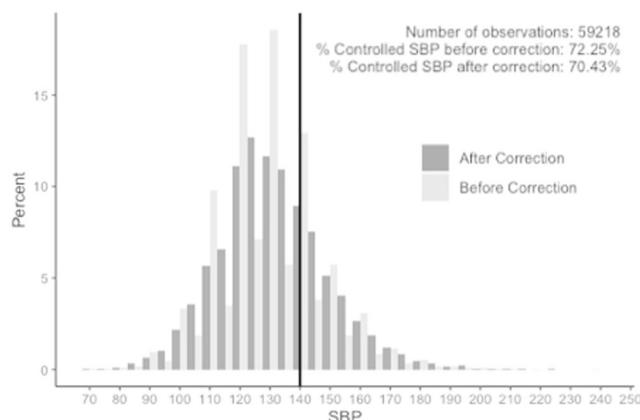

BACKGROUND: Accountable Care Organizations (ACOs) reimburse health systems based on performance, including blood pressure (BP) control (proportion controlled BP among hypertensive patients using last measurement of year). We hypothesized that terminal digit bias—intentional or unintentional rounding preference when measuring BP—misclassifies BP control.

METHODS: ACO patients were from 2 Columbia University outpatient Medicine practices in 2013- 2016. BP is manually measured and recorded by providers using anaeroid sphygmomanometers in one practice. In the other, BP is automatically measured and manually recorded by medical assistants using oscillometric devices. Using last BP measurement/year in electronic health records, we compared systolic BP distributions and proportion controlled (<140/90 mmHg) in hypertensives and normotensives combined. We identified terminal digit preference by examining BP distributions. We corrected for it by creating smoothed distributions reflecting the expected frequency of terminal digits (10% in the absence of bias), and reassessed mean BP and proportion controlled BP.

RESULTS: 337,408 BP observations (65.01% manual group) represented 24,643 unique Medicare Shared Savings Plan ACO patients (90.37% manual group). The manual BP practice had mean patient age 72 years old and 54% female; the automated BP practice had mean age 68 and 64% female. BPs in the manual BP practice exhibited terminal digit preference bias, which was eliminated by correction (Figure). Digit preference was less apparent in the automated measurement practice (data not shown). Percent ACO patients with controlled BP changed little in both populations after correction for terminal digit preference bias [all changes to % controlled <2%; chi squared p < 0.001 manual BP practice, p = 0.64 automated BP practice].

CONCLUSIONS: Terminal digit preference bias occurred in a practice where BP is measured manually, but not where it is measured automatically. Terminal digit preference bias had minimal effect on proportion with controlled systolic BP and likely did not impact the ACO performance benchmark. Nonetheless, biased BP measurement may lead to incorrect diagnoses and treatment decisions. Automated

BP measurement appears to minimize this bias.

TEST ORDERING AND RESULT ACKNOWLEDGEMENT PRACTICES AT TWO CANADIAN ACADEMIC HEALTH CENTRES

Keith M. Lee¹; Peter Cram². ¹University of Toronto, Toronto, ON, Canada; ²University of Iowa, Iowa City, IA, USA. (Control ID #3184584)

BACKGROUND: Physician test ordering practices have been shown to differ according to physician demographics characteristics and practice setting. Few studies have compared inpatient test ordering intensity between physicians from different specialties. Similarly, there is a paucity of data examining the utilization of electronic test result acknowledgement systems despite strong evidence that these systems can reduce "missed" test results. Moreover, the vast majority of studies come from the US. We examined physician test ordering and result acknowledgement practices at two large Canadian academic hospitals.

METHODS: Using electronic health record (EHR) data, we identified all patients hospitalized on 5 different clinical services (Critical Care, General Surgery, General Internal Medicine, Nephrology, and Orthopedics) at Toronto General Hospital and Toronto Western Hospital between February 1, 2017 and February 28, 2017. We obtained data including patient demographics, hospital length of stay, hematology and biochemistry test orders and associated results, and result urgency level (categorized as normal, abnormal, or critical). We reviewed EHR data regarding whether tests were acknowledged by the ordering physician in his/her electronic "in-box" at any time after the results were finalized. We compared testing intensity (tests ordered per-patient per-admission and per-day), result urgency, and acknowledgement status between clinical services using two-sided Chi-squared tests.

RESULTS: Our 5 clinical services had a total census of 1571 patients over our study window. Mean length of stay was 15.0 days. The mean number of hematology-plus-biochemistry tests per-patient per-admission was lowest for Orthopedics (106.9) and highest for Critical Care (537.1). In contrast, the mean number of hematology-plus-biochemistry tests per-patient per-day was lowest for Critical Care (6.7) and highest for General Internal Medicine (23.4). 7.4% of all tests were reported as critical, ranging from 2.6% in Nephrology to 8.8% in General Internal Medicine. 27.2% of all test results were reviewed by a physician using the EHR "in-box" acknowledgement function. 38.5% of tests for patients admitted to General Internal Medicine were reviewed using the "in-box" function, as compared to 9.9% in General Surgery, 13.3% in Orthopedics, 15.5% in Nephrology, and 28.9% in Critical Care.

CONCLUSIONS: Test ordering intensity varies markedly across specialty. In our health system, a significant proportion of tests are flagged as critical, raising concern of alert fatigue particularly for General Internal Medicine where critical results are most common. Physician utilization of our result acknowledgement system was low, which is concerning given

evidence of the substantial problem of overlooked (or "missed") test results.

THE "KIND CARE BUNDLE" - A TRANSITION TOWARD COMPASSIONATE CARE

Cynthia M. Cooper^{1,2}; Galina Gheihman². ¹Massachusetts General Hospital, Boston, MA; ²Harvard Medical School, Boston, MA. (Control ID #3180251)

BACKGROUND: Negative behaviors in practicing clinicians are often learned during medical training through observation and mimicry - the so-called "hidden curriculum." Compassion and empathy are inconsistently reinforced in exchange for efficiency. This devaluing of kindness and connection may contribute to clinician burnout and result in suboptimal patient care. To counteract this trend, we developed a curriculum emphasizing self-reflection and teaching concrete verbal and non-verbal behaviors for showing attention, consideration, and compassion in patient interactions. The "Kind Care Bundle" was taught to medical students immediately prior to the start of their core clinical rotations. **METHODS:** The Kind Care session was taught at Massachusetts General Hospital in Aug-Sept 2018 over 5 weeks.

Groups consisted of 7-8 students. In each 3-hr. session, students first recalled a time when they felt cared for or witnessed compassionate care. These experiences were discussed to identify verbal and non-verbal demonstrations of care. The "Kind Care Bundle" was introduced with the Three Es: Entry, Encounter and Exit. The Three Es outline concrete behaviors for showing attention, consideration and compassion in patient interactions. Using question prompts, pairs of students interviewed inpatients to practice the Three Es and solicit patients' perspectives on compassionate care. Finally, students debriefed after the interviews and completed a post-session feedback survey. Mixed-methods analysis was used to evaluate Likert scale statements and free-text responses.

RESULTS: 37 (92.5%) of 40 students completed the feedback form. The session organization was evaluated as 'Excellent' by 73% of students and 'Very Good' by 27%. The session relevance was evaluated as 'Excellent' by 81% of students and 'Very Good' by 16%. Students reported the bundle filled an educational gap. Major themes in the qualitative analysis included: (1) appreciation of the sessions' emphasis on Concrete Behaviors: 'It's hard to teach 'being kind'...but these concrete actions can be useful and important to put into action,' (2) the Importance of Empathy: 'Getting the patient's perspective on Kind Care is clutch' and (3) the Opportunity to Reflect on one's own experience of compassion: 'A light bulb went off! I was like 'duh' that's how we need to treat patients.' Motivations for using the bundle in the future included Impact on Patient Experience, Clinical Success, Professional Ideals and Self-Care.

CONCLUSIONS: The Kind Care curriculum is an educational activity that prompts students to reflect on their own experiences of compassionate care and practice a bundle of concrete behaviors to improve student/patient interactions. The pilot session was highly rated by pre-clinical students at Massachusetts General Hospital. A next step is expansion to all pre-clinical students at Harvard Medical School. It may have use in other student and clinician populations and at other institutions.

THE ART OF PRECEPTING: INNOVATIVE STRATEGIES TO PREPARE SENIOR RESIDENTS FOR CLINIC PRECEPTING

Rebecca Davis³; Ehren K. Dancy²; Emily Sandberg⁴; Deepa R. Nandiwada¹. ¹University of Pennsylvania, Ardmore, PA; ²Hospital of the University of Pennsylvania, Philadelphia, PA; ³Thomas Jefferson University, Philadelphia, PA; ⁴University of Pennsylvania, Philadelphia, PA. (Control ID #3185994)

BACKGROUND: Our aim was to improve senior resident confidence regarding the transition to attending through a reverse direct observation preceptor curriculum. The curriculum is two pronged first with a direct observation component where residents observe attendings with guided facilitation sheets followed by attending observation of senior residents

precepting medical interns (junior precepting). Although the concept of "junior precepting" is not new, the idea of a facilitated direct observation to better prepare residents for the junior precepting experience is novel.

METHODS: Residents and attendings in an internal medicine primary care track were involved in the development of a reverse direct observation precepting curriculum. During resident observation of attendings, an assessment tool was created to evaluate the attending's preceptor "toolkit" highlighting microskills from the one-minute preceptor as well as a guided one on one discussion with the preceptor about their personal practices. Residents were then asked to commit to trying something they observed during their scheduled junior precepting sessions. The assessment tool included open ended questions regarding attending precepting style on topics such as attending chart review time/verification, presence vs absence of documentation during precepting, and use of electronic for teaching.

RESULTS: Six attendings were observed by six different senior residents in the primary care program for a total of 30 observed encounters. In analysis of the attending preceptor toolkit, the median attending practice was to seek a commitment to plan as well as reinforce clinical decisions done well with correction of mistakes in half of the cases. Probing learner thought process for arrival of plan commitment was not done during the majority of encounters. Qualitatively attending style at this clinic was split between writing notable past medical history and listening to the resident while reviewing the chart. The majority of attendings spent less than 5 minutes chart reviewing. The tech most often used centered around EMR optimization tips to streamline guidelines into management. Under the tips and behaviors section, resident observers most often cited specific phrasing that helped to elicit further information from the learner without creating a negative atmosphere for learning. In this single site assessment of this novel reverse direct observation precepting curriculum, initial data suggests that resident observers may benefit from observation sessions both prior to and following their own mock-precepting sessions to better prepare them for a junior precepting experience.

CONCLUSIONS: In this single site assessment of this novel reverse direct observation precepting curriculum, initial data suggests that resident observers may benefit from observation sessions both prior to and following their own mock-precepting sessions to better prepare them for a junior precepting experience.

THE ASSOCIATION BETWEEN OPIOID DOSE FLUCTUATION AND INCIDENT HEROIN USE

Ingrid A. Binswanger^{1, 2}; Komal J. Narwaney¹; LeeAnn M. Quintana¹; Stanley Xu¹; Susan M. Shetterly¹; Jennifer Lyden^{4, 2}; Jo Ann Shoup¹; Jason M. Glanz^{1, 3}. ¹Kaiser Permanente Colorado, Aurora, CO; ²University of Colorado School of Medicine, Aurora, CO; ³Colorado School of Public Health, Aurora, CO; ⁴Denver Health, Denver, CO. (Control ID #3185991)

BACKGROUND: Opioid guidelines recommend tapering opioids for chronic pain if the risks of treatment outweigh the benefits. However, attempts to taper opioids can lead to dose fluctuation. Tapering attempts can cause increased pain and withdrawal symptoms, which may lead providers to increase the dose again or prompt individuals to seek illicit opioids to control their pain. Dose increases could enhance the euphoric effects of opioids, increasing the risk for addiction and heroin use. Thus, dose fluctuations may increase the likelihood that individuals seek heroin. We sought to examine the association between opioid dose fluctuation and incident heroin use.

METHODS: We conducted a matched nested case-control study in a Colorado-based integrated health system. We first defined a cohort of health plan members 18 between January 2006 and May 2018 on chronic opioid therapy (COT; 3 opioid dispensings in 90 days). The date of the 3rd opioid dispensing was the index dose date. Within the cohort, we identified heroin use that came to medical attention in the electronic health record using text string searches. This was followed by detailed medical record review by trained abstractors to verify heroin use and estimate the date of heroin onset, which represented the index date. Incident cases of heroin use after COT

initiation in continuously enrolled patients were matched to up to 20 controls who did not have evidence of heroin use on milligrams morphine equivalents (MME), calendar time, and length of follow-up. The exposure of interest was dose fluctuation, defined as greater than the median of the standard deviation of the dose over each control patient's follow-up (8.6 MME). Conditional logistic regression was used to estimate matched odds ratios (mOR) and 95% confidence intervals (CI), adjusting for age, sex, race/ethnicity, insurance type, mental health diagnosis, and mean MME in the 3 months prior to the index date.

RESULTS: In the cohort of 23,144 patients receiving COT, the text string search identified 1,731 (7.5%) patients with mention of heroin use. After medical record review, we identified 261 confirmed cases for whom we could estimate a heroin onset date. Among these, the first occurrence of heroin use occurred after COT started in 52 cases. Three cases could not be matched to a control. Cases (n=49) were more likely than controls (n=866) to be young, male, Latino, and insured by Medicaid. Dose fluctuation was strongly and independently associated with the risk of heroin use (mOR=5.87, 95% CI, 2.05-16.27).

CONCLUSIONS: Among patients prescribed COT, we identified a strong association between opioid dose fluctuation and the risk of heroin use. Our measure of heroin use was based on documentation in addiction treatment and other medical settings. We did not evaluate whether fluctuation in dose exacerbated prior or current heroin use. When managing COT, physicians should consider heroin use as a potential sequela of dose fluctuation.

THE ASSOCIATION BETWEEN SLEEP OPPORTUNITY AND INCIDENCE OF DELIRIUM IN GENERAL MEDICINE INPATIENTS

David Sterken¹; Rae Wannier²; Priya A. Prasad²; Yumiko Abe-Jones¹; Nader Najafi¹; Margaret Fang¹; Kirsten Kangelaris¹; Stephanie E. Rogers¹; Sara C. LaHue¹; Vanja Douglas¹; Ari Hoffman¹. ¹UCSF, San Francisco, CA; ²UCSF, Berkeley, CA. (Control ID #3184403)

BACKGROUND: Overnight interruptions in the hospital are thought to worsen sleep and increase patients' risk of delirium, but this relationship has not been well-quantified. Our group has developed a novel metric of overnight interruptions called "sleep opportunity." Using this metric, we conducted a single-center retrospective analysis to describe the association between overnight interruptions and the incidence of delirium in general medicine inpatients.

METHODS: Using our Epic-based electronic health record, we identified all admissions to the adult general medicine service at an 800-bed urban teaching hospital from April 9, 2017 to November 30, 2018. We excluded patients who were delirious on admission, had a Glasgow Coma Scale < 10 within 24 hours of admission, or were in the intensive care unit during admission. The primary outcome was incident delirium, defined as the first positive score on the Nursing Delirium Screening Scale (NuDESC), which is a validated delirium screening tool that is assessed each shift as part of routine nursing care with score 2 defined as positive. The primary predictor was sleep opportunity per night, defined as the longest continuous block of time without interruptions by hospital staff between 10:00 PM and 6:00 AM, calculated using timestamps for tasks such as vital signs, medications, and procedures. We developed a multivariable mixed-effects logistic regression model to assess the relationship of quartiles of sleep opportunity to the incidence of delirium during the following 24 hours and adjusted for confounders using a propensity score for quartiles of sleep opportunity. This propensity score included age, Elixhauser Comorbidity Index, diagnosis-related group weight, admission AWOL score (screening tool for risk of developing delirium), prior diagnosis of dementia by ICD codes in previous encounters, whether vital signs were ordered to be checked overnight, and whether a delirium-prevention order set had been ordered. We also included level of care as a fixed effect in our model.

RESULTS: We identified 8,913 eligible admissions during our study period with 20,278 eligible patient-nights. The mean sleep opportunity per patient-night was 4.98 (SD = 1.75) hours. The incidence of delirium was

10.39% (SD = 0.32) of admissions. Compared to the highest quartile of sleep opportunity (6.57-8.00 hours), the lowest quartile of sleep opportunity (0.93-3.62 hours) was associated with a significantly increased odds of incident delirium (adjusted odds ratio 1.80 [95% CI: 1.11-2.93]). The middle quartiles (3.62-4.67 hours and 4.67-6.57 hours) were not significantly different from the highest quartile (adjusted odds ratios 1.36 [0.84-2.22] and 1.56 [0.98-2.46], respectively).

CONCLUSIONS: Lower sleep opportunity overnight in the hospital was associated with an increased risk for incident delirium, highlighting the clinical importance of minimizing unnecessary interruptions. These results also show that our sleep opportunity metric has clinically meaningful correlates.

THE ASSOCIATION BETWEEN SUBCLINICAL HYPOTHYROIDISM AND CARDIOVASCULAR RISK FACTORS ACCORDING TO AGE AND GENDER - AN INDIVIDUAL PARTICIPANT ANALYSIS OF LARGE INTERNATIONAL COHORTS

Manuel R. Blum^{1, 3}; Oliver Baretella^{1, 2}; Lea Wildisen²; Elisavet Moutzouri^{1, 2}; Cinzia Del Giovane²; Douglas Bauer⁴; Anne R. Cappola⁵; Bjørn O. Monasterio Foundation, Pisa, Italy; ¹⁰Radiation Effects Research Foundation, Nagasaki, Japan; ¹¹University Hospital Zurich, Zurich, Switzerland; ¹²National Poisons Information Centre, Tox Info Suisse, Associated Institute of the University of Zurich, Zurich, Switzerland; ¹³University of Cambridge, Cambridge, United Kingdom; ¹⁴Newcastle University, Institute of Genetic Medicine, Newcastle upon Tyne, United Kingdom; ¹⁵Faculdade de Medicina de Marília, Marília, Brazil; ¹⁶University of Greifswald, Institute for Community Medicine, Clinical-Epidemiological Research, Greifswald, Germany; ¹⁷The University of Western Australia, Crawley, WA, Australia; ¹⁸University of Copenhagen, Copenhagen, Denmark. (Control ID #3169994)

BACKGROUND: Subclinical hypothyroidism (SHypo) has been linked to an increased risk for coronary heart disease (CHD). Moreover, SHypo has been associated with several modifiable cardiovascular risk factors, but population-based data on these associations are inconsistent. Also, the impact of hormonal substitution in SHypo on CHD remains unclear with the lack of adequately powered trials. By pooling individual participant data from large prospective cohort studies, this international cross-sectional study assessed the association between SHypo and cardiovascular risk factors across wide age ranges to help clarify the possibly increased risk for cardiovascular events in patients with SHypo.

METHODS: Cardiovascular risk factors (arterial hypertension, dyslipidemia, inflammatory status as determined by hs-CRP) as primary outcomes were assessed in euthyroid (TSH 0.45-4.5 mU/l) and participants with SHypo (TSH >4.5 mU/l, normal free thyroxine) from large cohorts within the *Thyroid Studies Collaboration* (www.thyroid-studies.org). Participants on exposure-/outcome-modifying medications [antihypertensives, lipid-lowering drugs, antidiabetics, and (anti-)thyroid medication] were excluded and analyses stratified by gender due to significant interactions. Multilevel mixed-effects linear regression models adjusted for age

and smoking status were used.

RESULTS: Among 50,045 participants (mean age 58, range 18-100 years, 59% women, 27% current smokers) from 13 international cohorts, 2,832 (6%) individuals had SHypo. All associations significantly differed by gender (p for interaction<0.001; HDL-cholesterol p for interaction=0.03), except for hs-CRP (p for interaction=0.60). Systolic blood pressure was higher with SHypo vs euthyroidism in women (138±10 vs 135±11 mmHg, p <0.01), but not in men (138±7 vs 138±7 mmHg, p =0.70) as was total cholesterol (women 6.10±0.56 vs 6.03±0.52 mmol/l, p <0.001; men 5.41±0.53 vs 5.74±0.41 mmol/l, p =0.39). With SHypo HDL-cholesterol levels were lower (women 1.48±0.06 vs 1.51±0.05 mmol/l, p <0.001; men 1.16±0.04 vs 1.23±0.04 mmol/l, p <0.001) and triglyceride levels higher (women 1.50±0.24 vs 1.38±0.22 mmol/l, p <0.001; men 1.68±0.31 vs 1.67±0.24 mmol/l, p <0.05) in both women and men, while LDL-cholesterol levels were slightly higher only in women (4.16±0.56 vs 4.12±0.55 mmol/l, p <0.001; men 3.68±0.51 vs 3.96±0.44 mmol/l, p =0.83). hs-CRP levels were similar in SHypo vs euthyroidism for both genders (women 2.01±0.70 vs 1.91±0.67 mg/l, p =0.24; men 1.81±0.67 vs 1.64±0.68 mg/l, p =0.39). Cardiovascular risk factors did not significantly differ across age groups.

CONCLUSIONS: SHypo is associated with elevations of traditional cardiovascular risk factors (but not hs-CRP levels) that differ according to gender, but not age. However, the differences may not be of clinical relevance as they are small. Therefore, cardiovascular risk factors do not appear to be a strong argument to substitute SHypo.

THE ASSOCIATION OF LANGUAGE PREFERENCE AND OUTCOMES IN HISPANICS WITH ATRIAL FIBRILLATION

Ephraim Leiderman¹; Faraj Kargoli²; Jeremy Miles¹; John Fisher²; Kevin Ferrick²; Andrew Krumerman². ¹Jacobi Medical Center, New Rochelle, NY; ²Montefiore Medical Center, Bronx, NY. (Control ID #3179846)

BACKGROUND: According to the U.S. Census Bureau in 2011, 21% of Americans speak a language other than English at home. Of non-English speakers, 13% identify as Spanish-speaking primarily. This likely results in many Spanish-speaking individuals visiting physicians who cannot communicate with them in their primary language. The association between language preference and outcomes in atrial fibrillation is unknown.

METHODS: This study analyzed the association of language preference with length of hospital stay and all-cause mortality in Hispanics admitted with atrial fibrillation. This is a retrospective study of Hispanic patients aged 18 years or older admitted with a primary diagnosis of atrial fibrillation between the years 2000 and 2010. Deaths were ascertained from the social security index as well as records from the New York Department of Health. Multivariable logistic regression models were used to determine predictors of survival adjusted for age and comorbidities.

RESULTS: A total of 957 patients were identified with a mean follow up of 3.7 years. 476 (50%) patients reported Spanish as their primary language. Overall mortality was higher in the Spanish-speakers relative to English-speakers. (34% vs 26%, p < 0.001). After adjusting for age and co-morbidities, Hispanic Spanish-speakers did not have increased mortality when compared to Hispanic English-speakers (OR: 1.063, CI: 0.777-1.454). However, Spanish language preference was associated with a significantly increased length of hospital stay (4.50 days (95% CI 4.20-4.80) vs 5.45 days (95% CI 5.01-5.89)).

CONCLUSIONS: This study illustrates the importance of recognizing the association of an increased length of hospital stay and Spanish language preference in hopes of improving the efficiency

of atrial fibrillation management and decreasing the cost of hospitalization.

THE ASSOCIATION OF SHARED DECISION-MAKING FOR DIABETES PREVENTION WITH BLOOD PRESSURE CONTROL AND HYPERTENSION MEDICATION USE: 12-MONTH RESULTS FROM THE PREDIABETES INFORMED DECISION AND EDUCATION (PRIDE) STUDY

Vu⁵; Keith Norris¹; Carol Mangione⁵. ¹UCLA, Los Angeles, CA; ²UCLA/VA Greater Los Angeles, Los Angeles, CA; ³University of California, Los Angeles, Los Angeles, CA; ⁴ucla, Los Angeles, CA; ⁵David Geffen School of Medicine at UCLA, Los Angeles, CA. (Control ID #3185754)

BACKGROUND: Intensive lifestyle change (e.g., the Diabetes Prevention Program/DPP) and metformin both reduce type 2 diabetes risk. Shared decision-making (SDM) may help patients select the option for diabetes prevention best aligned with their preferences. The PRIDE study of SDM for diabetes prevention resulted in greater uptake of both lifestyle change and metformin, as well as greater weight loss at 12 months. In the current analyses, we examined the effect of PRIDE on change in blood pressure (BP) control and hypertension (HTN) medication use from baseline to 12-month follow-up.

METHODS: PRIDE is a cluster-randomized trial of SDM for diabetes prevention within a large regional health system. PRIDE enrolled overweight/obese adults with prediabetes (HbA1c 5.7-6.4%) from 10 randomly selected SDM intervention clinics, and used propensity score matching to identify control patients from 10 randomly selected usual care clinics. Intervention participants were invited to participate in a face-to-face SDM visit with a pharmacist who used a decision aid (DA) to engage participants in possible options for diabetes prevention; DPP, DPP +/- metformin, metformin only, or usual care. The endpoints for the current analyses were change from baseline to 12 months in 1) BP control defined by <140/90 and 2) number of HTN medication classes. To assess BP at 12 months, we used the closest available BP measured in clinic within 9-16 months of baseline. We classified HTN medications into 13 classes: thiazide diuretics, loop diuretics, potassium-sparing diuretics, aldosterone receptor blockers, beta-blockers, ACEs, ARBs, direct renin inhibitors, non-dihydropyridine CCBs, dihydropyridine CCBs, alpha blockers, centrally acting medications and direct vasodilators. Endpoints were extracted from the local electronic health record. Analyses were adjusted for clinic but no other covariates.

RESULTS: PRIDE included 515 intervention participants and 1,296 controls with measured BP at baseline, of whom 185 intervention and 552 control participants had an existing HTN diagnosis. We had complete data on 12 month BP values for 456 intervention participants (88.5%) and 1,046 control participants (80.7%). As compared to control participants (72.4%), intervention participants (77.4%) were more likely to have controlled blood pressure at baseline ($p=0.04$). However, there was no statistical difference in change of blood pressure control between groups over time ($p=0.82$). Among participants with diagnosed HTN, there was no difference in the mean number of anti-hypertensive medication classes taken by intervention (1.58) and control (1.56) patients at baseline ($p=0.87$). There was also no statistical difference in the change in number of anti-hypertension medication classes between groups over time ($p=0.27$).

CONCLUSIONS: A prediabetes SDM intervention led by pharmacists was not associated with improvements in BP control or differences in the number of HTN medications at 12 months, in an intention-to-treat analysis. **THE CONFIDENT COUNSELOR: THE IMPACT OF A CULINARY NUTRITION CURRICULUM ON MEDICAL STUDENTS' READINESS TO DISCUSS HEALTHY LIFESTYLE**

INTERVENTIONS WITH THEIR PATIENTS

Nathan Wood¹; Rebecca Gleit²; Diane L. Levine³. ¹Wayne State University, New York, NY; ²Stanford University, Stanford, CA; ³Wayne State University, Detroit, MI. (Control ID #3181165)

BACKGROUND: The World Health Organization estimates that 80% of non-communicable diseases could be prevented if 4 key lifestyle practices were followed, the first of which is a healthy diet. For many, education on this tenet comes from their physician. However, as few as 20% of medical schools currently offer a dedicated nutrition course, and physicians perform lifestyle counseling in as few as 34% of their patient encounters. We hypothesized that an engaging culinary nutrition course intervention would better equip medical students to counsel their future patients on a healthy diet.

METHODS: With all first-year medical students at our school eligible, 10 participants enrolled in a voluntary, 4-part, 8-hour culinary nutrition course comprised of culinary-nutritional instruction and hands-on cooking in small groups. Assessment surveys were completed immediately prior to, immediately following, and 2 months after the intervention. Surveys included self-reported measures of attitudes regarding teaching healthy diet principles and an objective evaluation of culinary knowledge. The primary outcome was within-subject changes in attitude regarding counseling patients on the tenets of a healthy diet. Secondary outcomes included within-subject improvements and sustainability of culinary knowledge.

RESULTS: Overall survey completion was 99% across the 3 time-points. At baseline, the participants reported — on a 10-point scale (10 = highest) — high confidence in their ability to counsel patients on practicing a healthy diet based on their medical knowledge (mean 6.0 [95% confidence interval 5.1, 6.9]) and nutritional knowledge (5.9 [5.3, 6.5]) and low confidence based on their culinary knowledge (4.5 [3.3, 5.7]). Immediately post-intervention, participants' confidence in their nutritional knowledge (standardized mean difference 2.12 [95% confidence interval 1.02, 3.21]) and culinary knowledge (1.99 [0.92, 3.06]) significantly improved. There were no statistically significant differences between the immediately post-intervention and 2 months post-intervention timepoints ($P = 0.189, 0.494$). Overall, the participants reported feeling more prepared to counsel patients on a healthy diet immediately post-intervention compared to baseline (1.93 [0.87, 2.99]), and this did not change significantly 2 months later ($P = 0.322$). Scores on the objective test of culinary knowledge were significantly improved at both immediately post-intervention (3.20 [1.84, 4.56]) and 2 months post-intervention (1.09 [0.12, 2.05]) compared to baseline.

CONCLUSIONS: A culinary nutrition pilot course improved medical students' culinary-nutritional knowledge and confidence in counseling patients. Gains were maintained for 2 months post-intervention. Adding a culinary nutrition course to medical school curricula may result in improved abilities of students to provide dietary counseling. Further studies are needed to confirm results.

THE DOCTOR SAYS YOU CANNOT HAVE IT: A QUALITATIVE STUDY OF NON-PRESCRIPTION BUPRENORPHINE USE AMONG PARTICIPANTS AT HARM REDUCTION AGENCIES

Benjamin Hayes¹; Andrea Jakubowski¹; Aaron D. Fox². ¹Montefiore Medical Center, New York, NY; ²Montefiore Medical Center, Bronx, NY. (Control ID #3185960)

BACKGROUND: Buprenorphine is an effective opioid use disorder (OUD) treatment. Barriers to care limit access to formal buprenorphine treatment, but people with OUD may use diverted buprenorphine (i.e., acquired without a prescription) to "self-treat" OUD. Few studies have explored diverted buprenorphine use in detail. This qualitative study investigated why people use diverted buprenorphine instead of seeking prescriptions.

METHODS: In-depth, semi-structured interviews were conducted at harm reduction agencies in New York City. Participants were adults with self-reported OUD and prior buprenorphine use. Transcribed interviews were independently coded by three investigators, who generated preliminary themes from the coded data. Thematic analysis entailed iterative reading of

transcripts with identification of common patterns and relationships between themes.

RESULTS: Of the 17 participants, most were latinx, mean age was 42, all primarily used heroin, and one had an active buprenorphine prescription. The overarching goal of all participants was to maintain control over their drug use without being reliant on healthcare providers. We identified 3 primary themes that reflect this goal: 1. Diverted buprenorphine is useful as a short-term tool to moderate heroin use. Participants used diverted buprenorphine as either: a) bridging to prevent opioid withdrawal when heroin was unavailable, or b) temporarily unwanted, or self-detox, to assist in stopping heroin use. 2. Seeking a prescription for buprenorphine was less desirable than use of diverted buprenorphine for two main reasons: The barriers to care: "They told me they want to send me something in the mail, but I never received nothing. I bought [suboxone] on my own. If I'm going to go through a lot of things [a prescription is] not better"; or concerns that the prescription could be withdrawn: "Something will happen that they will shut you off and then you have to withdraw. That's why I went to the heroin because I could find it anytime I wanted. With suboxone, you cannot do that once the doctor says you cannot have it." 3. The pharmacologic effects of buprenorphine were not ideal for some participants. This fell within two common scenarios: participants who were not ready to stop heroin use, and those concerned that buprenorphine would not prevent withdrawal. 4. Buprenorphine may be taken for euphoric effects, but this was during limited circumstances.

CONCLUSIONS: Participants expressed motivations to maintain control over their drug use and sometimes used diverted buprenorphine to meet these objectives. Some participants desired to continue heroin use, which limited engagement in formal buprenorphine treatment. Other participants expressed concerns that prescribed buprenorphine was difficult to access or could be withdrawn by the prescriber, which made diverted buprenorphine more desirable. Though buprenorphine treatment may not meet the needs of some people with OUD, those seeking buprenorphine should have easy and reliable access to care.

THE EDUCATION CENTERED MEDICAL HOME IMPROVES PRIMARY CARE TRAINING AND MAY MITIGATE BURNOUT: A RANDOMIZED MEDICAL EDUCATION TRIAL

Bruce L. Henschen¹; David T. Liss¹; Blair Golden²; Kenzie A. Cameron¹; Jennifer Bierman³; Elizabeth R. Ryan⁴; Diane Wayne³; Daniel Evans¹. ¹Northwestern University, Chicago, IL; ²Northwestern McGaw, Chicago, IL; ³Northwestern University Feinberg School of Medicine, Chicago, IL; ⁴Indiana University School of Medicine, Gary, IN. (Control ID #3184582)

BACKGROUND: Traditional medical student clinical clerkships lack continuity of care, are associated with erosion of student empathy, and may increase burnout. Longitudinal clerkships may improve these outcomes, but rigorous studies are lacking. The Education-Centered Medical Home (ECMH) is a four-year, longitudinal, team-based primary care clerkship emphasizing continuity with patients, peers, and preceptors. We investigated effects of the ECMH on student attitudes and behaviors in a randomized medical education trial.

METHODS: We randomized students from two successive incoming classes to ECMH or to an enhanced Individual Preceptorship (IP). In ECMH, teams of 16 students (4 per class) spend four years in the same primary care clinic, working in pairs with a single outpatient preceptor to care for a medically-complex patient panel. In IP, students spend two years one-on-one with a preceptor, followed by a traditional primary care clerkship in the third year. ECMH students continue their longitudinal clinic while completing other clerkships in the third year. Otherwise, students' curricular hours and learning objectives are equal. We surveyed students four times (baseline, M1,

M2, and M3 year) using the Maslach Burnout Inventory (MBI); the Patient-Physician Orientation Scale (PPOS); the C3 survey assessing the 'hidden curriculum'; and the Attitudes Toward Health Care Teams (ATHCT) scale. We analyzed results using an intent-to-treat approach.

RESULTS: 329 students were randomized; 316 (96%) completed surveys. In regression analyses controlling for demographics and baseline interest in primary care or pediatrics, ECMH participation resulted in significantly greater continuity of care (mean # patients actively followed per student, 2.2 ECMH vs. 0.3 IP, p<0.001), greater perceptions of positive role modeling from preceptors and peers (C3 mean, 4.6 ECMH vs 4.3 IP, p<0.001), and more positive attitudes toward health care teams (ATHCT mean, 3.2 ECMH vs 3.0 IP, p=0.007) compared to IP across all three years. Regardless of initial assignment, 75% of students would recommend ECMH to a hypothetical incoming medical student. Regarding burnout, there was no effect on emotional exhaustion or cynicism, but ECMH students reported improved professional efficacy over three years (MBI-PE 4.1 ECMH vs 3.9 IP, p = 0.02). ECMH was associated with increasing professional efficacy across the study duration.

CONCLUSIONS: In a randomized medical education trial, students in ECMH reported positive effects on their learning environment, improved attitudes toward team-based care, and accelerated professional development. A four-year, outpatient clerkship model, layered onto a 'traditional' block clerkship curriculum, can produce improvements in primary care education and may promote student resiliency.

THE EFFECT OF A DIGITAL HEALTH INTERVENTION ON DECREASING BARRIERS AND INCREASING FACILITATORS IN COLORECTAL CANCER SCREENING IN VULNERABLE PATIENTS

Nancy M. Denizard-Thompson¹; Kathryn Weaver²; Doug Case²; John G. Spangler³; David P. Miller². ¹Wake Forest University School of Medicine, Winston-Salem, NC; ²Wake Forest School of Medicine, Winston-Salem, NC; ³Wake Forest School of Medicine, Winston Salem, NC. (Control ID #3178634)

BACKGROUND: Colorectal cancer (CRC) is a major health problem for vulnerable populations. Understanding the factors that influence receipt of screening is paramount to improving CRC screening rates. In our randomized control trial conducted in a vulnerable population, we found an absolute 15% increase in CRC screening among patients randomized to the Mobile Patient Technology for Health-CRC (mPATH-CRC) program, an iPad application that informs patients of screening need, helps make a screening decision, allows "self-order", and sends electronic messages to help complete the test. We now investigate what factors led to the success of the intervention and mediated the common known barriers and facilitators of CRC screening.

METHODS: All data for the present analysis was collected as part of a randomized-controlled trial to determine the impact of mPATH-CRC on colorectal cancer screening within 24 weeks. Participants were enrolled from 6 community-based primary care practices between June 2014 and May 2016 and randomized to either usual care or mPATH-CRC. Six potential mediators were considered. These include the ability to form a screening decision (Y/N), the intent to have colorectal screening in the next month (Y/N), patient/doctor discussion about colorectal screening (Y/N), perceived benefits to screening (1-5), perceived barriers to screening (1-5), and self-efficacy (1-5). We used the method proposed by Lacobucci to assess the significance of the mediation, and logistic regression was used to determine which patient characteristics were associated with screening.

RESULTS: 450 participants who were between the ages of 50 and 74 and due for colorectal screening were randomized. A total of 408 patients had complete data. In unadjusted analyses, participants in the mPATH arm were twice as likely to complete screening compared to the control arm (OR 2.70, 95% CI 1.66-4.39). After adjusting for all potential mediators, the odds ratio for mPATH-CRC fell to 1.68 and was no longer statistically significant (95% CI 0.98 - 2.88). Significant mediators of screening were perceived benefits, self-efficacy, ability to form a decision, and the occurrence of a patient/doctor screening discussion. The most powerful mediator was the occurrence of a patient/doctor discussion. In the full logistic regression model, only two factors were associated with completing screening: the occurrence of a patient/doctor discussion (OR 6.25, 95% CI 2.85-13.7) and lower perceived barriers (OR 1.55, 95% CI 1.00-2.40).

CONCLUSIONS: In summary, mPATH-CRC doubled the proportion of patients who completed CRC screening in a vulnerable patient population. The mPATH program influenced screening by affecting patients' attitudes, knowledge, and beliefs about screening and triggering healthcare provider discussions. The most powerful mediator was engaging in a patient/doctor discussion, highlighting that digital health interventions like mPATH are an important adjunct to the patient/doctor relationship but not a replacement.

THE EFFECT OF A PATIENT DECISION AID ON DECISIONAL QUALITY AMONG PATIENTS WITH LUMBAR DISC HERNIATION

O. Kenrik Duru¹; Christopher Saigal¹; Sylvia Lambrechts¹; Richard Hwang²; Aaron Reyes²; Lorna Kwan¹. ¹UCLA, Los Angeles, CA; ²David Geffen School of Medicine, Los Angeles, CA. (Control ID #3185687)

BACKGROUND: Among patients with low back pain and sciatica, the most common underlying condition is lumbar disc herniation (LDH). As there are several potential potential first-line treatments, LDH is considered a preference-sensitive condition such that providers should elicit patients' goals and values to help them select the treatment option that best aligns with their preferences. In this study, we compared decisional conflict in patients with lumbar disc herniation who completed an internet-based Patient Decision Aid (PDA) prior to their treatment consultation with patients not using a PDA.

METHODS: Patients seeking treatment for LDH at L4-L5 and/or L5-S1 were offered an internet-based PDA prior to their specialist consultation with a spine surgeon or physiatrist, while patients in usual care were not offered the PDA. All patients completed a post-visit questionnaire, either in person or by phone, which included validated questions from the SURE test for clinical practice, Decisional Conflict Scale (DCS) and the Shared Decision Making Questionnaire. We performed bivariate analyses to examine the association between decisional conflict and measures of decisional quality.

RESULTS: Overall, 40% in the implementation group (n=87) and 47% in the usual care group (n=174) reported decisional conflict after their visit ($p=0.253$), and the implementation group was more likely to know the treatment options than the usual care group (91% vs. 83%, $p=0.004$). Among patients who reported decisional conflict, the implementation group was more likely to know benefits and risks of the treatment options compared to the usual care group (72% vs. 41%, $p=0.003$). However, no differences were seen in other comparisons, including satisfaction with the decision, discussion of treatment options with the doctor, or inclusion in the treatment decision. Within the implementation group, patients without decisional conflict were more likely to

know treatment options (96% vs 82%, $p=0.011$), expect to stick with their decision (96% vs 71%, $p=0.003$), be satisfied with their decision (96% vs. 71%, $p=0.003$), discuss treatment options with their doctor (92% vs. 59%, $p<0.001$), and feel included in the treatment decision (98% vs. 67%, $p<0.001$) compared to those with decisional conflict.

CONCLUSIONS: Use of a PDA prior to specialty consultation for LDH is associated with an increased likelihood of knowing the different treatment options for this condition, and among those with decisional conflict, greater knowledge of the benefits and risks of each treatment option compared to those in the usual care group. This analysis demonstrates that use of an internet-based PDA for LDH treatment options may not be sufficient in itself to enhance decisional quality among patients with decisional conflict. Further investigation is needed to identify subsets of patients who benefit most from PDA implementation and to enhance strategies that improve shared decision-making.

THE EFFECT OF RED BLOOD CELL TRANSFUSION ON FATIGABILITY IN HOSPITALIZED PATIENTS WITH ANEMIA

Micah T. Prochaska; Rilwan Babajide; Sarah Bradbury; David Meltzer. University of Chicago, Chicago, IL. (Control ID #3160994)

BACKGROUND: Anemia is a common condition in hospitalized patients, and fatigue is the primary symptom of anemia. Anemia-related fatigue is associated with decreased health-related quality of life and poor functional outcomes. Therefore, an important objective of treating anemia with red blood cell transfusion may be to reduce fatigue and increase patient activity. While data from previous studies suggests that transfusion improves fatigue in hospitalized patients with anemia, these studies did not examine whether transfusion and changes in fatigue may also effect patient's activity levels. This is important because if transfusion reduces fatigue, patients may become more active. Thus, the effect of transfusion on patients' fatigue in the context of their activity, a measure known as fatigability, may be a more accurate measure of the benefit of transfusion than fatigue alone. To date, there are no data on the effect of transfusion on fatigability. The objective of this study was to determine whether transfusion during hospitalization improves fatigability 30 days post-discharge.

METHODS: From June 2017-January 2018 hospitalized general medicine patients with a Hemoglobin (Hb)<10g/dL were approached for an inpatient interview and a 30-day post-discharge phone interview. Fatigability was measured using the Pittsburgh Fatigability Scale (PFS) at both times points. PFS scores range from 0-50, with higher scores indicating greater fatigability (more fatigue at lower activity levels). Patients were categorized into 4 groups based on their inpatient level of fatigability (high or low) and Hb (<8g/dL or 8g/dL). A "change in fatigability" score was calculated by subtracting PFS scores obtained during the post-discharge phone interview from the inpatient PFS score. Clinical and demographic data were obtained from hospital administrative data. Independent sample t-tests were used to compare changes in fatigability within each of the 4 groups between patients who received a transfusion and those who did not.

RESULTS: 140 participants completed both the inpatient and post-discharge interview. There were no significant baseline differences between those who were transfused and those who were not [(age 53 vs. 53; $p=0.94$), (female 67% vs. 59%; $p=0.39$), (African American 74% vs. 69%; $p=0.76$), (Charlson Comorbidity Index 2 vs 2, $p=0.59$), (median in-hospital PFS 32 vs. 32; $p=0.97$)]. For patients with high in-hospital fatigability (PFS<32) and a Hb<8g/dL, transfusion was associated with improvement in fatigability 30 days after hospital discharge, compared to patients not transfused (14.8 vs 2.2, $p=0.02$). The effect of transfusion was not statistically significant in any other group.

CONCLUSIONS: Transfusion is associated with improvements in fatigability after hospital discharge for patients with high inpatient fatigability and low Hb. This suggests that for highly fatigued hospitalized patients with anemia, transfusion may both reduce fatigue and increase activity.

THE EFFECT OF STARTING THE PROTEIN SPARING MODIFIED FAST ON WEIGHT CHANGE OVER 5 YEARS: A COHORT ANALYSIS

Elizabeth Pföh¹; Gilbert Lowenthal¹; Laura Jeffers¹; Bartolome Burguera¹; Derrick Cetin¹; Bo Hu¹; Niyati M. Gupta²; Michael B. Rothberg¹. ¹Cleveland Clinic, Cleveland, OH; ²Cleveland Clinic Foundation, Cleveland, OH. (Control ID #3185236)

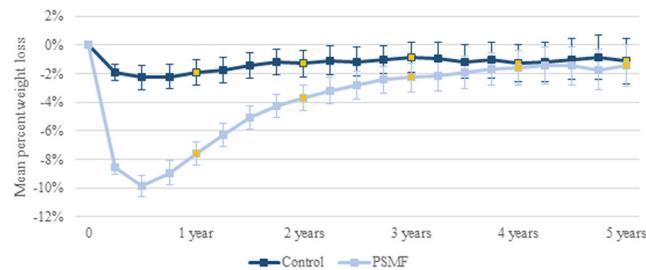

BACKGROUND: Ketogenic diets have been highlighted as a way to lose weight while experiencing reduced hunger. The protein-sparing modified fast (PSMF) diet induces ketosis and rapid weight loss but is difficult to maintain. Our objective was to track weight change for individuals initiating a PSMF or contrasting diet for up to five years.

METHODS: This was a retrospective cohort study of patients in a large integrated health system between 2007 and 2014. We included patients who discussed starting the PSMF diet or had a serum uric acid and a registered dietitian visit within 30 days. The main predictor was starting the PSMF diet vs another diet. The main outcome was percent weight change from baseline, calculated quarterly. Patients were censored at their final weight or if they underwent bariatric surgery. After fitting a regression model adjusted for demographic, medication use and specialist visits, we compared the effect of diet on weight change at each time point.

RESULTS: Of 1,419 eligible patients, 879 (62%) started the PSMF. The PSMF group was slightly younger (52 vs. 54, p<0.01), with a higher BMI (41.9 vs. 40.4, p<0.001). In the adjusted analysis, patients in the PSMF diet group averaged 2.7% more weight loss than patients in the other diet group (95%CI: -3.5, -2.0, p<0.001) (Figure). PSMF patients lost more weight initially, but by year 4, there was no difference between the diets. Compared to the control diet, patients starting the PSMF were more likely to experience 5% weight loss at 1 year (55% vs 20%, p<0.001) and 3 years, (33% vs. 23% p<0.05), but not 5 years(34% vs 30%, p=0.16).

CONCLUSIONS: In clinical practice, the PSMF reliably achieves rapid weight loss in the first six months, but only a small percentage of patients are able to maintain significant weight loss long-term.

Figure. Average weight loss adjusted for demographic and health care utilization characteristics for the PSMF and Control diet participants

THE FINANCIAL COST OF INTERPROFESSIONAL AMBULATORY TRAINING: WHAT'S THE BOTTOM LINE?

Lauren Block¹; Adam Block²; Joseph Conigliaro³; Nancy A. LaVine³. ¹Northwell Health, Lake Success, NY; ²New York Medical College, Valhalla, NY; ³Northwell Health, New Hyde Park, NY. (Control ID #3181791)

BACKGROUND: The goal of interprofessional training programs is to improve clinical care and trainee interest in primary care careers by cultivating a cooperative, patient-centered team culture. Initiation and sustainability of interprofessional training programs is predicated upon familiarity with the benefits and costs associated with program operation. We sought to quantify the additional costs associated with running an interprofessional

training program by comparing faculty and staff costs to a traditional residency training program at the same training site.

METHODS: The IMPACCT (Improving Patient Access, Care, and cost through Training) program at Northwell Health provides team-based clinical practice, interprofessional (IP) education, and career mentoring to internal medicine residents, medical students, and physician assistant, pharmacy and health psychology trainees. Trainees are supervised by physician, pharmacy, PA, and psychology faculty, with support from a dedicated medical assistant and a patient coordinator. A total of 10 residents are trained annually alongside 60 other IP trainees. Focusing on the additional staffing needs and faculty ratios, we compared annual costs associated with the IP clinic to those of an adjacent traditional clinic which trains 60 residents per year. Both programs meet ACGME staffing requirement for resident supervision, operate on a 4+1 schedule, have equivalent numbers of patient care sessions and have otherwise equivalent overhead costs. As an equal number of patients were seen per resident per week in the IP and traditional models, productivity was considered equivalent. Calculations were made using U.S. Department of Labor median salaries by profession for the state of New York.

RESULTS: Faculty and staff to resident ratios were higher in the IP model than the traditional residency training model. The interprofessional model cost \$11,390 more per resident per year than the traditional model, a total of \$113,897 annually for the ten residents in the program. Main costs were reflective of the higher faculty/staff to resident ratios, including additional salary of \$60,292 for pharmacy, \$15,272 in psychology, \$22,172 in physician (faculty:resident 1:2 IP vs 1:2.5), \$8485 in coordinator (1:2 IP vs 1:3), and \$7676 in medical assistant salaries (1:2 IP vs 1:3). Benefits of improved quality, training and patient experience were not studied in this analysis.

CONCLUSIONS: Operating an interprofessional training program costs an additional \$11,390 per resident per year, largely in higher faculty and staff to resident ratios and the services of psychology and pharmacy faculty in the IP training clinic. Given this was an interprofessional training program, these costs also funded the training of additional pharmacy, PA, and psychology students. In an academic setting, some of these costs may be funded by grants and other agreements.

THE FIRST 2 YEARS OF THE ACA: QUALITY, COST, UTILIZATION, AND PATIENT EXPERIENCE

David M. Levine¹; Jeffrey A. Linder²; Bruce E. Landon³. ¹Brigham and Women's Hospital, Boston, MA; ²Northwestern University Feinberg School of Medicine, Chicago, IL; ³Harvard Medical School, Boston, MA. (Control ID #3185562)

BACKGROUND: The Affordable Care Act (ACA) expanded insurance coverage to Americans earning less than 400% of the federal poverty level (FPL) via subsidies for private insurance and, in states that elected it, Medicaid expansion. Prior work has shown resulting improvements in insurance rates and experience with care and decreased high-burden spending among the poor. No nationally-representative analysis has examined the association of the ACA with quality, cost, utilization, and patient experience.

METHODS: We analyzed data from the 2011 to 2015 Medical Expenditure Panel Survey (annual response rate: 48%-55%), a nationally representative annual survey of non-institutionalized Americans and their respective clinicians, hospitals, pharmacies, and employers. We compared Americans, 18 to 65 years old, earning greater than (n=29248) or less than (n=71405) 400% of the FPL before (2011 to 2013) and after (2014 and 2015) the ACA using a difference-in-differences (DiD) approach with adjustment for 20 sociodemographic covariates. For quality and experience outcomes, we examined previously published composites based on 43 individual measures: 5 "high-value" care composites (e.g. cancer screening); 3 "low-value" care composites (e.g. inappropriate imaging); an overall patient experience rating; a physician communication composite; and an access-to-care composite. For cost outcomes, we examined total cost of care and out-of-pocket expenditures. For utilization, we examined outpatient, emergency, and inpatient encounters and prescribed medicines.

RESULTS: Over 2 years of implementation, Americans earning <400% FPL compared to >=400% FPL received more high-value diagnostic and preventive testing (DiD, +1.8%; p<0.01), but no difference in cancer screening, diabetes care, counseling, or medical treatments. Americans earning <400% FPL had similar low-value antibiotic use and medical treatments, but worse low-value imaging (DiD, -3.1%; p=0.04), improved global health care ratings (DiD, +2.2%; p=0.04), and improved physician communication ratings (DiD, +2.8%; p<0.01) with non-significantly better access to care (DiD, +2.1%; p=0.14). There were no significant differences in utilization of preventive visits (DiD, +2.1%; p=0.06), inpatient, outpatient, emergency, or pharmacy services, nor in the cost of care (total cost DiD, +\$233; p=0.38; total out of pocket cost, -\$47; p=0.15).

CONCLUSIONS: In its first 2 years among Americans earning <400% FPL, the ACA improved diagnostic and preventive testing and patient experience, worsened low-value imaging, and had minimal to no impact on other quality composites, cost, or utilization. Despite decreasing the uninsurance rate by over 25%, the ACA to date has had a relatively limited impact on the quality of care experienced by lower income Americans. Future efforts are needed to assure access and quality for this population as significant disparities in quality persist.

THE HIGH COST OF LOW VALUE CARE

Thomas McGinn¹; Stuart Cohen¹; Sundas Khan¹; Safiya Richardson²; Michael Oppenheim¹; Jason J. Wang¹. ¹Zucker School of Medicine at Hofstra/Northwell, Manhasset, NY; ²Donald and Barbara Zucker School of Medicine at Hofstra/Northwell, Manhasset, NY. (Control ID #3186288)

BACKGROUND: A fundamental problem with health care delivery in the United States is that a large percentage of the care delivered is not indicated and often harmful. In many clinical situations there is readily available evidence to inform proper decision making to reduce unnecessary testing and treatments, but that evidence is not utilized. Our research team developed a clinical decision support (CDS) tool based on the Wells' criteria for pulmonary embolism (PE) in which computed tomography pulmonary angiography (CTPA) is not recommended in low probability patients. As part of a cost analysis, we retrospectively characterized the rate of incidental findings on CTPAs performed despite the CDS recommendations.

METHODS: A retrospective analysis was conducted on patients evaluated for suspected PE in the emergency department at two tertiary academic hospitals between August 1, 2015 to July 31, 2017. A fellowship trained cardiothoracic radiologist performed a manual review of the reports of low and very low risk CDS patients with a CTPA result to account for incidental findings. Low risk patients were defined as a negative D-dimer during the visit (<500 ng/mL) and very low probability patients was determined based on a negative D-dimer and discharged home. For each follow up test recommended, the cost was estimated through their current procedural terminology (CPT) code using the 2018 Medicare physician fee schedule for area 2.

RESULTS: There were 12,759 patient visits representing 11,836 patients. For the 11,836 patients, 5,068 were patients in the low probability category and 3,645 were in the very low probability category. Of the very low probability group, 877 had a CTPA within 24 hours after a negative D-dimer. Review of the follow up recommendations for the 877 low probability patients resulted in 79.8% (700/877) with no follow up, 17.6% (154/877) had 1 item follow up recommended, 2.5% (22/877) had 2 items recommended, and 0.1% (1/877) had 3 items follow up recommended. The total costs of performing 877 CTPAs was \$317,140.74 and the follow up recommendations cost was \$53,619.79. If all tests were performed it represented an additional 17% cost increase compared to only performing the initial CTPA.

CONCLUSIONS: Avoiding unnecessary medical testing is important for several reasons including cost to the patient, health systems, and

country. A more concerning issue regarding expense and harm is the potential for unnecessary follow up tests performed which could have been avoided if the initial test had never been performed. The cost estimates were limited by using Medicare standard fees which may underestimate the actual procedure cost and additional evaluation is needed to establish the true cost of unnecessary follow up testing. In addition, CDS tools built to estimate pretest probability of PE and discourage the CTPA use in low-risk patients have been shown to improve the CTPA yield. Seamlessly integrating evidence into care is imperative in the reduction of unnecessary tests.

THE I-HOPE STUDY: IMPROVING HOSPITAL OUTCOMES THROUGH PATIENT ENGAGEMENT

James D. Harrison¹; Esther Avitia⁶; Michelle Archuleta²; Jim Banta³; Joy Benn⁴; Marisha Burden²; Vineet Chopra⁵; Rebecca Coker⁶; Shaker Eid⁷; Margaret Fang¹; Kathryn Fletcher⁸; Julie K. Hagan⁷; Jawali Jaranilla⁹; Monalisa Mullick¹⁰; Christopher Nyenpan¹¹; Lali Silva⁴; Melissa Wurst¹⁰; Georgiann Ziegler⁵; Luci Leykum^{6, 12}. ¹University of California San Francisco, San Francisco, CA; ²Denver Health, Denver, CO; ³Intensive Care Unit Patient & Family Advisory Council, University of California San Francisco, San Francisco, CA; ⁴Minnesota Hospital Association, Saint Paul, MN; ⁵University of Michigan, Ann Arbor, MI; ⁶University of Texas Health at San Antonio, San Antonio, TX; ⁷Johns Hopkins Bayview Medical Center, Baltimore, MD; ⁸Medical College of Wisconsin/Milwaukee VAMC, Tbd, AL; ⁹HealthEast Care System, Saint Paul, MN; ¹⁰Washington University in St. Louis, Saint Louis, MO; ¹¹Society of Hospital Medicine, Washington DC, DC; ¹²South Texas Veterans Health Care System, San Antonio, TX. (Control ID #3162633)

BACKGROUND: Issues with the quality and safety of hospital care have been well-documented. However, what is less understood are the perspectives of patients, families, caregivers, and other stakeholders regarding what they feel are the most important targets of improvement research. We systematically engaged a broad sample of these groups to solicit their input on important questions and to develop a prioritized agenda to drive Hospital Medicine research and quality improvement.

METHODS: The study was led by 9 researchers, 8 patients, and 2 administrators recruited from 8 academic medical centers, who formed a Steering Committee that managed the project. We applied a collaborative and consultative approach to stakeholder engagement based on validated methods from the James Lind Alliance. This included multiple and iterative stages to our project such as: 1) a multi-pronged, inclusive patient and stakeholder engagement strategy; 2) an online survey of patients and stakeholder organization leadership and members; 3) rigorous qualitative thematic analysis; 4) a two-day in-person meeting with patients and stakeholders to prioritize the submitted survey questions and plan dissemination efforts.

RESULTS: In total, 499 respondents (including 267 healthcare providers, 244 patients and caregivers and 63 researchers) from 47 organizations submitted a total of 782 high-priority research questions and suggestions for improving hospital care. These questions were categorized into 73 distinct topics, 53 that were health-system related and 20 disease-specific. Thematic analysis of categories revealed 36 commonly submitted question domains. Following a two-step prioritization process involving the study team and representatives from 30 stakeholder organizations, 11 questions were identified as top priorities (Table 1).

CONCLUSIONS: Through a dynamic and collaborative stakeholder engagement process, key patient and family-centered research questions have been identified and developed. These results can help drive a national conversation in the Hospital Medicine community about how to address these priority areas and should inform stakeholder agencies about key areas of research focus.

THE IMPACT OF A NOVEL STEPWISE APPROACH TO PRUNING MEDICATIONS IN AN INTERDISCIPLINARY POLYPHARMACY CLINIC

Gubin Li; Kelli Barnes; Sara Woods; Stuart Beatty. The Ohio State University, Columbus, OH. (Control ID #3184613)

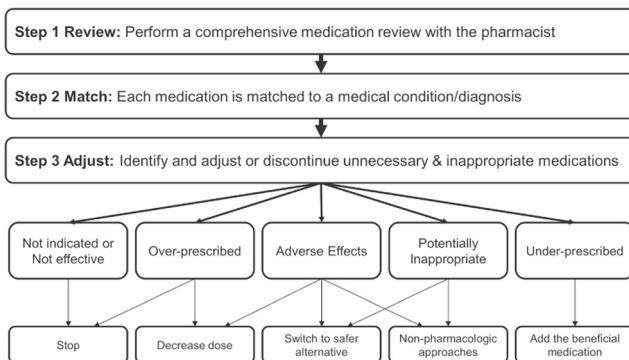

BACKGROUND: Polypharmacy refers to the use of multiple medications by a single patient. Undesirable effects of polypharmacy include adverse drug events, medication interactions, poor compliance and increased costs. Several implicit (judgement based) and explicit (evidence based) criteria are utilized to evaluate polypharmacy (Beers, STOPP/START, and Medication Appropriateness Index). However, implicit criteria are time consuming and not feasible for routine clinical practice, while explicit criteria do not accurately evaluate medication effectiveness. A comprehensive yet personalized approach is needed. The aim of this study is to assess the impact of a step-wise approach in an Interdisciplinary Polypharmacy Clinic on reducing medication burden.

METHODS: A single institution prospective cohort study was conducted. The participants included were 18 years old and on 6 chronic medications. All terminally ill or severely demented participants were excluded. The interdisciplinary team included a geriatrician, a pharmacist and a social worker. All participants underwent a 3-step approach to evaluate polypharmacy (Figure). By the end of the visit, the participant was counseled on all medication changes and received a personalized medication record. Quality of life improvements were evaluated with the Short Form-12 Quality of Life health survey (SF-12) at baseline and 1-month follow-up. The participant's pre- and post-intervention medication usage and quality of life was compared.

RESULTS: A total of 118 patients were included in the cohort. The mean age was 62.9 years. The mean number of medical comorbidities was 10.5. Prior to intervention, participants had a mean of 15.65 medications compared to a mean of 13.44 after intervention ($p<0.001$), with an average reduction of 2.25 medications. Among the medications discontinued, 80.0% were NSAIDs, and 31.9% had anticholinergic effects. SF-12 data was collected for 89 patients. SF-12 scores trended toward slight improvement at 1 month in both the physical component ($p=0.101$) and mental component ($p=0.626$).

CONCLUSIONS: Our study demonstrates polypharmacy can be systematically reduced through a simple stepwise interdisciplinary approach. Importantly, there were no negative effects on quality of life after medication reduction.

3 Steps to “Pruning” Polypharmacy

THE IMPACT OF GENDER ON INPATIENT MORTALITY OF HYPERTENSIVE LATINO PATIENTS ACROSS CKD STAGE 3 TO ESRD IN THE UNITED STATES.

Ricardo R. Correa¹; Rodrigo Aguilar²; Carmen Cervantes³; Mark Nader².

¹University of Arizona, Phoenix, AZ; ²Marshall University, Huntington, WV; ³AVentura Hospital, Hollywood, FL. (Control ID #3167834)

BACKGROUND: Hypertension and chronic kidney disease are two of the most important risk factors for cardiovascular disease, a major cause of death in the US population. The impact of gender in this equation remains unclear, more so, on how it affects the Hispanic population. Studies comparing the outcomes and difference in inpatient mortality between male and female with hypertension and CKD are sparse. Our aim was to determine if gender in Latino population affect the inpatient survival rate among hypertensive patients across different CKD stages.

METHODS: Data was extracted from the 2005 to 2012 Nationwide Inpatient Sample (NIS). Using propensity score matching, female hypertensive with chronic kidney disease (stage 3, 4, 5 or ESRD) patients were matched with hypertensive males at a 1:1 ratio. We compared inpatient mortality, both crude mortality and mortality per CKD stage, length of stay and total hospital charges between male and females. Analyses were performed using SAS version 9.3 (SAS Institute, Cary, NC, USA).

RESULTS: Among 227,923 hospitalized hypertensive patients, 118,132 (51.83%) were males and 109,791 (48.17%) females. 18.76%, 10.31%, 3.85% and 67.17% were Females with CKD 3 to ESRD respectively. Males across CKD stages 3 to ESRD were 19.47%, 9.54%, 3.63% and 67.43% respectively. In-hospital crude mortality was significantly higher for males compared to group of females before match, (3.89 vs 3.74 $p=0.05$), interestingly, mortality was higher after match for females (3.85 vs 3.79 $p=0.48$). Mean length of stay for hypertensive females were significantly higher than males, irrespective of CKD stage (6.74 vs 6.70 days, $p=0.001$), however at the male group had an expense of higher hospital charges (63,686 vs 61,667 dollars, $p=0.001$).

CONCLUSIONS: Latino hypertensive men with any stage of CKD are more at risk of dying than their counterpart women and have higher hospital charges. Further studies are needed to explore these associated genders in difference outcomes in this population.

THE IMPACT OF MEDICARE STAR RATING ADHERENCE MEASURES ON MEDICATION ADHERENCE FOR TARGETED AND NON-TARGETED MEDICATIONS

Natasha Parekh^{1, 2}; Kiraat D. Munshi³; Inmaculada Hernandez⁴; Walid F. Gellad^{1, 5}; Rochelle Henderson³; William H. Shrank². ¹University of Pittsburgh Medical Center, Pittsburgh, PA; ²UPMC Center for High-Value Health Care, Pittsburgh, PA; ³Express Scripts Holding Company, St. Louis, MO; ⁴University of Pittsburgh, Pittsburgh, PA; ⁵VA Pittsburgh/University of Pittsburgh, Pittsburgh, PA. (Control ID #3183269)

BACKGROUND: In 2012, Medicare incorporated medication adherence for oral antidiabetics, renin-angiotensin system (RAS) antagonists, and statins as highly weighted measures in star rating calculations. In the same year, health plans began receiving Quality Bonus Payments for achieving higher star ratings. It is unclear how these policy changes affected adherence to medications targeted by these policies and whether any impact spilled over to other chronic disease medications.

METHODS: We performed quasi-experimental interrupted time series analyses with multivariable segmented linear regression models to assess monthly changes in medication adherence (as measured by proportion of days covered) over a seven-year period from 2010 to 2016 using Medicare administrative claims data from a large pharmacy benefits manager. We conducted two separate sets of analyses: the first examined whether

policy changes affected medication adherence for the 3 targeted therapy classes, and the second assessed the association of policy changes with improvements in adherence to five chronic disease therapy classes not considered in star ratings calculations (thiazides, beta blockers, calcium channel blockers, non-statin anti-hyperlipidemics, and levothyroxine). For the second analysis, we further compared adherence between beneficiaries who concomitantly used and did not use star rating medications.

RESULTS: We studied 240,811 Medicare beneficiaries on oral antidiabetics, 500,958 on RAS antagonists, 471,135 on statins, 464,910 on beta blockers, 392,762 on thiazides, 397,359 on calcium channel blockers, 165,151 on non-statin anti-hyperlipidemics, and 323,803 on levothyroxine. There was a significant increase in monthly adherence for all star rating and non-star rating medications after 2012 ($p<0.001$). Adherence for oral antidiabetics, RAS antagonists, and statins was 11.2%, 8.1%, and 3.7% higher than it would have been in the absence of star ratings policy changes, respectively ($p<0.001$). The change in adherence for non-star rating anti-hypertensives and anti-hyperlipidemics was higher among those concomitantly on star ratings medications compared with those who were not ($p<0.001$). Levothyroxine adherence trends did not significantly differ between those using and not using star rating drugs.

CONCLUSIONS: Incentivizing medication adherence in the star rating program was effective in increasing adherence to medications targeted by the policy change and also non-targeted medications that treat the same diseases. As policymakers seek to determine the optimal number and type of quality measures for improving health services delivery without increasing administrative burden, it is important to consider that incentives not only can improve performance of targeted measures, but can also spill over to promote improved performance in related outcomes. Our findings can ultimately inform future approaches to quality measure development and implementation.

THE IMPACT OF OVERLAP BETWEEN MEDICARE'S VOLUNTARY ACCOUNTABLE CARE ORGANIZATIONS AND BUNDLED PAYMENTS ON THE COSTS AND QUALITY OF CARE
Amol S. Navathe^{1, 3}; Sarah Dykstra²; Joshua M. Liao^{1, 1}; Rachel M. Werner^{3, 1}. ¹University of Pennsylvania, Philadelphia, PA; ²The Wharton School, University of Pennsylvania, Philadelphia, PA; ³CMC VA Medical Center, Philadelphia, PA. (Control ID #3179179)

BACKGROUND: While both voluntary accountable care organizations (ACOs) and bundled payments have demonstrated promising early results, it remains unclear to what extent outcomes are affected when the two models overlap (i.e., when patients receive care from organizations participating in both models).

METHODS: Our analysis focused on episodes for lower extremity joint replacement surgery (LEJR) and 5 medical conditions (acute myocardial infarction, congestive heart failure, chronic obstructive pulmonary disease, sepsis, pneumonia). We used 2011-2016 Medicare claims and program data to categorize beneficiaries attributed to Medicare Shared Savings Program (MSSP) ACOs into those who were hospitalized for 1 of the 6 episodes at hospitals in the Bundled Payments for Care Improvement (BPCI) initiative (*Overlap*) versus non-BPCI hospitals (*MSSP-only*). We used a difference-in-differences method and hierarchical generalized linear models among 68,548 *Overlap* and 988,933 *MSSP-only* patients receiving care at 529 ACOs, 402 BPCI hospitals, and 3,114 non-BPCI hospitals to evaluate differential changes with respect to 90-day episode outcomes: (1) post-discharge institutional care spending (combination of skilled nursing, inpatient rehabilitation, and acute hospital facilities) (2) discharge to an institutional post-acute care (PAC) provider, and (3) readmissions. Spending models used a log link and gamma distribution while others used an identity link and normal distribution. Covariates included patient characteristics (age, sex, Elixhauser comorbidities) as well as hospital, ACO, and quarter fixed effects. We clustered standard errors by hospital and used an $=0.05$.

RESULTS: Across 6 episodes, mean beneficiary age and sex did not vary between *Overlap* and *MSSP-only* groups, while differences in mean Elixhauser mortality score were significant, but small. For LEJR episodes, institutional post-discharge spending was 8.1% lower (95% CI -12.9% to -3.4%, $p<0.001$) and institutional PAC provider use was 2.6% lower (95% CI -3.3% to -1.8%, $p<0.001$) among *Overlap* patients compared to *MSSP-only* patients. Readmissions were unchanged (0.3%, 95% CI -0.2% to 0.9%, $p=0.20$). Across medical condition episodes, *Overlap* patients had 7.1% greater post-discharge institutional spending (95% CI 2.8% to 11.3%, $p<0.001$) and 2.1% more readmissions (95% CI 1.4% to 2.8%, $p<0.001$) compared to *MSSP-only* patients, but no differential changes in discharge to institutional PAC (0.2%, 95% CI -0.4% to 0.7%, $p=0.59$).

CONCLUSIONS: Among ACO-attributed patients, admission to a BPCI hospital was associated with lower post-discharge institutional spending and PAC utilization for LEJR but not medical conditions. This suggests that ACOs may benefit when attributed beneficiaries are admitted to bundled payment hospitals for some episodes (i.e., LEJR), but not others.

THE IMPACT OF PENNSYLVANIA'S MANDATED PRESCRIPTION DRUG MONITORING PROGRAM PORTAL ON NEW-START OPIOID PRESCRIBING TO OPIOID-NAÏVE PRIMARY CARE PATIENTS WITHOUT CANCER.

Jonathan Arnold; Scott D. Rothenberger; Kevin Kraemer; Janel Hanmer. University of Pittsburgh, Pittsburgh, PA. (Control ID #3184972)

BACKGROUND: Prescription drug monitoring programs (PDMPs) are in use by most states to identify patients at high-risk for adverse events from opioid prescribing. Pennsylvania (PA) deployed a PDMP portal in August 2016 and mandated its use by prescribers as of January 2017. Behavioral economics suggests that increasing the burden of prescribing will decrease the prescribing rate, independent of patient risk, a concern shared by patient and provider groups. Our objective was to evaluate the impact of PA's PDMP mandate on opioid prescribing in an opioid-naïve patient population by primary care providers (PCPs).

METHODS: We conducted an interrupted time-series study of ambulatory opioid prescribing at a large regional health system. We included 14 months prior to the PA PDMP portal availability (July 2015-August 2016) and 14 months following its mandated use (January 2017-February 2018). We included all patient visits to an internal or family medicine practice with a pain-related diagnosis by patients who had been previously established in primary care. We excluded patients with a cancer diagnosis or evidence of a prior opioid prescription within 12 months. We used generalized linear mixed models including random effects at the provider and practice levels and fixed-effects for baseline trend, post-PDMP offset and post-PDMP trend change. The CDC released its guideline for prescribing opioids in chronic pain in March 2016 and we included fixed effects in our analysis as post-CDC offset and post-CDC trend change. We evaluated several outcomes included percentage of visits with an opioid prescription, quantity of opioids prescribed per visit in milligram morphine equivalent (MME), and quantity of opioids prescribed per prescription. A review of state and institutional policies did not identify other significant policy changes occurring at the same time as the PDMP portal deployment and mandate.

RESULTS: We included 384,440 patient visits with 808 providers at 272 practices. Opioids were prescribed in 3.6% of all visits, an average of 18.3 MME per visit and 509 MME per prescription. The prescribing rate was decreasing at a relative 2.6% per month prior to the PDMP ($p<0.001$) without a change associated with the PDMP mandate. The PDMP mandate was not associated with any change in the quantities of opioid prescribed per visit or per prescription. The CDC guidelines were associated with a relative 8.5% decrease in the rate of opioid prescribing ($p=0.045$), no change in the baseline trend in prescribing rate, and no change in the quantities of opioid prescribed per visit or per prescription.

CONCLUSIONS: The deployment of a PDMP portal in PA and its mandated use by providers was not associated with a change in the rate or quantity of opioids prescribed by PCPs to opioid-naïve patients with non-cancer pain. There is no evidence that the increased burden by mandating use of the PDMP changed PCP prescribing behaviors for this opioid-naïve patient population.

THE IMPACT OF PRICE CHANGES ON PROVIDER BEHAVIOR: EVIDENCE FROM SHARP CHANGES IN MEDICARE PROFESSIONAL AND FACILITY FEES

Zirui Song, Harvard Medical School, Boston, MA; Massachusetts General Hospital, Boston, MA. (Control ID #3186116)

BACKGROUND: Understanding how providers respond to fee changes is central to health policy. The price of medical care differs by site of care—services delivered in a facility setting garner a "professional fee" for the physician and a "facility fee" for the hospital, the sum of which typically exceeds the single fee paid in an office setting. This study evaluates a natural experiment in Medicare prices using a sharp change in fees for coronary stents.

METHODS: In 2013, Medicare lowered the professional fee for a patient's initial stent, while raising the professional fee for additional stents. Simultaneously, Medicare raised the facility fee for all stents. This study examines its effect on multiple margins of physician response—spending, volume, site of care, stent choice, patient selection, offsets on inpatient stenting, and spillovers onto the commercially-insured population 4 years into the policy. It uses 2009-2016 Medicare claims and segmented regression adjusted for age, sex, risk, secular trends, seasonality, cost-sharing, and geography. Standard errors were clustered by MSA.

RESULTS: The population included 405,836 Medicare beneficiaries nationwide and 9,222,719 individuals with employer-sponsored insurance. On average over 4 years, the Medicare policy led to an increase in spending of \$2.36 per beneficiary per year on cardiac stents, a 15.6% increase over pre-intervention spending levels ($p<0.001$). This was driven by increased spending on drug-eluting stents in the facility setting (\$2.02 per beneficiary per year increase, $p<0.001$). The volume of stents placed increased, on average, 0.63 stents per 1,000 beneficiaries per year (7.9% increase, $p<0.001$), with drug-eluting stents in the facility setting explaining this growth. The quantity of patient-days during which stenting took place increased by 52 days per 1,000 beneficiaries per year (1.1% increase, $p=0.001$), and stents placed per patient-day increased by 0.28 per year ($p=0.008$) over the 4 years. The share of patients stented without active chest pain increased, whereas that with active chest pain declined. Beneficiary cost-sharing remained stable. In terms of offsets, inpatient volume decreased by 0.04 hospitalizations per 1,000 beneficiaries per year ($p<0.001$). Commercially-insured populations saw an increased spending of \$0.47 per enrollee per year (10.4% increase vs. pre-intervention, $p<0.001$)—smaller than the Medicare effect due to lower volume and price increases.

CONCLUSIONS: Medicare's cut in physician fees and increase in facility fees led to increased spending, driven by changes in site of care, treatment choice, treatment intensity, and share of patients with stable coronary artery disease stented. Moreover, Medicare faced the full costs of this policy; hospitalizations were partially offset, and smaller increases in spending and volume among commercially-insured populations took place. Altering Medicare prices exerts multiple downstream effects on provider behavior with potentially important unintended consequences.

THE IMPACT OF SOCIAL MOVEMENTS ON TEAM-BASED PRIMARY CARE: A QUALITATIVE ASSESSMENT OF PERCEPTIONS OF #METOO AND #BLACKLIVESMATTER

Cati Brown-Johnson¹; Nadia Safaeinili²; Jonathan G. Shaw¹; Marcy Winger³; Megan Mahoney⁴. ¹Stanford University School of Medicine, Stanford, CA; ²Stanford University, Stanford, CA; ³Stanford University Medical School, Stanford, CA; ⁴Stanford University, Palo Alto, CA. (Control ID #3185638)

BACKGROUND: Social movements such as #metoo and #blacklivesmatter can impact the practice environment. Implementation science frameworks posit that the environment surrounding interventions can impact them. Studies of the impact of national policy and social movements on workplace culture have been conducted in medical contexts, but systematic reports are limited. These national conversations may be particularly relevant to team-based primary care interventions, which bring together healthcare staff with diverse training and backgrounds, and may be primarily supported by female medical assistants (MAs). To our knowledge, this project is the first research-based exploration of the impact of #metoo and #blacklivesmatter on team-based primary care.

METHODS: Qualitative interviews (n=26) were conducted as part of an evaluation of team-based care across 5 academic practices. Interviewees (providers, including nurse practitioners/physician assistants n=12; MAs n=10; management n=4) were asked how, if at all, #metoo or #blacklivesmatter impacted interactions with staff or patients. Interviews were recorded; audio files and transcripts were coded for emergent themes by two researchers.

RESULTS: Interviewees were predominately women (n=22), as these clinics were largely staffed by women. Some interviewees had not heard of #metoo or #blacklivesmatter (n=6). Perceived impacts of #metoo included team meetings to discuss sexual harassment, implementing protocols to curb harassing behavior by patients, and utilizing case conferences to debrief the emotional toll of hearing "sad stories" from female patients who had experienced trauma. A small minority of interviewees reported perceiving that male colleagues were dismissive of female staff concerns, or "just didn't understand." Providers reported noticing increased clinical focus on supporting transgender and non-binary patients as a possible outgrowth related to the #metoo movement. Perceived impacts of #blacklivesmatter were reported less frequently. The majority of interviewees responded to questions about #blacklivesmatter by noting that they treat everyone the same. A mix of MAs and providers reported tailoring their behavior for non-white patients, with one provider noting that she is more likely to attend to complaints from both non-white patients and women as a result of these national conversations. Another provider reported asking new patients "How has healthcare been for you? Have you had barriers in the past?" due to awareness that race/ethnicity can impact healthcare access.

CONCLUSIONS: Our novel exploratory study demonstrates that national movements can impact team-based primary care. Next steps include investigating how conversations around movements like #metoo or #blacklivesmatter might be leveraged to contribute to safer working environments for staff and more equitable care for patients.

THE IMPACT OF THE AFFORDABLE CARE ACT MEDICAID EXPANSION ON RACIAL/ETHNIC AND SEX DISPARITIES IN HIV TESTING: NATIONAL FINDINGS FROM THE BEHAVIORAL RISK FACTOR SURVEILLANCE SYSTEM

Anitha Menon; Payal Patel; Renuka Tipirneni. University of Michigan, Ann Arbor, MI. (Control ID #3180729)

BACKGROUND: More than half of Americans have not been tested for HIV in their lifetime, and over a third of all HIV diagnoses are made less than a year before the progression to AIDS. While the cause of low testing rates is multifactorial, a major barrier to universal HIV testing is lack of universal access to healthcare. The Affordable Care Act (ACA) Medicaid expansion led to large coverage gains in states that expanded, which may translate to improvements in health outcomes. Prior work has shown that overall HIV testing rates increased after the ACA. This study assessed the differential impacts of ACA Medicaid expansion on racial/ethnic (e.g. Black race) and racial/ethnic-sex (e.g. white females) disparities in HIV testing.

METHODS: The group primarily targeted by the 2014 Medicaid expansion - low-income (138% of the federal poverty level) adults ages 19-64 who are non-pregnant and non-disabled - was studied using the Behavioral Risk Factor Surveillance System (BRFSS) data from all 50 States and the District of Columbia. A quasi-experimental study design was used with triple difference-in-differences (DDD) logistic regression analyses to

assess the differential impacts of race/ethnicity groups and race/ethnicity-sex groups. All 30 states and D.C. that expanded Medicaid by December 2015 were included in the treatment group and all 20 non-expansion states were included in the control group. Outcomes were 1) ever having received an HIV test and 2) having received an HIV test in the last year.

RESULTS: Overall, Medicaid expansion was associated with a statistically significant increase in the probability of both ever having received an HIV test and having received an HIV test in the last year, consistent with prior work. However, following the Medicaid Expansion, Black females were less likely to have increased rates of ever having HIV testing (65% pre-expansion and 59% post-expansion) when compared to a white male reference group (33% pre-expansion and 34% post-expansion) and across other race/ethnicity-sex groups ($p=0.016$). Findings were similar for HIV testing in the last year.

CONCLUSIONS: Medicaid expansion increased the overall probability of HIV testing among low-income, nonelderly adults, but it had differential impacts among different race/ethnicity-sex categories. Black females were the least likely to experience an increased probability of receiving an HIV test following the expansion. Though they had higher baseline HIV testing rates than white men, the negative trend in testing rates is concerning as Black females are disproportionately affected by HIV. Moreover, as the CDC recommends that all adults be tested for HIV at least once, these findings demonstrate that not all groups are approaching this testing goal. These data should guide further research on the drivers of HIV testing disparities, changes in HIV testing practices for clinicians, and policy changes that aims to expand insurance coverage and HIV testing in the United States.

THE IMPACT OF THE BALANCING INCENTIVES PROGRAM ON INFORMAL CAREGIVER BURDEN IN THE UNITED STATES

Rebecca E. Anastos-Wallen¹; Paula Chatterjee¹; Rachel M. Werner².

¹University of Pennsylvania, Philadelphia, PA; ²University of Pennsylvania and Philadelphia VA, Philadelphia, PA. (Control ID #3185793)

BACKGROUND: There are an estimated 34.2 million adults in the US who provide informal care to sick family members or friends. These caregivers are known to have higher rates of stress and poorer health than their non-caregiver peers. The Balancing Incentives Program (BIP), established under the Affordable Care Act, provided federal funding for states to shift long-term care out of institutional settings and into the home. However, the effect of BIP on informal caregivers is unknown. We compared changes in caregiving activities and measures of wellbeing among caregivers in states that participated in BIP compared to control states.

METHODS: As BIP states shifted more care into the home, we hypothesized that caregivers in those states might provide more frequent care. Given increased support services at home, we also hypothesized that caregivers might have improved wellbeing. To test these hypotheses we studied respondents to the American Time Use Survey who self-identified as caregivers and either lived in a state that participated in BIP or in a state that was eligible to participate but did not (non-BIP). We used quasi-experimental design with difference-in-difference regression to assess the likelihood of a respondent being a caretaker, frequency of caregiving, and wellbeing measures related to time slept and time spent on self-care.

RESULTS: From 2011-2017, we identified 4,311 informal caregivers in non-BIP states and 7,316 in BIP states. Caregivers in BIP states were more likely to report providing daily care after BIP implementation (3.1%, $p=0.04$). Consistent with the goals of the program, caregivers in BIP states had some improvement in markers of wellbeing (gains in sleep of 13.9 minutes, $p=0.01$; gains in time spent on self-care of 12.0 minutes, $p=0.03$) compared to control caregivers. These effects were more pronounced among caregivers with more than a high school education (18.3 minutes of sleep, $p=0.004$), annual family incomes greater than \$50,000 (14.4 minutes of sleep, $p=0.03$), and who were employed full time (14.5 minutes of sleep, $p=0.03$).

CONCLUSIONS: Caregivers in BIP states were more likely to provide daily care than caregivers in non-BIP states after BIP took effect. They also

were able to spend more time on self-care and sleep compared to peers in non-BIP states. Further efforts to shift long term care from institutional to home-based settings may have a positive effect on informal caregivers. While continued support for the BIP program may serve to mitigate stressors faced by this at-risk population, caregivers with higher levels of education and income may experience these benefits disproportionately.

THE INCIDENCE OF DIAGNOSTIC ERROR IN HOSPITALIZED ADULTS: A SYSTEMATIC REVIEW AND META-ANALYSIS

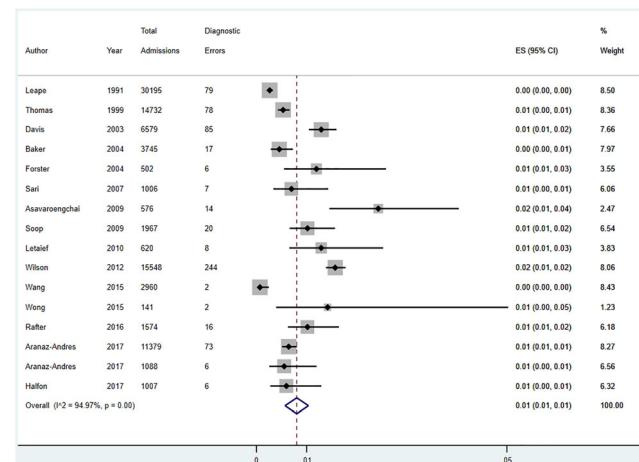

Victor P. Bilan^{1, 2}; Benjamin Rodwin^{1, 2}; Naseema Merchant^{1, 2}; Craig G. Gunderson^{1, 2}. ¹Yale School of Medicine, New Haven, CT; ²VA Connecticut Healthcare, West Haven, CT. (Control ID #3182980)

BACKGROUND: Achieving a correct and timely diagnosis is fundamental to medical practice, but the diagnostic process is fraught with potential for error. The National Academy of Medicine's 2015 report *Improving Diagnosis in Health Care* identified diagnostic error as the next "quality chasm" to be addressed by the patient safety movement. Nonetheless the actual incidence of diagnostic error remains uncertain due to difficulties in measurement and the heterogeneity of approaches used, including autopsy studies, reviews of malpractice claims, and surveys of physicians and patients. We performed a systematic review of studies that assess rates of diagnostic error using physician review of case series of hospitalized patients.

METHODS: A systematic literature search was conducted for studies that reported series of hospitalized patients and used physician review to determine the frequency of diagnostic error. Our search included MEDLINE, EMBASE, and the Cochrane library from database inception through October 3, 2018. The rates of diagnostic error from individual studies were pooled using random-effects meta-analysis. Heterogeneity was estimated using the I^2 statistic.

RESULTS: 6,137 studies were screened for inclusion. Twenty studies met inclusion criteria of which sixteen were of consecutive admissions representing 93,619 patients and were included in the primary meta-analysis. The pooled incidence of diagnostic error was 0.8% (95% CI, 0.5% to 1.1%).

CONCLUSIONS: Whereas previous estimates have suggested that all adults will experience clinically significant diagnostic errors during their lifetimes, the results of this study suggest that diagnostic errors are a real but relatively infrequent cause of adverse events in hospitalized patients, as determined by retrospective chart review of consecutive patient series. Most studies did not further stratify diagnostic errors according to clinical context or actual missed diagnosis; this information will be necessary to inform future efforts at improving the diagnostic process.

THE INFLUENCE OF GEOGRAPHIC DISPERSION ON OUTCOMES OF HOSPITALIZED MEDICINE SERVICE PATIENTS
Rachel Kohn; Michael O. Harhay; Brian A. Bayes; Hummy Song; Scott D. Halpern; Meeta P. Kerlin; S R. Greysen. University of Pennsylvania, Philadelphia, PA. (Control ID #3139478)

BACKGROUND: Specialty wards (e.g., cardiology or oncology wards) group clinically similar hospitalized patients in efforts to improve outcomes and costs. When these wards exceed capacity, subsequent patients overflow to "geographically dispersed" alternate wards. Geographic dispersion has been associated with care inefficiency and worse outcomes on specialty wards, but has not been studied in a large, diverse sample of hospitalized medicine service patients.

METHODS: We performed a retrospective cohort study in 3 diverse University of Pennsylvania Health System (UPHS) hospitals. We included all medicine, family medicine, and geriatric service patients admitted from emergency departments (EDs), intensive care units (ICUs), or other wards in 2014 and 2015. Data were obtained from Penn Data Store, a UPHS clinical data warehouse that includes all payers. The primary exposure was placement on non-medicine wards, i.e., "geographical dispersion." We excluded patients who switched from medicine to non-medicine wards and vice-versa (n=427 [2%]). The primary outcome was hospital length of stay (LOS). The secondary outcomes were hospital discharge to home and skilled nursing facilities (SNFs) and in-hospital mortality. We performed mixed effects linear and logistic regression models with a random effect to account for clustering by hospital. We first performed univariate analyses of geographical dispersion and each outcome separately. We then performed separate multivariable regression models, adjusting for age, gender, race, ethnicity, insurance type, body mass index, number of Elixhauser comorbidities, days spent in ICUs, number of ward transfers during hospitalization, number of previous inpatient, ICU, and ED visits during the prior 12 months, numbers of unique medications and procedures during hospitalization, the Centers for Medicare and Medicaid Services four-level severity risk adjustment (mild, moderate, major, severe), and hospital admission source.

RESULTS: The study population included 19,032 visits among 18,956 patients in 33 wards. Median age was 60 years, (IQR 45-74), 55% were female, and 61% were black. Thirty-three percent of patients were geographically dispersed. Median LOS was 4 days (IQR 2-6), 77% of survivors were discharged home, 14% were discharged to SNFs, and 10% died. In multivariable regression, geographically dispersed patients had longer LOS (1.1 days, 95% CI 1.1-1.2, p<0.0005) and higher odds of discharge to SNF (OR=1.1, 95% CI 1.0-1.2, p=0.04). Geographically dispersed patients had lower odds of discharge to home but this was not statistically significant (OR=0.9, 95% CI 0.9-1.0, p=0.08). In-hospital mortality did not differ between the groups (OR=1.0, 95% CI 0.6-1.5, p=0.9).

CONCLUSIONS: Geographically dispersed hospitalized medicine patients had significantly increased LOS (>1 day longer) and higher odds of discharge to SNF. Future studies are needed to confirm these findings and explore underlying mechanisms of these associations.

THE INTERACTION OF NEIGHBORHOOD ENVIRONMENTS AND GENETIC RISK FOR TYPE 2 DIABETES: RESULTS FROM MESA AND CARDIA

Paul Christine¹; Jennifer A. Smith¹; Bhramar Mukherjee¹; Sara Adar¹; Kari Moore²; Alain Bertoni³; Penny Gordon Larsen⁴; Wei Zhao¹; Mercedes R. Carnethon⁵; James B. Meigs⁶; Laura Rasmussen-Torvik⁵; Leslie Lange⁷; Myriam Fornage⁸; Sharon Kardia¹; Ana Diez-Roux².
¹University of Michigan, Ann Arbor, MI; ²Drexel University, Philadelphia, PA; ³Wake Forest, Winston-Salem, NC; ⁴University of North Carolina, Chapel Hill, NC; ⁵Northwestern University, Chicago, IL; ⁶Massachusetts General Hospital, Boston, MA; ⁷University of Colorado, Aurora, CO; ⁸University of Texas Health Science Center, Houston, TX. (Control ID #3186418)

BACKGROUND: Genetic studies have documented the impact of genes on risk of type 2 diabetes (T2D). Similarly, a substantial body of research has demonstrated the impact of neighborhood environments on T2D risk by shaping health behaviors. However, no studies have examined whether genetic risk for T2D may be modified by neighborhood environments.

METHODS: We analyzed the interaction between genetic risk (summarized via genetic risk score [GRS]) and neighborhood environment in relation to T2D in 5704 individuals from the Multi-Ethnic Study of Atherosclerosis (MESA) from 2000-2012, and in 2609 individuals from the Coronary Artery Risk Development in Young Adults (CARDIA) cohort from 1985-2011. Neighborhood environment included the availability of supermarkets/fruit and vegetable markets and recreational establishments, and neighborhood socioeconomic status (SES). Interval-censored survival analyses were used to estimate hazard ratios (HRs) for pooled prevalent and incident T2D associated with neighborhood environments, GRS, and their interaction. Additive and multiplicative joint effects were estimated to examine the independent associations of genetic risk, neighborhoods, and their interaction on T2D risk.

RESULTS: In models with continuous exposures, associations between genetic risk and T2D were modestly weaker in individuals residing in neighborhoods with more supermarkets/fruit and vegetable markets and recreational establishments (multiplicative interaction p-values, 0.03 to 0.19). Models with dichotomized exposures showed similar results. For instance, MESA participants jointly exposed to above-median genetic risk (HR=1.19; 95% CI [0.99, 1.39]) and below-median availability of recreational establishments (HR=1.52; 95% CI [1.26, 1.78]) had an observed joint HR that was greater than expected under additive interaction (observed HR=2.00 [95% CI 1.67, 2.32]; additive interaction p-value, 0.02), indicating synergism between the two exposures. Results for neighborhood SES were mixed.

CONCLUSIONS: Residing in neighborhoods with more health-promoting resources may decrease the risk of T2D in genetically susceptible individuals. While much emphasis has been placed on using genetic risk to focus on individual prevention, this study suggests that T2D prevention efforts focused on modifying neighborhood environments may represent another fruitful, population-based approach.

THE INTERSECTION BETWEEN PROFESSIONALISM AND INCLUSION: A MIXED METHODS ANALYSIS

Dominique Alexis¹; Matthew Kearney²; Jaya Aysola¹; Eve Higginbotham¹. ¹University of Pennsylvania, Philadelphia, PA; ²Drexel University, Philadelphia, PA. (Control ID #3183100)

BACKGROUND: Little is known about how to effectively operationalize professionalism in our evolving landscape throughout healthcare systems and academic environments. Moreover, to date, how effectively inclusion is integrated into the development of policies and practice related to professionalism is unknown. Building an inclusive environment for all requires a deeper understanding of how we redefine and apply professionalism standards to meet the needs of a diverse workforce. The objective of this study aimed to examine the intersection between inclusion and professionalism.

METHODS: We examined survey data (n=3500) as well as submitted narratives (n= 56) in a mixed-methods analysis designed to evaluate professionalism within healthcare learning and working environments. We first evaluated the relationship between respondent demographic characteristics and their responses to the following professionalism questions: 1) I have considered changing jobs due to inappropriate, disruptive, or unprofessional behavior by a co-worker or supervisor; 2) I value institutional initiatives, policies, and/or educational resources related to professional behavior in the workplace; 3) My institution supports a culture of professionalism. Thereafter, we coded and analyzed a subset of submitted narratives (n=56) submitted by employees and/or students that referenced professionalism from our cultural audit of inclusion to identify emerging themes.

RESULTS: Of the 3500 respondents, 11%, 64%, and 10% self-identified as non-Hispanic Black, female, and LGBTQ, respectively. In comparison to white males, females and minorities placed greater value on institutional policies and educational resources related to professionalism. All respondents agreed that the institution supports a culture of professionalism, however, women, underrepresented minorities, and LGBTQ groups were significantly more likely to consider leaving after experiencing unprofessional behavior. Analysis of the narratives revealed a set of themes including causes and outcomes across a spectrum of professional-to-unprofessional experiences. Key contributors to unprofessional behaviors that emerged include a hostile environment, silent bystanders, the lack of boundaries and respect, and unequal application of standards. Narratives also revealed the effects of unprofessionalism on physical health, pressure to conform, and attrition.

CONCLUSIONS: A mixed methods analysis of survey data and submitted narratives providing an assessment of organizational inclusion revealed diverse individuals with varied cultural perspectives perceive and experience professionalism in the workplace differently compared to others. Based on the disparate responses from women, underrepresented minorities, minorities, and LGBT, there is unequal application of professional standards. Our findings highlight the need to revisit how organizations set professionalism standards, and ensure they are inclusive and applied equitably.

THE LACK OF FORMAL EDUCATION ON OUTPATIENT BILLING

Azra Bhimani; Sun Yoo. UCLA, Los Angeles, CA. (Control ID #3159529)

BACKGROUND: A growing number of resident physicians are entering the primary care workforce every year. Upon graduating, they face the responsibility of independently and accurately billing for clinical services. Studies show there is inadequate training on billing for outpatient services during residency. Inaccurate billing can lead to financial repercussions and issues with compliance, and underutilization of annual wellness visits can lead to more out of pocket expenses for patients. We hypothesized that a majority of residents in the UCLA internal medicine training program lack the confidence to bill accurately in the outpatient setting and would be interested in receiving formal education on this topic. We also hypothesized underutilization of Medicare Wellness Exam (MWE) codes and Transitional Care Management (TCM) codes.

METHODS: We created two 10-question surveys for residents and faculty in the Internal Medicine program at UCLA over a 2-month period. The surveys included questions on confidence in billing encounters, differentiating 99213 and 99214 codes, utilizing MWE and TCM codes, and interest in a formal curriculum on billing. We also looked at billing data from 2,096 encounters at these clinics over a 4-month period to assess the difference in types of codes billed between PGY-levels.

RESULTS: 32 residents and 15 faculty physicians working at 3 UCLA Internal Medicine clinics participated in each survey. 2,096 encounters from 2 of these clinics over a 4-month period were analyzed. Less than 10% of residents felt very or extremely confident in their ability to bill encounters accurately. Over 80% of faculty felt they needed to change resident billing codes to more accurately reflect encounters. 93% of residents and 100% of faculty felt that residents would benefit from formal education on billing. Of the 2,096 encounters billed, only 3% were billed as TCM visits and 1% as MWE visits.

CONCLUSIONS: As more residents are pursuing primary care careers, a growing aspect of their practices will include coding. Multiple studies, including ours, have shown lack of confidence and errors in practice amongst residents when it comes to coding for outpatient services. In addition, TCM and MWE codes were being underutilized. Based on our study and numerous others, it is integral for training programs to incorporate formal education on outpatient billing.

THE LONG-TERM IMPACT OF SIMULTANEOUS PARTICIPATION IN MEDICARE ACCOUNTABLE CARE ORGANIZATIONS AND BUNDLE PAYMENTS ON OUTCOMES FOR LOWER EXTREMITY JOINT REPLACEMENT

Joshua M. Liao^{4, 1}; Ezekiel J. Emanuel^{1, 1}; Athendar Venkataramani^{1, 1}; Qian Huang²; Atul Gupta²; Claire T. Dinh¹; Eric Z. Shan¹; Dylan Small^{1, 1}; Norma B. Coe^{1, 1}; Erkuan Wang¹; Xinshuo Ma¹; Jingsan Zhu¹; Deborah Cousins¹; Amol S. Navathe^{1, 3}. ¹University of Pennsylvania, Philadelphia, PA; ²The Wharton School, University of Pennsylvania, Philadelphia, PA; ³CMC VA Medical Center, Philadelphia, PA; ⁴University of Washington, Seattle, WA. (Control ID #3179243)

BACKGROUND: Based on savings from the Bundled Payments for Care Improvement (BPCI) program, Medicare continues to scale voluntary lower extremity joint replacement (LEJR) bundles among hospitals nationwide via new programs. Concurrently, a growing number of hospitals have participated in voluntary Accountable Care Organizations (ACOs) through initiatives such as the Medicare Shared Savings Program (MSSP). Because ACOs and bundled payments share the goal of containing costs while maintaining or improving quality, hospitals participating in LEJR bundles may achieve better performance and synergies from simultaneous "co-participation" in ACOs.

METHODS: Hospitals participating in MSSP ACOs and BPCI Model 2 for LEJR bundles were categorized as being in BPCI ("Bundles Only"), MSSP ("ACO Only"), both ("Co-Participant"), or neither ("Non-Participant"). Using 2011-2016 Medicare claims and two-stage least squares instrumental variable regression to mitigate confounding from changes in unobservable patient characteristics, we evaluated the association between co-participation and changes in episode spending and quality (mortality, unplanned readmissions, LEJR complications, ED visits) over 3 years among 671,288 fee-for-service Medicare beneficiaries receiving LEJR at acute care hospitals nationwide. The sample included 212 *Bundles Only*, 448 *ACO Only*, 105 *Co-Participant*, and 1,943 *Non-Participant* hospitals. Historical hospital referral patterns before BPCI began were used to generate the predicted probability of hospitalization for LEJR at an eventual BPCI hospital, which was used as an instrument for actual hospitalization for LEJR at a BPCI hospital. Standard errors were computed using bootstrapping and statistical tests were 2-tailed using an =0.05 for significance.

RESULTS: Across hospital groups, there were small differences in beneficiary (e.g., case-mix, prior hospital and institutional post-acute care utilization) characteristics. Hospital characteristics (e.g., size, ownership and teaching status, market share) also varied. Over 3 years, average episode spending decreased at both *BPCI Only* (2.9% decrease in average episode spending, 95% CI -3.4% to -2.5%) and *Co-Participant* (2.8% decrease in average episode spending, 95% CI -3.4% to -2.1%) hospitals compared to *Non-Participant* hospitals ($p < 0.001$ for both). *BPCI Only* hospitals also had lower unplanned readmission rates than *Non-Participant* hospitals (1.1% decrease, 95% CI -1.4% to -0.7%, $p < 0.001$). Compared to *BPCI Only* hospitals, *Co-Participant* hospitals did not have differential changes in episode spending but did have higher unplanned readmission rates (1.1% increase, 95% CI 0.58% to 1.7%, $p < 0.001$).

CONCLUSIONS: Compared to participation in BPCI Model 2 only, co-participation in MSSP ACOs was not associated with LEJR episode savings but was associated with higher rates of unplanned readmissions. Our findings support current Medicare policy that does not encourage co-participation.

THE NET BENEFIT OF ORAL ANTICOAGULATION AMONG OLDER ADULTS WITH ATRIAL FIBRILLATION

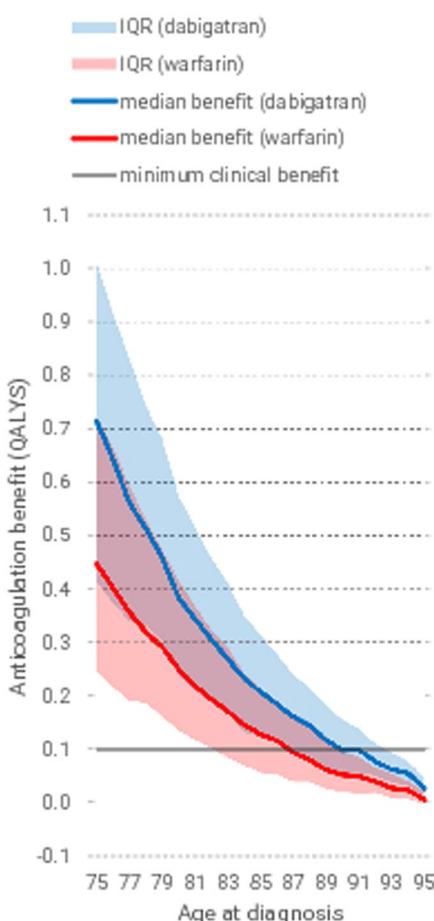

Sachin J. Shah¹; Margaret Fang¹; Daniel E. Singer²; Kenneth Covinsky¹; Alan S. Go³; Mark H. Eckman⁴. ¹University of California, San Francisco, San Francisco, CA; ²Massachusetts General Hospital, Boston, MA; ³Kaiser Permanente Northern California, Oakland, CA; ⁴University of Cincinnati, Cincinnati, OH. (Control ID #3178343)

BACKGROUND: Guidelines categorize all patients aged 75+ with atrial fibrillation (AF) as "high risk for ischemic stroke" thus warranting anticoagulation. While age increases the risk of ischemic stroke, it also increases the risk of hemorrhage and death from other causes; the latter two are not accounted for in guidelines recommendations. The age at which there is equipoise between benefit and harm when accounting for the risk of hemorrhage risk and death from other causes is not known.

METHODS: We examined all patients 75 years with incident AF in the Anticoagulation and Risk Factors in Atrial Fibrillation - Cardiovascular Research Network cohort. In a patient-level analysis, we accounted for patients' stroke risk (CHA2DS2-VASc score), hemorrhage risk (HAS-BLED score), and age-, sex-, comorbidity-adjusted life expectancy. Using an established 28-state Markov state transition model, we estimated the quality-adjusted life years (QALYs) with 3 strategies: warfarin, dabigatran, no anticoagulation. In each monthly cycle, patients face a chance of stroke, hemorrhage, and death from a competing cause. Stroke or hemorrhage leads to any of 3 health states: death, mild or severe neurologic sequelae, symptom resolution. The simulation runs for the life expectancy of the patient. We used an established threshold of 0.1 QALY to define minimal clinical benefit.

RESULTS: 14946 patients were included with a median age of 81 years and CHA2DS2-VASc score of 4. With warfarin, at age 87, the median patient gained 0.09 QALYs (IQR 0.04, 0.16) relative to no treatment. With dabigatran, at age 90, the median patient gained 0.10 QALYs (IQR 0.06, 0.16) relative to no treatment.

CONCLUSIONS: Accounting for the risk of stroke, hemorrhage, and death from competing causes, for the median patient anticoagulation with warfarin results in equipoise at age 87 and with dabigatran at age 90. Consensus guidelines should emphasize shared decision making for all patients considering anticoagulant therapy, particularly when treating the oldest patients.

THE OBESITY PARADOX AND ACUTE KIDNEY INJURY IN ORTHOPEDIC SURGERY PATIENTS

Matthew Hennrikus²; William Hennrikus⁶; Erik B. Lehman³; Michael Skolka⁴; Katelyn McCann⁵; Eileen Hennrikus¹. ¹Penn State College of Medicine, Hershey, PA; ²Tulane University Medical School, New Orleans, LA; ³Pennsylvania State University, Hershey, PA; ⁴Penn State Health, Hershey, PA; ⁵University of Massachusetts Medical School, Worcester, MA; ⁶Walter Reed National Military Medical Center, Bethesda, MD. (Control ID #3163093)

BACKGROUND: The Obesity Paradox postulates that obesity, counter-intuitively, is protective against mortality in certain chronic conditions such as chronic kidney disease and congestive heart failure. This study examined the effects of obesity and acute kidney injury (AKI) on length of hospital stay and on two year mortality.

METHODS: We retrospectively reviewed the electronic medical records of all adult elective orthopedic surgery patients over two years in a large academic hospital. The 1783 patients who met inclusion criteria were divided into obese (body mass index, BMI > 30, n=1123) and non-obese groups (BMI < 30, n=660). Demographics, comorbidities, and perioperative variables were included in multivariate logistic regression analyses with AKI, LOS, and two year mortality as primary outcomes in all, obese and non-obese patients. Two-year mortality data was obtained from hospital electronic records and the social security death index.

RESULTS: AKI developed in 5% (n=90) of the post-surgical orthopedic patients. Obese patients had a 1.86 times higher odds (95% CI 1.07-3.22, p=0.028) of developing AKI than non-obese patients. AKI increased length of hospital stay in both obese (1.28 ± 0.38 days, p=0.001) and non-obese patients (1.61 ± 0.78 days, p=0.039). The adjusted odds of 2-year mortality were increased by AKI (OR 2.08, 95% CI 1.03-4.22, p=0.041) but decreased by obesity (OR 0.53, CI 0.33-0.85, p=0.009). Of patients who developed AKI, only the non-obese patients had statistically significant higher likelihood of 2-year mortality (OR 3.869, CI 1.26-11.84, p=0.018).

CONCLUSIONS: In adult elective orthopedic surgery patients, obese patients had an increased risk of AKI, and patients who developed an AKI had longer hospital stays. However, obesity was a protective factor for 2-year mortality for all post-surgical patients including patients who developed an AKI.

THE OPIOID EPIDEMIC AND THE HOMEBOUND OLDER ADULT: A SURVEY OF HOME-BASED PRIMARY CARE PROVIDERS

Vassiliki Pravodelov, Boston University School of Medicine, Boston, MA. (Control ID #3184513)

BACKGROUND: The Centers of Disease Control and State Public Health Departments have guidelines to regulate controlled substances. Though interventions to adhere to these guidelines are available in the ambulatory setting, none exist in the home-based primary care setting. This study aims to examine the attitudes, knowledge and trends of geriatrics providers in regards to prescribing and monitoring controlled substances in home care.

METHODS: The study took place at a large urban safety-net hospital. The study team administered an anonymous 57-item survey. The subjects were 17 geriatrics providers, including registered nurses, nurse practitioners, and physicians, who practice in the home care setting.

RESULTS: The survey response rate was 100%. Approximately 60% of responders noted that >30% of their patients have chronic nonmalignant pain (CNMP). Almost all providers believed that diversion (82%) and misuse (100%) of prescription opioid pain medication in the community served by the practice is a moderate/serious problem. 82% reported that they were aware of the state regulations regarding controlled substance

prescribing, but less than half of the providers (43%) responded correctly to specific questions about the content of these regulations. 53% noted that they use the state prescription monitoring program on at least a monthly basis. 82% felt confident in their ability to identify red flags of drug use disorder in patients prescribed controlled substances. Providers seldom signed Patient Provider Agreements (10%) and rarely ordered urine/saliva drug testing (2%). 41% of providers were confident to negotiate a Patient Provider Agreement while just 17% of providers were confident to interpret urine/saliva drug tests. Pill counts only occurred when the providers suspected a problem. Providers acknowledged many barriers in adhering to current state regulations including a knowledge deficit, lack of cooperation from patients/caregivers, lack of resources, and difficulty in obtaining urine toxicology samples due to comorbidities.

CONCLUSIONS: This study highlights current attitudes and practices of geriatrics home-based primary care providers in regards to controlled substance prescribing and monitoring. It suggests that although CNMP is a common problem among patients, providers often feel that they cannot comply with all the recent federal and state regulations for several reasons. Furthermore, it suggests that though older adults have been on the margins of the opioid epidemic, primarily due to lack of data, opioid misuse and diversion is viewed as a significant problem in this population. The results of this study may serve as a stepping stone in developing efficient and effective plans for safely prescribing and monitoring controlled substances in the geriatrics home care setting.

THE OSA PATIENT AND CAREGIVER EXPERIENCE OF PAP. A QUALITATIVE ANALYSIS OF ONE-ON-TWO SEMI-STRUCTURED MOTIVATIONAL INTERVIEWS

NAZIA NAZ S. KHAN¹; Ade B. Olomu²; Shireesha Bottu¹; Margaret Roller¹; Robert C. Smith¹. ¹MICHIGAN STATE UNIVERSITY, East Lansing, MI; ²Michigan State University, East Lansing, MI. (Control ID #3185019)

BACKGROUND: The prevalence of Obstructive Sleep Apnea (OSA) is increasing. Positive Airway Pressure (PAP) is the mainstay therapy for OSA. Despite its several benefits that include improvement in sleep quality, daytime symptoms of fatigue, drowsiness, and quality of life, reduction in blood pressure and decrease the risk of traffic accidents, nearly 25% of patients discontinue PAP use within 2 weeks. There is some evidence that partner involvement in education regarding OSA and PAP therapy may help improve PAP adherence. The aim of this qualitative analysis was to identify OSA patients' preferences, partner experiences, barriers and facilitators to adherence to PAP, and to assess understanding of the educational content delivered during a group visit (GV).

METHODS: 28 interventional arm patients (from a larger study) with a new diagnosis of OSA and their caregiver participated in the 60-90 minutes in-person GV conducted from 1-17 weeks of receiving the PAP machine. Thirteen GVs (1 to 3 patients with their caregiver/GV) were held during the course of the study. A qualitative thematic analysis was conducted on the one-on-two (Research assistant with patient and caregiver) semi-structured motivational interview, which was the fourth and last part of the intervention during the GV. The first three sessions of the GV included i) An Interactive Educational Session focused on education on OSA, its effect on health, PAP and its effects, and the importance of family/partner support; ii) peer coaching from an OSA patient; iii) hands-on experience with the PAP machine from a respiratory therapist. The 10-15 minutes interview with the patient and caregiver focused on obtaining the personal and emotional history, providing support, assessed understanding of the OSA and negotiated plan and commitment.

RESULTS: Of the 28 participants, 16 were female and 12 were male. Mean age was 58 years. Of the 28 caregivers, 21 spouses, 2 sons/daughter, 1 friend, 1 sister and 3 were identified as girlfriend/significant other/partner of the patient. The qualitative analysis considered patients' attitudes, behavior, and emotional effects of their OSA experience associated

with the four themes: OSA symptom and diagnosis, using the PAP machine, perceptions about the GV, and factors that determine PAP adherence. Patients had positive, negative or mixed emotions towards the different aspects of the OSA diagnosis and PAP machine. The sense of relief and the desire to live a long life were the two positive underlying emotions; fear and frustration of the OSA diagnosis and PAP machine are the two negative emotions, experienced in varying levels of intensity.

CONCLUSIONS: We concluded that patients' and caregivers' positive experiences of PAP could be enhanced by a patient-centered interaction and that it was important to explicitly address their fears and concerns to further enhance the use of PAP.

THE PATIENT-CENTERED MEDICAL HOME IN GOVERNMENT-BASED AND INTEGRATED DELIVERY AND FINANCE SYSTEMS: A SYSTEMATIC REVIEW

Clark A. Veet¹; Inmaculada Hernandez⁵; Thomas R. Radomski³; Christopher A. D'Avella²; Charles B. Wessel⁴; William H. Shrunk¹; Elizabeth C. Swart¹; Natasha Parekh². ¹UPMC, Pittsburgh, PA; ²University of Pittsburgh Medical Center, Pittsburgh, PA; ³University of Pittsburgh School of Medicine, Pittsburgh, PA; ⁴University of Pittsburgh, Pittsburgh, PA; ⁵University of Pittsburgh, Pittsburgh, PA. (Control ID #3164140)

BACKGROUND: As healthcare reimbursement moves from volume to value-focused, new delivery models aim to coordinate care and improve quality. A popular model, the patient-centered medical home (PCMH), aims to promote focused, well-coordinated, and accessible healthcare to improve outcomes and decrease costs. Prior studies have shown mixed outcomes regarding the ability of PCMHs to achieve these objectives. Additionally, it is unclear whether PCMHs operating within government-based systems or integrated delivery and finance systems (IDFS) where healthcare payers and providers are vertically integrated impact utilization and cost outcomes.

METHODS: We performed a systematic review of clinical trials and observational studies that identified PMCH or equivalent interventions. Ten reviewers performed screening, data extraction, and risk of bias assessment. Primary outcomes included emergency department (ED) visits, hospital admissions, outpatient visits, and total cost of care. We categorized PCMHs as operating within government systems (including Veterans Affairs and Indian Health Service), IDFS, and non-IDFS.

RESULTS: A systematic search of PubMed, the Cochrane Library, and Embase from 2004 to April 2017 yielded 13,939 unique publications. 64 studies were included. 29% were government systems, 24% were IDFS, and 47% were non-IDFS. Utilization outcomes were reported in 74% of studies and included ED visits, hospitalizations, or outpatient visits. Of the 35 studies reporting ED visits, 17 (48%) showed lower ED utilization. ED visits decreased in 41% of 11 government studies, 75% of 8 IDFS studies, and 38% of 16 non-IDFS studies. Of the 31 studies on admissions, 11 (35%) showed decreased admissions. Admissions decreased in 50% of 12 government studies, 28% of 7 IDFS studies, and 25% of 12 non-IDFS studies. PCP visits decreased in 8 (47%) of 17 studies. PCP visits increased in all 6 government studies while specialty visits decreased in 50% of 4 government studies. Among IDFS studies, PCP visits decreased in all 4 studies while specialty visits decreased in 1 (33%) of 3 studies. Among 7 non-IDFS studies, PCP visits increased in 42% of studies while only 14% showed decreased specialty care. Economic outcomes were reported in 25 (39%) studies, most commonly as total cost of care. Reduced costs were observed in 60% of 5 government studies, 50% of 8 IDFS studies, and 33% of 12 non-IDFS studies.

CONCLUSIONS: Our study uniquely assessed whether PCMH model effectiveness differed between government systems, IDFS, and non-IDFS. ED visits decreased most within IDFS, while hospital admissions decreased most within government systems. Notably, government systems observed an increase in PCP visits. It is unclear if this change reflects the effectiveness of the PCMH model or patient characteristics. Cost

reductions were reported in less than half of studies. This study has important implications for understanding how system-based factors affects the success of PCMH interventions.

THE PERCEIVED HEALTH IMPACT OF SIGNIFICANT PLACES AMONG AFRICAN AMERICAN ADULTS WITH CARDIOVASCULAR RISK FACTORS

Michelle J. White¹; Stephanie Hoover²; Katelyn Holliday¹; Nicole Robinson-Ezekwe²; Leah Frerichs³; Kiana Bess²; Anissa Williams²; Giselle M. Corbie-Smith². ¹Duke University, Durham, NC; ²University of North Carolina, Chapel Hill, NC; ³University of North Carolina at Chapel Hill, Chapel Hill, NC. (Control ID #3183908)

BACKGROUND: Environmental factors have been demonstrated to contribute to cardiovascular (CV) disparities among African American adults in the American South. Research has focused on observed built environment characteristics surrounding participants' place of residence, or pre-determined constructs (e.g., walkability). However, the built environment is perceived and experienced differently by individuals in ways that may moderate its influence on self management behaviors, yet limited research has explored such perceptions in-depth. We sought to examine African American adults' perceptions of the places that have significance in their lives and how these places impact their health. **METHODS:** We conducted a thematic analysis of African American adults (N=25) in two North Carolina counties considered to be at the highest level of disadvantage based on multiple economic factors. Participants were recruited from a community-based behavioral CV risk reduction intervention. All had at least one risk factor for CV disease. We asked participants to identify significant places including where they spent the most time, meaningful places in their day to day lives, and healthy and unhealthy places on local maps. Using these maps as a reference during semi-structured interviews, participants described the health impact of each location. Data were transcribed verbatim and coded using NVivo 12.

RESULTS: The average age of participants was 63 (SD=10) and 88% were female. Places participants defined as meaningful and places where they spent the most time included churches and relatives' homes. Healthy places included their homes and local gyms. Unhealthy places included fast food restaurants and relatives' homes where unhealthy food was served. Participants illustrated the impact of these places on diet and physical activity by describing both the physical characteristics (i.e. presence of a running track; menu of healthy food) and the social characteristics and influences within the place (i.e. attending church with people who are trying to live a healthy lifestyle; caring for grandchildren at home who prefer fast food). Participants also described how they "spread the word" about lessons acquired from the intervention within their significant places.

CONCLUSIONS: Participants identified several significant places that impacted their health and described how their health behaviors within significant places were influenced by both physical and social characteristics. As we seek to improve CV interventions for African Americans in the American South, it will be important to further assess the effect of significant places beyond place of residence and how the social and physical characteristics of these places interact to influence CV outcomes. Better understanding of social influence, particularly the manner in which healthy behaviors are reinforced, hindered, and disseminated within significant places, could be leveraged to improve the reach of CV interventions.

THE POCUS SUPERVISION SAFETY GAP: ATTENDING PHYSICIAN KNOWLEDGE IN POINT-OF-CARE ULTRASOUND LAGS BEHIND INTERNAL MEDICINE RESIDENTS

James E. Anstey²; Stephanie Conner²; Meghan T. O'Brien³; Farhan Lalani¹; Trevor Jensen². ¹University of California San Francisco, San Francisco, CA; ²UC-San Francisco, San Francisco, CA; ³UCSF, San Francisco, CA. (Control ID #3185369)

BACKGROUND: Point-of-Care-Ultrasound (POCUS) is increasingly recognized as a useful tool in hospital medicine. POCUS training opportunities for US Internal Medicine residents have been rapidly expanding, but education for hospitalist attendings may lag behind creating a potential safety gap in supervision. We developed a test assessing four domains of knowledge within routine applications of POCUS used in hospital medicine and compared attending and resident physician performance at a single academic teaching hospital.

METHODS: Hospital medicine faculty experienced in POCUS developed a 15-item test designed to assess the application of POCUS in hospital medicine practice. The test focused on four domains of use: basic knowledge, image interpretation, clinical integration, and understanding of limitations. The test questions were developed to address common use-cases for POCUS and be performed in a short time (<10 minutes). An invitation to complete the test was sent by email to all internal medicine residents (n= 180) and hospital medicine attendings (n=97). Respondents were instructed not to guess, and each question included an option "Not sure". Test results (% correct) were compared for attendings and residents using unpaired t-tests and analysis of variance.

RESULTS: A total of 58 residents (32% response rate) and 41 (41%) attendings completed the test. The mean resident score was 55.6% (95% CI 49.8- 61.3) and mean faculty score was 45.3% (95% CI 27.9- 54.1) with a mean difference of 10.3% (95% CI 0.32 - 20.3; p = 0.022). Attendings performed significantly worse than residents in the domains of basic knowledge (mean difference 22.0% [95% CI 9.1- 34.9], p=0.001), image interpretation (mean difference 10.8% [95% CI 0.2- 21.5], p=0.046), and understanding of limitations (mean difference 14.7% [95% CI 1.7- 27.8], p=0.027). Additionally, respondent's scores differed by level of clinical experience. Interns scored a mean of 45.5%, and senior residents 61.7%. Faculty of 0-3 years' experience scored a mean of 59.3%, 4-6 years 51.6%, 7-10 years 33.3%, and faculty with >10 years' experience, a mean of 23.6%, (p = 0.0002; ANOVA).

CONCLUSIONS: Our study revealed that, while resident physicians at our institution have limited knowledge and require ongoing supervision, our hospital medicine faculty had a significantly lower baseline of POCUS knowledge than the residents they supervise. Specifically, hospitalists were more deficient in domains of basic knowledge, image interpretation, and importantly, understanding of limitations. Hospitalists more recently out of training scored higher than those with more attending experience, which may reflect the recent wave of POCUS training in internal medicine resident programs. As resident physicians continue to gain valuable new skills in POCUS, this data argues for comprehensive faculty curricula with emphases on supervision, appropriate use, and knowledge of limitations of POCUS use in hospital medicine to address and prevent this supervision safety gap.

THE PREVALENCE AND CAUSES OF DELAYED ENDOSCOPIES FOR HOSPITALIZED PATIENTS

Molly A. Kantor; Sara Lewin; Kendall Beck; Ryan David; Helge Eilers; Bertina Herman; Cameron Locke; Scott Pasternak; Sajan Patel; Najwa El-Nachef. University of California, San Francisco, San Francisco, CA. (Control ID #3184503)

BACKGROUND: Hospitalized patients often require urgent gastrointestinal endoscopy, and timely procedures are associated with better patient outcomes. However, there is limited literature describing the timeliness of inpatient endoscopic procedures and potential causes of delay. To address this, we conducted a single-center observational study of all inpatient endoscopies to characterize the prevalence and causes of delay.

METHODS: We identified all inpatients planned to undergo endoscopy at our 600-bed urban academic medical center using the electronic health record and paper endoscopy unit records. All endoscopies were performed as part of routine clinical care. We obtained the procedure request date and procedure completion date; a delay was defined as any difference

between these dates. For all identified cases of delay, a gastroenterologist or hospitalist reviewed the medical chart and indicated the reason(s) for delay using a structured data collection tool. For each requested endoscopy, the type of endoscopy and sedation, indication for endoscopy, and length of delay were also collected.

RESULTS: During the study period, 715 endoscopies were requested and 680 (95.1%) were performed; 35 (4.9%) were cancelled. Most (303, 44.6%) endoscopies were esophagogastroduodenoscopies (EGDs), followed by combined EGD-colonoscopies (173, 25.4%), flexible sigmoidoscopies (107, 15.7%), and colonoscopies (79, 11.6%). Of completed endoscopies, 88 (12.9%) were delayed. The most common causes of delay are shown in Table 1. The majority of delays were avoidable (66, 75.0%), due to scheduling delays (44, 50.0%) and issues with bowel preparation (18, 20.5%). The most common unavoidable delays were due to clinical instability (11, 12.5%). Endoscopies were delayed for an average of 1.4 days (1-8 days, median 1) representing 120 days of delay.

CONCLUSIONS: Delays in endoscopy at a single academic medical center were common, and most delays were due to avoidable causes. Interventions to reduce delay should target scheduling delays and issues with bowel preparation.

Table 1: Causes of Endoscopy Delay

| Reason for Endoscopy Delay | n (%) |
|--|-------------------|
| Avoidable Delays | 66 (75.0%) |
| Schedule delay | 44 (50.0%) |
| Anesthesia schedule delay | 11 (12.5%) |
| Endoscopy schedule delay | 1 (1.1%) |
| Unspecified schedule delay | 32 (36.4%) |
| Issues with bowel preparation | 18 (20.5%) |
| Patient unable to tolerate preparation | 10 (11.4%) |
| Poor bowel preparation | 8 (9.1%) |
| Other competing procedures | 5 (5.7%) |
| Unavoidable delays | 15 (17.0%) |
| Clinical instability | 11 (12.5%) |
| Violated <i>ni per os</i> requirement | 2 (2.3%) |
| Refused procedure | 1 (1.1%) |
| Other clinical reason | 8 (9.1%) |
| Unknown | 7 (8.0%) |

THE PREVALENCE OF DIAGNOSTIC ERROR IN SEVEN-DAY READMISSIONS OF GENERAL MEDICAL PATIENTS

Molly A. Kantor^{1, 2}, Katie Raffel^{1, 2}; Peter Barish^{1, 2}; Armond Esmaili^{1, 3}; Hana Lim^{1, 4}; Feifei Xue^{1, 2}; Suman Ranji^{1, 4}. ¹University of California, San Francisco, San Francisco, CA; ²University of California, San Francisco, San Francisco, CA; ³San Francisco VA Medical Center, San Francisco, CA; ⁴Zuckerberg San Francisco General Hospital, San Francisco, CA. (Control ID #3180388)

BACKGROUND: Diagnostic errors have been cited as a potential contributor to hospital readmissions, particularly early readmissions (e.g. within 7 days), but little is known about their frequency and characteristics. We performed structured chart review of all medical patients readmitted within 7 days of discharge from a single academic medical center to describe the prevalence of diagnostic error and characterize contributing factors.

METHODS: Our study included all patients discharged from the inpatient medical service and re-admitted to our 600-bed urban academic

medical center within 7 days to any service from 1/1/18-9/30/18. Each case underwent independent structured review by two trained board-certified internists, followed by adjudication to achieve consensus. Cases of discrepancy were reviewed by the larger diagnostic review team. Diagnostic errors were identified using the modified "Safer Dx Instrument," a validated tool to identify diagnostic error in primary care visits. When identified, errors within the diagnostic process were then characterized using the Diagnostic Error Evaluation and Research (DEER) taxonomy tool, an error classification system. Multiple contributing factors could be identified in the same admission. For all cases identified to contain diagnostic error, the discharging physician(s) from the index admission was contacted to provide further details of the clinical decision-making and circumstances that may have contributed to the error, which was then used to refine diagnostic error characterization.

RESULTS: During the study period, we identified 261 cases of 7-day readmission (4.6% of 5663 admissions), of which 258 (98.9%) were reviewed. A total of 18 (7.0%) admissions contained diagnostic error. In 17 of the 18 cases (94.4%), the error was judged as having "moderate" impact (such as short-term morbidity, increased length of stay, or invasive procedure), and 1 had no impact. In the DEER taxonomy, the most common culprit areas within the diagnostic process contributing to error were in Laboratory/Radiology Tests (25) and Assessment (17). The most common subcategories contributing to error were failure/delay in ordering needed test(s) [10, 56%], erroneous clinician interpretation of test(s) [6, 33%], and suboptimal weighing/prioritizing of finding or diagnosis [6, 33%]. Diagnostic errors represented a breadth of diagnoses; no single diagnosis was repeated among the 18 identified errors.

CONCLUSIONS: The prevalence of diagnostic error among 7-day medical readmissions was 7%, similar to prior estimates. Nearly all diagnostic errors had moderate clinical impact. Identified diagnostic errors represented a breadth of diagnoses; thus, disease-specific diagnostic improvement efforts may be of limited utility. The most common underlying drivers of diagnostic error were related to clinician diagnostic reasoning, highlighting the importance of efforts to augment diagnostic reasoning.

THE RELATIONSHIP BETWEEN SEXUAL ASSAULT HISTORY AND GYNECOLOGIC EXAM DISTRESS AND DELAY AMONG WOMEN VETERANS IN THE VA

Elisheva Danan^{1, 2}; Michele Spoont¹; Julian Brunner³; Elizabeth M. Yano³. ¹Minneapolis VA Health Care System, Minneapolis, MN; ²University of Minnesota Medical School, Minneapolis, MN; ³VA Greater Los Angeles Healthcare System, Sepulveda, CA. (Control ID #3185977)

BACKGROUND: Sexual assault affects 1 in 3 U.S. women and has lifelong consequences for women's health that can include sexually transmitted infections, pregnancy, posttraumatic stress disorder (PTSD), and a more than two-fold higher cervical cancer risk (OR 2.6). Routine cervical cytology (pap) testing has reduced the U.S. incidence of cervical cancer by over 50% in the past thirty years. However, women who have experienced sexual assault face barriers to completing cervical cancer screening related to anxiety, fear, exam discomfort, and access to care. Invasive medical exams can also trigger an exacerbation of PTSD symptoms. Risk of sexual assault and barriers to pap testing may be intensified for women Veterans, as compared to non-Veterans. During military service, 25% of women experience military sexual trauma (MST), which is associated with multiple poor health outcomes and health risk behaviors. MST can also affect women Veterans' relationship with the VA healthcare system. We hypothesize that, compared to women Veterans with no sexual assault history, women Veterans with a history of lifetime sexual assault are more likely to experience high levels of distress related to pelvic exams, and are more likely to report ever delaying a pap test or gynecologic exam.

METHODS: We analyzed data from a 2015 survey of women Veterans who use primary care and/or women's health services at 12 VAs in 9 states. We compared characteristics of women Veterans with and without

a history of lifetime sexual assault. Next, we conducted two hierarchical logistic regression analyses to examine associations of lifetime sexual assault with our outcomes: 1) distress associated with pelvic exams, and 2) ever delaying a pap test or gynecologic exam due to distress. Covariates were added to the model in conceptual blocks that included demographics, physical health, and health system factors.

RESULTS: Our sample included 1,152 women with a mean age of 49, of whom 675 (58%) reported lifetime sexual assault. Compared to women with no history of sexual assault, women with a history of sexual assault were older, had poorer self-rated physical health, were more likely to be current or former smokers, and had higher rates of positive screens for anxiety/depression and PTSD. In the full regression model, lifetime sexual assault was significantly associated with reporting a high level of distress related to pelvic examinations (OR 2.3, 95% CI 1.5-3.5), and with reporting ever delaying a gynecologic exam due to distress (OR 1.9, 95% CI 1.3-3.0).

CONCLUSIONS: Among women Veterans, sexual assault is significantly associated with pelvic exam distress and with delay of gynecologic exams. Trauma-sensitive primary care practices are needed to reduce discomfort, distress and anxiety around pelvic examinations in order to improve patient experiences and completion of critical preventive screening.

THE RELATIONSHIP OF LONELINESS TO SYMPTOM BURDEN, INTENSITY OF CARE, AND ADVANCE CARE PLANNING AT END OF LIFE IN OLDER AMERICANS

Nauzley C. Abedini; HwaJung Choi; Melissa Y. Wei; Kenneth Langa; Vineet Chopra. University of Michigan, Ann Arbor, MI. (Control ID #3156831)

BACKGROUND: Lonely adults are prone to a variety of poor health outcomes, including accelerated functional and cognitive decline, depression, and premature death. As a result, lonely adults may be prone to higher health-related suffering, triggering increased healthcare utilization and possibly undesired aggressive care, particularly as they approach end of life (EOL). However, little is known about the EOL experience of this population. We aimed to quantify the relationship of loneliness to symptom burden, intensity of care, and advance care planning in older adults at EOL.

METHODS: We conducted a pooled cohort analysis of lonely and not lonely decedents in the Health and Retirement Study (HRS) from 2004 to 2014, a nationally representative study of individuals over the age of 50. Proxy informants were interviewed regarding decedents' EOL experience within 2 years of a participant's death. We defined loneliness using the 3-item Revised University of California Los Angeles (R-UCLA) Loneliness Scale derived from a decedent's most recent HRS interview prior to death. We assessed baseline characteristics of lonely versus not lonely individuals, including demographics, socioeconomic status, multimorbidity, depressive symptoms, and measures of social network (including partner status) and social connection (reliance on others for support). We used multivariable logistic, ordinary least squares, and negative binomial regression where appropriate to examine the independent association between loneliness and (1) total symptom burden in the last year of life; (2) measures of intense EOL care; and (3) advance care planning.

RESULTS: Of 3,065 decedents, 33% were lonely. Loneliness was independently associated with total symptom burden at EOL ($\beta = 0.16$, 95% CI 0.05-0.28; $p=0.005$), after adjusting for demographics, socioeconomic status, multimorbidity, depressive symptoms, and measures of social network and social connection. Lonely decedents had higher odds of receiving life support in the last 2 years of life (AOR 1.52, 95% CI 1.03-2.24; $p=0.03$). However, loneliness did not have an independent association with other measures of EOL care intensity, including place of death, hospitalizations, ICU admissions, nursing home utilization, or hospice use. Lonely individuals had higher odds of engaging in EOL care discussions with their next of kin (AOR 1.70, 95% CI 1.13-2.54; $p=0.01$) and assigning a durable power of attorney (DPOA) (AOR 1.51, 95% CI

1.01-2.24; $p=0.04$), but had similar rates of documenting discussions and participating in EOL decisions.

CONCLUSIONS: Lonely older adults suffer from increased symptoms at EOL despite higher advance care planning and similar, if not higher, EOL healthcare utilization. These associations were independent of objective social network and social connection. Targeted interventions for lonely individuals are needed to improve EOL care and quality of life.

THE RELATIVE CONTRIBUTIONS OF HOSPITAL VS. SKILLED NURSING FACILITY QUALITY ON PATIENT OUTCOMES

Paula Chatterjee¹; Mingyu Qi¹; Rachel M. Werner². ¹University of Pennsylvania, Philadelphia, PA; ²University of Pennsylvania and Philadelphia VA, Philadelphia, PA. (Control ID #3185716)

BACKGROUND: Medicare will begin financially penalizing skilled nursing facilities (SNFs) with higher-than-expected readmission rates. Despite enthusiasm for the goal of reducing unnecessary readmissions from SNFs, some have raised questions about whether SNF readmissions are truly under the control of SNFs or whether they are more likely attributable to the quality of care received at the hospital from which the patient was discharged. We compared the relative contributions of hospital and SNF quality on readmission rates while controlling for unobserved patient characteristics.

METHODS: We performed a retrospective cohort study of Medicare beneficiaries with two hospitalizations followed by SNF admissions from 2010-2014. We divided beneficiaries into two groups: (1) patients who went to different hospitals but were discharged to the same SNF after both hospitalizations; and (2) patients who went to the same hospital but were discharged to different SNFs. The primary exposure was hospital-level and SNF-level quality, using a lagged measure of 30-day risk-standardized readmission rates for each. We estimated the risk-adjusted probability of readmission in the two groups of patients using a linear probability model with patient-level fixed effects.

RESULTS: We identified 232,243 patients who changed hospitals but not SNFs, and 276,095 who changed SNFs but not hospitals. We found that patients who went to the lowest-performing quartile of hospitals (highest risk-standardized readmission rate) had a 1.5% higher likelihood of readmission ($p<0.001$) compared to patients who went to the highest-performing hospitals (lowest risk-standardized readmission rate). In contrast, SNF performance had a larger impact on the likelihood of patient readmission. Patients who went to the lowest-performing SNFs had a 3.1% higher risk of readmission ($p<0.001$) compared to patients who went to the highest-performing SNFs.

CONCLUSIONS: The association between SNF quality and patient outcomes was larger than the association between hospital quality and patient outcomes among post-acute care patients. Holding post-acute care providers accountable for their quality may be an effective strategy to improve SNF quality and prevent readmissions among a comorbid and costly patient population. While some policymakers have raised concerns about the magnitude of post-acute care expenses, there may be a benefit to patients by prioritizing high quality post-acute care.

THE RETIREMENT MILESTONE: HOW CAN WE HELP OLDER ADULTS MAKE THE TRANSITION?

Jennifer Shiroky; Christine Caufield-Noll; Alicia I. Arbaje. Johns Hopkins Bayview Medical Center, Baltimore, MD. (Control ID #3185125)

BACKGROUND: Healthcare providers are in a unique position to help older adults transition into and optimize their health in retirement, yet there are few guidelines to assist providers. Over 40 million adults are approaching retirement; this major life milestone often leads to significant changes in psychological, social, financial, and physical dimensions of health. The objective of this study was to conduct a scoping review of

research on strategies and best practices for healthcare providers to help older adults thrive during retirement.

METHODS: For this scoping review, electronic databases (PubMed; Google Scholar; PsycINFO (EBSCO); and Scopus) were searched using keyword and controlled vocabulary terms including retirement, physicians, physician-patient relationship, counseling, and guidance. No date limitations were used. English-language articles focusing on those 55 years of age and older planning to or recently leaving the labor force who were screened or counseled by their healthcare providers about how to maintain or improve their health during this transition were included. All study types were included.

RESULTS: Database searches retrieved 530 citations. One hundred ninety-six citations were for abstract review and six article met criteria for full-text review. We found that the majority of articles focused on retirement from the medical profession or on measuring a particular intervention in the retired population. Few commented on the actual act of retirement. Importantly, no articles addressed how healthcare providers could help older adults in preparing for and moving through retirement. The few articles that did discuss the importance of addressing this transition were opinion pieces from the 1950s-1980s.

CONCLUSIONS: Surprisingly, the majority of literature focused on physician retirement, rather than on how healthcare providers can assist older adults with their retirement. There was essentially no literature evaluating strategies and best practices for healthcare providers to address the complexities of retirement and its effect on older adults' physical and mental health. Retirement, as it currently exists in the healthcare literature, is a potential untapped treasure trove of opportunities for new healthcare interventions to optimize older adults' health. This is especially critical as a large portion of the US population prepares to retire under turbulent times for social security and public and private insurance coverage. Future research can assess if and how healthcare providers approach retirement with older adults, what factors help older adults thrive in retirement, and what tools are needed for healthcare providers to use to address retirement during healthcare visits.

THE ROLE OF FAMILY ON DIABETES MANAGEMENT FOR LATINO ADULTS

Olivia Jordan¹; Amanda Benitez³; Deborah L. Burnet²; Michael T. Quinn²; Arshiya A. Baig². ¹University of Chicago Pritzker School of Medicine, Chicago, IL; ²University of Chicago, Chicago, IL; ³Enlace Chicago, Chicago, IL. (Control ID #3184542)

BACKGROUND: Mexican Americans have one of the highest prevalence of diabetes within the U.S. Hispanic community with 18.3% affected. Diabetes self-care behaviors are essential to diabetes management and often performed in the context of family support. However, few studies explore this relationship in Mexican-Americans. Our study aims to better understand how family influences diabetes self-care management in the Mexican-American community and how family is impacted by a loved one's diagnosis of diabetes.

METHODS: We analyzed qualitative data from semi-structured interviews with Latino adults with diabetes and focus groups with adults with diabetes and their family members conducted in a predominantly Mexican-American immigrant Chicago community. Interviews and focus groups were conducted in Spanish by trained, bilingual research staff and transcribed and translated to English. Data was coded using a modified template technique using Hyperresearch.

RESULTS: Data was collected from a total of 71 participants. The majority were diagnosed with diabetes (82%), from Mexico (86%), and female (80%). Participants with diabetes described a lack of social support from family, family not knowing what it is like to live with diabetes, the negative effect of diabetes on the family relationship, and difficulty maintaining changes when with family. Many participants with diabetes had difficulty motivating family to engage in a healthy lifestyle with them ("[My family is] used to eating differently; some of them want to eat what I

eat and others do not.") Even so, family was involved in day-to-day management of diabetes and provided emotional, informational, instrumental and companionship support. Suffering or death of family with diabetes and preventing diabetes in family were frequently mentioned as the main motivator to improve diabetes control. Many participants with diabetes shared information from diabetes education programs that led to positive behavioral changes in some family members. Family members noted that family responsibilities sometimes interfered with providing adequate support for their loved one with diabetes. Most family members expressed that diabetes affected their wellbeing and that of the whole family. Family members had a desire to learn more about the disease because they often did not know how to help ("You know, he's your dad and you're trying to at the same time please him but also in our culture, you respect your elders and you can't always tell them no.")

CONCLUSIONS: While lack of support and engagement from family members can undermine successful diabetes management, many participants had immediate family members available to support them. Most family members wished to learn more about how to help. Future patient education interventions with Mexican Americans with diabetes should use a culturally competent approach to educate family members on how to adopt supportive strategies to aid patients' diabetes self-management and implement behavioral changes at the family level.

THE SUPPORTIVE CHURCH ENVIRONMENT SCORE: A NOVEL SCORE TO QUANTIFY HOW SUPPORTIVE A CHURCH SETTING IS TOWARDS LOWERING CVD RISK FACTORS

Shanna A. Tucker¹; Priscilla Amanquah³; Rosio Ramos²; Naa-solo Tettey⁴; Holly S. Andersen⁴; Erica Phillips². ¹New York Presbyterian-Weill Cornell, New York City, NY; ²Weill Cornell Medicine, New York, NY; ³Hunter College, New York City, NY; ⁴Ronald O. Perleman Heart Institute, New York-Presbyterian Hospital, New York City, NY. (Control ID #3185360)

BACKGROUND: Age-adjusted obesity prevalence and cardiovascular disease (CVD) risk factors continue to disproportionately affect African Americans (AA). Multiple studies have shown that faith-based interventions can improve many of these factors, such as fruit and vegetable (F&V) intake. The development of a quantitative measure of the supportive health environment of churches, or the correlation of that support with church members' CVD risk behaviors have not been studied. The goal of this study was to develop and test a quantitative measure of how supportive a church's environment is towards promoting lifestyle habits that decrease CVD risk, termed the Supportive Church Environment Score (SCEC).

METHODS: Predominantly AA churches were enrolled in a 10-week faith-based cardiovascular risk reduction program led by trained lay health educators. Program participants completed a pre and post assessment inclusive of measures of CVD risk behaviors and 11 activities about the church environment. One point was assigned to each activity for a maximum score of 11. Higher scores suggest participants perceive that their church promotes CVD health activities. We evaluated the relationship between each participant's SCEC score and their daily F&V intake, physical activity, and blood pressure control. We also compared the average SCES score between churches and average F&V intake between churches.

RESULTS: At the time of this analysis 9 churches (136 participants) completed the baseline assessment. The mean age was 62.5 (SD 1.2), 80% AA, 83% women, 34% married and 97% had a high school education or higher. The mean servings of F&V were 1.7 for both. Table 1 depicts the number of participants (n) per church and average SCES. While there was a significant difference between mean SCES ($p < 0.001$), there was no significant difference between mean daily F&V intake between churches. We found no correlation between baseline perceived individual SCEC with daily F&V intake, physical activity level or blood pressure.

CONCLUSIONS: We were able to develop a quantitative measure of health promotion activities for faith-based organizations. This early analysis of baseline data is limited by a small sample size and a pervasively

low consumption of F&V overall regardless of the supportive church environment. A larger sample size, and other drivers of F&V intake, such as income, education and knowledge of the benefits of F&V intake, will need to be factored into the analysis.

TIMELY PRIMARY CARE FOLLOW-UP AND 30-DAY READMISSION RATES: A RETROSPECTIVE ANALYSIS FROM A RESIDENT-BASED PRIMARY CARE CLINIC

Niloofar Latifi; Robert N. Stuver; Tara M. Skorupa; Jorge Fradinho; Rebecca Glassman; Kelly L. Graham. Beth Israel Deaconess Medical Center, Boston, MA. (Control ID #3184619)

BACKGROUND: The transition in care from hospital to ambulatory setting is a vulnerable period for patients. Previous analyses on whether timely post-discharge visits with a primary care provider (PCP) reduce readmissions have shown mixed results. The primary aim of our project was to investigate the hypothesis that a primary care visit within 14 days of discharge leads to a reduction in 30-day readmission rates.

METHODS: We performed a retrospective analysis of all Medicare and Medicare Advantage patients discharged from our hospital from 10/1/2017 - 9/30/2018 who have a PCP at our hospital-based primary care practice. Patients discharged to rehab or a long-term care facility were excluded. Patients were evaluated for having a timely post-discharge primary care appointment, defined as occurring within 14 days of discharge, in accordance with the Medicare Transitional Care Management period. They were further categorized based on our predictor variable of having an appointment scheduled at time of discharge, and then if this appointment was kept or cancelled/missed. The primary outcome was a readmission within 30 days of discharge. We used a chi square test to determine if rates of readmissions were significantly different between groups.

RESULTS: Our study population included a total of 1069 patients. At discharge, 585 patients (55%) had a primary care visit scheduled within 14 days. The 30-day readmission rate for patients with a kept appointment was 17%, compared to 21% for cancelled/missed appointments, and 36% in patients without a scheduled appointment at time of discharge ($P<0.001$). For patients who saw a specialist but not a PCP within 14 days of discharge, the 30-day readmission rate was 28.8%, versus 19.5% for those who saw both a specialist and a PCP ($P=0.52$) (Table 1).

CONCLUSIONS: A statistically significant reduction in 30-day readmission rates was observed in patients who are seen by a PCP within 14 days of discharge compared to those who do not keep their appointment or do not have an appointment scheduled at discharge. There is a decrease in 30-day readmission rates when patients are seen by a PCP in addition to a specialist that did not reach statistical significance. Our study demonstrates the importance of timely PCP follow up within the 14-day post-discharge period, as well as the benefit to scheduling appointments for patients at the time of discharge to reduce 30-day readmission rates.

TOWARDS VIRAL HEPATITIS ELIMINATION: AN INNOVATIVE STRATEGY TO SCREEN AT-RISK POPULATIONS IN THE EMERGENCY DEPARTMENT WITH LINKAGE TO PRIMARY CARE

Su H. Wang¹; Ruth P. Brogden¹; Eric Handler²; Briana Marcantonio³; Alyssa Gallipani^{4, 5}. ¹Saint Barnabas Medical Center, Florham Park, NJ; ²Saint Barnabas Medical Center, Livingston, NJ; ³Saint Barnabas Medical Center, West Orange, NJ; ⁴Fairleigh Dickinson University, Madison, NJ; ⁵RWJBarnabas Health, West Orange, NJ. (Control ID #3184952)

BACKGROUND: Globally, deaths from viral hepatitis (VH) surpass HIV, malaria and tuberculosis. In the US, VH is a large driver of rising hepatocellular carcinoma rates. However, with hepatitis B vaccines & treatment and hepatitis C curative therapies, the World Health Organization has deemed that VH can be eliminated by 2030. Massive scale-up in screening is required to increase the current low diagnosis rates, and

shifting of care from specialists to primary care is critical to achieving elimination. Both CDC and USPSTF recommend screening for VH in those at-risk: people born in 1945-1965 should be screened for hepatitis C (HCV) and foreign-born people from hepatitis B (HBV) endemic countries should be screened for HBV. We set up automated VH screening in the Emergency Department (ED) to reach the at-risk and vulnerable in New Jersey, where 21% of the residents are foreign-born and provided navigation and VH care in a primary-care

METHODS: Electronic Health Record (EHR) modifications include an algorithm for eligibility with date of birth and country of birth. If bloodwork is ordered by a provider, VH lab test(s) are automatically generated: HCV antibody (HCV Ab) with reflex to HCV RNA and/or a hepatitis B surface antigen (HBsAg). Alerts notify nursing of patient eligibility and positive tests. The patient navigator (PN) receives real time alerts of positive tests to contact patients, meeting them in person or calling to educate and arrange follow-up. The PN has direct access to schedule patients at a primary care practice of internists trained in VH care. Team meetings of physicians, pharmacist and navigators are held to discuss patient status, including those undergoing HCV cure.

RESULTS: Since March 2018, 7,550 patients have been screened for HCV, with 243 (3.2%) HCV Ab+ and 84 (1.1%) with current infection. Fifty-six percent (47) were newly diagnosed and 54 (64.3%) linked to care. HCV RNA+ patients were 61% male with a mean HCV RNA 2,987,000 IU/mL. Twenty five HCV patients were seen at our practice with 13 initiating HCV therapy for 8-12 weeks. So far, 9 (70.0%) have undetectable HCV RNA at week 4, and 3 (12%) with confirmed cure post-therapy. For HBV, 6,466 were tested with 76 (1.2%) infected, 34 (44.7%) newly diagnosed, and 42 (55.3%) linked to care. Haiti, Jamaica and Ecuador were the top countries-of-origin for those screened, and Haiti, China and Ghana, the top countries of the HBV-infected patients.

CONCLUSIONS: Automated VH testing in the ED is a model for efficient, large-scale screening of at-risk patients, many difficult to reach due to barriers in language, cultural or healthcare access. Navigation is important to provide transition-of-care from the ED to appropriate follow-up. Primary care providers can manage VH patients, and a healthcare team approach can facilitate successful HCV cures

TOXIDROME PATTERNS AND OUTCOMES IN A MEDICALLY-SUPERVISED OVERDOSE PREVENTION PROGRAM FOR HOMELESS PEOPLE IN BOSTON

Gabriel R. Wishik-Miller^{1, 2}; Jessie M. Gaeta^{1, 2}; Melanie W. Racine¹; James J. O'Connell^{1, 3}; Travis P. Baggett^{1, 3}. ¹Boston Health Care for the Homeless Program, Boston, MA; ²Boston University School of Medicine, Boston, MA; ³Massachusetts General Hospital, Boston, MA. (Control ID #3183938)

BACKGROUND: In response to rising opioid overdose deaths among homeless individuals, Boston Health Care for the Homeless Program (BHCHP) opened the Supportive Place for Observation and Treatment (SPOT) in 2016. SPOT provides medical monitoring and harm reduction services to people who are intoxicated and sedated, often because of concurrent use of opioids and other sedating substances. To inform the development and dissemination of this unique care model, our objective was to characterize toxidrome patterns and describe outcomes of SPOT users.

METHODS: We analyzed data on adult (age 18-64 yrs) visits to SPOT between 1/1/17-12/31/17 in which the following measures were recorded: blood pressure, heart rate, respiratory rate, pulse oximetry, and Inova Sedation Scale level. Other measures included self-reported age, sex, and substances consumed, including opioids, non-opioid sedatives (e.g. benzodiazepines), stimulants (e.g. cocaine), cannabinoids, and alcohol. Care outcomes included duration of visit, administration of oxygen or naloxone, and manner of discharge. We used k-means cluster analysis to characterize toxidromes based on vital sign patterns. We used multinomial logistic regression to assess the demographic and substance consumption predictors

of toxicome cluster membership. We used linear and logistic regression to examine the association between cluster membership and care outcomes.

RESULTS: 156 visitors had 305 episodes of care. 72% of episodes reported opioid consumption and 63% reported consumption of a non-opioid sedative. Cluster analysis revealed 3 toxicome patterns. Cluster A (26.6% of episodes) had mild sedation and normal vital signs. Cluster B (44.5%) had higher levels of sedation and non-hypoxic vital sign abnormalities. Cluster C (28.9%) was comparable to cluster B with the addition of hypoxia. In multivariable modeling, consumption of non-opioid sedatives significantly predicted membership in cluster B (aOR 2.75, 95% CI 1.40-5.40) or cluster C (aOR 3.38, 95% CI 1.48, 7.70) as opposed to cluster A. Older age (aOR 1.54 per 10 years, 95% CI 1.00-2.35) and female gender (aOR 2.51, 95% CI 1.03, 6.10) were significantly associated with membership in cluster C vs. A. Cluster B (mean 4.4 hrs) and cluster C (mean 4.8 hrs) episodes were longer than cluster A episodes (mean 2.3 hrs, p<0.001 for both). Cluster C episodes were more likely to require supplemental oxygen. Only 3 episodes required naloxone. Most episodes (85.7%) ended in discharge to one's own care, without differences by cluster. No deaths were observed.

CONCLUSIONS: Among patients of a medically-supervised overdose prevention program, reported use of non-opioid sedatives strongly predicted more complex clinical courses. Despite this, few episodes required hospital transfer, very few required naloxone, and no deaths occurred. The SPOT experience suggests that many drug toxicomes can be managed effectively in the outpatient setting with early identification and appropriate monitoring and intervention resources.

TRAINEES AND TRANSITIONS TO POST-ACUTE CARE: EVIDENCE FOR IMPROVEMENT

Julia E. Limes¹; Catherine Callister¹; Robert E. Burke²; Eric A. Young²; Christine D. Jones³. ¹University of Colorado, Denver, CO; ²Denver VA Medical Center, Denver, CO; ³University of Colorado, Denver, Aurora, CO. (Control ID #3186051)

BACKGROUND: A significant proportion of patients are discharged from the hospital with post acute care supports including skilled nursing facilities (SNFs) and home health care (HHC) services. These patients are often medically complex, with a higher risk of readmission and significant implications if the discharge transition does not go smoothly. Little is known about resident knowledge and perceptions of SNF and HHC transitions.

METHODS: We developed a cross-sectional survey for residents to assess their knowledge, attitudes, and experience with discharging patients to SNF or HHC. The questions were based on prior qualitative and survey studies of discharge to SNF and HHC. A 36-question survey was sent to 193 internal medicine (IM) and medicine-pediatrics residents at a large academic IM training program. Respondents selected answers on a 4-point Likert scale and entered free-text comments.

RESULTS: A total of 100 (51.8%) residents responded. Residents felt confident in their ability to effectively transition patients to SNFs (80.8% agree or strongly agree) and HHC (65.6% agree or strongly agree). Two-thirds of residents identified the discharge summary as their sole method of communicating care instructions to SNFs, but only 19.2% of respondents reported always completing a discharge summary prior to discharge. In addition, only 43.4% usually or always provide a contact number for the inpatient team. In terms of knowledge about services provided at a SNF, 36.4% of residents knew how much physical therapy (PT), occupational therapy (OT), or speech therapy is provided at a SNF and 32.3% knew how frequently nursing services are provided. The perceived method of communicating care instructions to HHC agencies was more variable, with 45.7% communicating via discharge orders, 35.1% through a discharge summary, and 19.1% with a phone call by the case manager. Only 34.4% of residents usually or always provide a contact number for the inpatient team at discharge. Residents had similar gaps in knowledge

about the frequency of RN care (39.1% knew the frequency) and PT/OT (39.4%), the length of a HHC episode (37.5%), and what is required for wound care orders (46.8%). In the free response section, residents expressed that the most effective educational methods would include: more exposure to each setting, specific teaching by attendings and case managers with patients discharging to SNFs and HHC, and feedback about those patients after discharge.

CONCLUSIONS: Residents feel confident in their ability to effectively transition patients to SNFs and HHC but identify gaps in their knowledge about the frequency and type of care provided in each setting. Residents do not report a standardized practice for how to communicate care plans with SNFs and HHC agencies. We identified specific targets for educational and process interventions and the most effective educational methods.

TRANSDISCIPLINARY STRATEGIES FOR PHYSICIAN WELLNESS: QUALITATIVE INSIGHTS FROM DIVERSE FIELDS

Rachel Schwartz^{1, 2}; Marie Haverfield^{3, 2}; Cati Brown-Johnson⁴; Amrapali Maitra⁵; Aaron A. Tierney⁶; Shreyas Bharadwaj³; Jonathan G. Shaw⁷; Farzad Azimpour^{8, 3}; Sonoo Thadaney³; Abraham Verghese¹; Donna M. Zulman⁹. ¹Stanford University, Stanford, CA; ²VA Palo Alto Health Care System, Menlo Park, CA; ³Stanford University, Menlo Park, CA; ⁴Stanford School of Medicine, Stanford, CA; ⁵Brigham and Women's Hospital, Harvard Medical School, Boston, MA; ⁶Stanford University School of Medicine, Mountain View, CA; ⁷Stanford University School of Medicine, Stanford, CA; ⁸MYIA Labs, San Francisco, CA; ⁹Stanford University and VA Palo Alto, Stanford, CA. (Control ID #3165677)

BACKGROUND: While barriers to physician wellness have been well detailed, concrete solutions are lacking. We looked to professionals across diverse fields whose work requires engagement and interpersonal connection with clients. The goal was to identify effective strategies from non-medical fields that could apply to preserving physician wellness.

METHODS: We conducted semi-structured interviews with 30 professionals outside the field of clinical medicine whose work involves fostering effective connections with individuals. Participants were from diverse professions, including the protective services (e.g., police officer, firefighter), business/finance (e.g., restaurateur, salesperson), management (e.g., CEO, school principal), education, art/design/entertainment (e.g., professional musician, documentary filmmaker), community/social services (e.g., social worker, chaplain), and personal care/services (e.g., massage therapist, yoga instructor). Interviews covered strategies that professionals use to initiate and maintain relationships, practices that cultivate professional fulfillment and preserve wellness, and techniques that facilitate emotional presence during interactions. Data were coded using an inductive thematic analysis approach.

RESULTS: Professionals identified self-care strategies at both institutional and individual levels that support wellness. Institutional-level strategies include scheduling that allows for self-care, protected time to connect with colleagues, and leadership support for debriefing after traumatic events. Individual strategies include emotionally-protective distancing techniques, and engagement in a bidirectional exchange that is central to interpersonal connection and professional fulfillment.

CONCLUSIONS: Across diverse fields, professionals employ common institutional and personal wellness strategies that facilitate meaningful engagement, support collegiality, and encourage processing after intense events. The transdisciplinary nature of these wellness strategies highlights universal underpinnings that support wellbeing in those engaging in people-oriented professions.

TRANSLATING CHRONIC KIDNEY DISEASE RESEARCH INTO PRIMARY CARE PRACTICE

Cara Litvin¹; Steven Ornstein²; Paul Nietert¹; Ruth Jenkins¹. ¹Medical University of South Carolina, Charleston, SC; ²The PPRNet Foundation, Charleston, SC. (Control ID #3185329)

BACKGROUND: Chronic kidney disease (CKD) is common in the primary care setting. Early interventions may prevent progression of renal disease and reduce risk for cardiovascular disease. The purpose of this study was to assess whether implementation of a primary care improvement model results in improved identification and management of CKD compared to usual care.

METHODS: This 18-month group randomized trial was conducted from November 1, 2016 to April 30, 2018 in 21 practices in 13 U.S. states. Seventy-one physicians and 41 midlevel providers participated. All practices received performance reports as frequently as monthly on a set of 11 CKD clinical quality measures (CQMs) reflecting clinical practice guidelines related to screening for albuminuria in at-risk patients, monitoring (eGFR, albuminuria and hemoglobin), use of ACE-inhibitors or ARBs, blood pressure and glycemic control, statin therapy, and avoidance of NSAIDs. To promote implementation of practice improvement strategies derived from prior research and adapted to overcome known barriers to CKD care, 11 practices randomized to the intervention group hosted an on-site visit and 2 follow up webinars, and sent 2 representatives to a "best practice" meeting. The primary outcomes were changes in practice adherence to CKD CQMs over the 18-month trial. Linear mixed-effects regression models were used to compare changes over time for each CQM between intervention and control practices. Qualitative analyses of data obtained from site visits, webinars and the meeting were used to assess each practice's fidelity to implementation of the improvement strategies.

RESULTS: There were statistically significant greater improvements in intervention practices for annual screening for albuminuria in patients with diabetes or hypertension (absolute change 22% in intervention group vs. -2.6% in control group, $p<0.0001$) and annual monitoring for albuminuria in patients with CKD (absolute change 21% in intervention group vs. -2.0% in control group, $p<0.0001$). Avoidance of NSAIDs in patients with CKD declined in both intervention and control groups, with a significantly greater decline in the control practices (absolute change -5.0% in intervention group vs. -10% in control group, $p<0.0001$). There were no other significant changes found for the other CQMS. There was variable implementation of CKD-specific improvement strategies across the intervention practices.

CONCLUSIONS: Implementation of a primary care improvement model designed to improve CKD identification and management resulted in significantly improved care on 3 out of 11 CKD CQMs compared to usual care over 18 months. Incomplete adoption of improvement strategies may have limited further improvement. Achieving improved adherence to other CKD guidelines likely requires a longer and more intensive intervention.

TRAUMA EXPOSURE, HEALTH STATUS, AND DISEASE BURDEN AMONG MINORS SEEKING ASYLUM IN THE US

Joseph Shin¹; Lynne M. Rosenberg¹; Kevin Ackerman²; Maria Minor²; Pooja Shah³. ¹Weill Cornell Medicine, Brooklyn, NY; ²Weill Cornell Medical College, New York, NY; ³Weill Cornell Medicine, New York, NY. (Control ID #3185350)

BACKGROUND: Over the past decade, there has been an unprecedented influx of immigrant children seeking asylum or other forms of humanitarian relief into the US. For example, between 2009 and 2014, there was a 1,437% increase in unaccompanied alien children apprehended at the Southwest Border from El Salvador, Guatemala and Honduras. Driven primarily by epidemic levels of domestic, gang, and gender-based violence, many of these children have experienced multiple types of trauma in their country of origin, as well as additional trauma during migration and post-migration. Previous studies of immigrant, asylee, and refugee children identify a relationship between trauma exposure and poor mental health outcomes. Comparatively little is known about the trauma exposure and health status of this current wave of immigrant children, or the impact of more recent changes and conditions in their countries of origin, during migration, or related to US immigration policies and practices.

METHODS: This study is a retrospective analysis of completed forensic health evaluations for child and adolescent immigrants evaluated as part of Physicians for Human Rights' Asylum Program between January 2014 and April 2018.

RESULTS: Evaluations for 183 individuals were included in this analysis (114 male and 69 female), with an average age of 15 years at the time of evaluation. Most were from the "Northern Triangle" countries (89%) comprised of El Salvador (36%), Guatemala (19%), and Honduras (34%). They experienced multiple forms of trauma including direct physical (78%) and sexual violence (18%), threats of violence/death (71%) and forced gang conscription (24%), and witnessed acts of violence (59%). The perpetrators were most often family (47%) and gang members (60%). Major vulnerability factors present in this group included parental separation (66%) or parent death (11%). Health evaluations revealed that 76% had at least one major mental health diagnosis, most commonly post-traumatic stress disorder (64%), major depressive disorder (40%), and anxiety disorder (19%).

CONCLUSIONS: Child and adolescent asylum seekers often have multiple types of repeated trauma exposures resulting in significant medical and mental health consequences. It is essential to enhance culturally sensitive, trauma-informed care for these vulnerable populations, while limiting practices and policies that could contribute to further trauma exposure and negative health outcomes during all phases of migration.

TRAUMA INFORMED CARE NEEDS ASSESSMENT OF INTERNAL MEDICINE RESIDENTS

Jenny X. Wen; Colleen Christmas; Anika A. Alvanzo. Johns Hopkins University School of Medicine, Baltimore, MD. (Control ID #3186633)

BACKGROUND: In the US, 60-90% of adults have experienced emotional trauma—defined as an event or series of events (such as abuse, loss, or chronic stressors) that negatively affect health. Trauma exposure is strongly associated with proportional increases in chronic diseases, behavioral health disorders, and risky behaviors. These negative sequelae disproportionately affect ethnic minorities and urban, underserved populations. Physicians and healthcare providers can play important roles in intervention or re-traumatization of victims. However, current standard medical training does not include trauma or Trauma Informed Care (TIC). We aimed to examine the knowledge, attitudes, perceived skills, and behaviors of Internal Medicine residents regarding managing patients with histories of trauma, as well as residents' desires for additional training in trauma informed care.

METHODS: We conducted an online survey of residents enrolled in 4 Internal Medicine programs in Baltimore, Maryland to assess the following behaviors: recognizing, screening, managing, and referring patients with trauma histories. The questionnaire was based on PREMIS (Physician Readiness to Manage Intimate Partner Violence Survey) and addressed residents' knowledge, attitudes, self-assessed preparedness, and close personal experiences with trauma. Nonparametric tests (Kruskal-Wallis, Fisher's exact, and Wilcoxon rank sum) were used for analysis.

RESULTS: Of the 168 residents who responded to the survey (54% response rate), 44% were female, 55% White, 28% Asian, 4% Black and 13.2% unknown/other. Knowledge and preparedness were very limited. 83% percent of respondents underestimated trauma prevalence; 31.7% felt inadequately prepared to appropriately respond to positive disclosures. 59.5% reported they seldom asked about trauma in the past 6 months, and 8.8% never asked. Factors significantly associated with higher frequency of screening patients include greater perceived preparedness to identify, respond to, and refer patients ($p = .0001$ -.012); familiarity with referral resources ($p=.005$); comfort in discussing trauma with patients ($p = .003$); and perceived faculty ($p = .001$) and workplace support ($p = .038$). 68.7% had previous training on some trauma-related topics in medical school, and 42.2% did in residency; 91.8% wished for additional training on trauma and trauma informed care. Differences among genders, races, years in training, and program sites were minimal.

CONCLUSIONS: Internal Medicine residents in Baltimore had very limited knowledge about trauma prevalence and risks for comorbidities. Although most residents feel TIC is relevant to clinical practice, they feel unprepared to identify, respond to, manage, and refer patients with histories of trauma. Our results support the need for integration of trauma and Trauma Informed Care training into graduate medical education for Internal Medicine residents.

TRENDS IN DIVERSITY OF MEDICAL SCHOOL MATRICULANTS RELATIVE TO THE US POPULATION

Lanair A. Lett^{2, 2}; Whitney Orji¹; Jaya Aysola^{3, 2}; Ronnie Sebro^{2, 2}. ¹Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; ²University of Pennsylvania, Philadelphia, PA; ³Penn Medicine, Philadelphia, PA. (Control ID #3184958)

BACKGROUND: Over the past several decades, there has been increasing effort to improve physician workforce diversity, including the institution of formal accreditation guidelines by the Liaison Committee of Medical Education (LCME) in 2009. Recently, several studies examining trends in diversity at the undergraduate, graduate and faculty level, have reported modest improvements in the proportions of racial/ethnic and sex groups within medicine. However, these studies fail to account for the shifting demographics of the US population. With this analysis, we provide a method of assessing the racial/ethnic diversity of medical school matriculants relative to the increasing diversity of the US population.

METHODS: The S-score, a measure of representation given a population distribution, was used to analyze the Association of American Medical Colleges data on self-reported race/ethnicity and sex of allopathic medical school matriculants, compared to population distribution of the medical school-aged population (20-34-year-olds), from 2002 to 2017. Linear trends over time were estimated using Pearson correlation.

RESULTS: The number of medical school matriculants increased from 16,488 to 21,326 between 2002 and 2017. During that time, proportions of 20-34-year-old Black, Hispanic, and Asian males and females in the US grew, while proportions of White males and females decreased. From 2002 to 2012, Black males ($r=0.83$, 95% CI: 0.46, 0.96) and Black females ($r=0.9$, 95% CI: 0.65, 0.97) were increasingly underrepresented amongst medical school matriculants. From 2013 to 2017, neither Black males ($r=0.45$, 95% CI: -0.71, 0.95) nor females ($r=-0.85$, 95% CI: -0.99, 0.14) experienced significant trends in representation. From 2002 to 2012, representation of Hispanic males varied without a significant trend ($r=0.45$, 95% CI: -0.2, 0.83), while Hispanic females were increasingly underrepresented ($r=0.86$, 95% CI: 0.53, 0.96). Both groups were underrepresented from 2013 to 2017. White males were increasingly overrepresented from 2002 to 2012 ($r=-0.62$, 95% CI: -0.89, -0.03), while White females were increasingly underrepresented ($r=0.75$, 95% CI: 0.28, 0.93). From 2013 to 2017, neither White males ($r=0.84$, 95% CI: -0.16, 0.99) nor White females ($r=0.86$, 95% CI: -0.99, 0.08) experienced significant trends in representation. Asian males and females were overrepresented from 2002 to 2017.

CONCLUSIONS: Despite increasing in number and proportion, Black and Hispanic students remain underrepresented amongst medical school matriculants when compared to the US population. To facilitate national progress in enrollment of underrepresented minority students, future studies should use the S-score to evaluate the efficacy of diversity initiatives at the local level to identify successful interventions that can be scaled. The S-score can be adapted to the institutional, regional, or state levels and used to track progress with better resolution than previously reported in national studies.

TRENDS IN OBESITY AND MEDICAL EXPENDITURE AMONG WOMEN, 2008-2016: DIFFERENCES BY RACE/ETHNICITY

Joni S. Williams; Sneha Nagavally; Leonard E. Egede. Medical College of Wisconsin, Milwaukee, WI. (Control ID #3186374)

BACKGROUND: Two out of every three women in the U.S. have overweight or obesity, where annual medical expenditures exceed \$520 and \$4870, respectively. Evidence suggests women belonging to racial/ethnic minority groups have a higher prevalence of obesity compared to Non-Hispanic White (NHW) women. Obesity results in significant morbidity, preventable mortality, and increased medical expenditures among women; however, evidence assessing trends in obesity and medical expenditure by race/ethnicity is limited. Therefore, the aim of this study was to examine racial/ethnic differences in obesity trends and medical expenditures among a nationally representative sample of women.

METHODS: Nine years of data (2008-2016) from the Medical Expenditure Panel Survey (MEPS) Full Year Consolidated File were used for the analyses. Cochran-Armitage tests were used to determine statistical significance of trends in obesity and mean expenditure for women. Two-part statistical modeling (Probit and Gamma General Linear Model (GLM)) with a combination of binomial and positive distributions was used to evaluate differences in medical expenditure. Covariates included age, education, marital status, insurance coverage, region, comorbidity count, and year. Data were clustered to 3 time points: 2008-2010, 2011-2013, 2014-2016. BMI levels were classified as underweight (<18.5), normal (≥ 18.5 - 24.9, overweight (≥ 25.0 - 29.9), and obese (≥ 30.0 - 134.7). Analyses were weighted for the U.S. population.

RESULTS: Cochran-Armitage tests showed trends in obesity from 2008 to 2016 differed significantly between Hispanic ($p<0.001$), Non-Hispanic Black (NHB) ($p<0.001$), and Other ($p<0.001$) women compared to NHW women. Similarly, among obese women, trends in mean medical expenditures differed significantly between Hispanic ($p<0.001$), NHB ($p<0.001$), and Other ($p<0.001$) women compared to NHW women. From the two-part model, the Probit model indicated obese Hispanic (-0.28 (-0.35, -0.20)), NHB (-0.23 (-0.31, -0.16)), and Other (-0.27 (-0.42, -0.11)) women were significantly less likely to spend on healthcare compared to NHW women, after adjusting for covariates. The Gamma GLM showed that among obese women with positive medical expenditure, Hispanic women spent 14% less (\$1145.87; $p<0.001$), while NHB women spent 11% less (\$940.03; $p<0.001$) compared to NHW women, adjusting for covariates. No significant differences in incurred medical expenditure were observed between obese Other and NHW women after adjusting for covariates.

CONCLUSIONS: These findings suggest the need for further understanding of the factors and underlying mechanisms associated with differences in trends for obesity among minority and NHW women and trends in medical expenditures between obese Hispanic, NHB, and NHW women to address these disparities and target the unique needs of women with overweight and obesity in the U.S.

TRENDS IN SYSTOLIC BLOOD PRESSURE CONTROL AND MANAGEMENT IN THE UNITED STATES, 2006 TO 2015

Cecilia Scholcoff^{1, 2}; Jeffrey L. Jackson^{1, 2}; Cynthia Kay^{1, 2}; Sarah Nickoloff^{1, 2}. ¹Zablocki VAMC, Milwaukee, WI; ²Medical College of Wisconsin, Milwaukee, WI. (Control ID #3179298)

BACKGROUND: Hypertension (HTN) is one of the most common conditions affecting the U.S. population and an important risk factor for cardiovascular disease, heart failure, stroke and kidney disease. In this study, we assess prescribing and counseling patterns as well as systolic blood pressure (SBP) control in United States primary care settings over the past 10 years.

METHODS: We analyzed data over one decade (2006-2015) from the National Ambulatory Medical Care Survey (NAMCS). We abstracted blood pressure readings among all visits and stratified SBP control as <120 mm Hg, 120-139 mm Hg and 140 mm Hg. In addition, we abstracted whether the patient had a diagnosis of hypertension, the class and number of anti-hypertensive medications, whether anti-hypertensive medication was newly prescribed, and frequency of dietary and exercise

counseling. Analyses were done using recommended study weights using the STATA SURVEY program (V15.1, College Station, Tx).

RESULTS: Among primary care visits between 2006 and 2015, the prevalence of hypertension was 25-35%, gradually increasing over time (p for trend <0.001). The highest rate of uncontrolled HTN (SBP 140 mm Hg) was 25% in 2006. Subsequently, the rate of uncontrolled hypertension declined to 16-19% of visits for the remainder of the study period. In most years, nearly half of primary care patients diagnosed with hypertension were not receiving anti-hypertensive medications. About a third were treated with monotherapy, 20% with two medications and 5-10% with three or more medications. Among patients on anti-hypertensive medications, the class of medication prescribed was consistent over the decade. Angiotensin converting enzyme (ACE) inhibitors were used in 40-50% of patients, calcium channel blockers, beta blockers and angiotensin receptor blockers (ARBs) were used in 25-35% of patients, and thiazide diuretics were only used in 14-17% of patients. Patients with uncontrolled HTN received a new medication only 14-24% of the time. Overall, the rates of dietary and exercise counseling were low (7-15% of visits), but slightly increased if patients had a diagnosis of hypertension, had SBP 140 mm Hg, or if hypertension was the primary reason for the visit.

CONCLUSIONS: Although we found that almost a fifth of patients had uncontrolled hypertension, our results are promising and show that blood pressure control is improving in the United States. We did identify areas that need continued attention, such as guideline-based prescribing, medication intensification and the use of counseling as treatment for hypertension.

TRENDS OF HYPOGLYCEMIA-RELATED HOSPITALIZATIONS IN VETERANS WITH DIABETES FROM 2005 TO 2016

Molly Zhao^{1, 2}; Paul Conlin¹; David Mohr³; Julia Prentice². ¹Boston VA Healthcare System, Boston, MA; ²Boston University, Boston, MA; ³VA Boston Healthcare System, Boston, MA. (Control ID #3186347)

BACKGROUND: One quarter of U.S. older adults with diabetes are potentially over-treated with glucose lowering medications that have a high risk of hypoglycemia. Individualizing hemoglobin A1c (A1c) target values has been recommended for managing diabetes (DM). This study examined trends of hypoglycemia-related hospitalizations across risk factors for hypoglycemia over time among veterans, a population with a T2D prevalence that is twice higher than the general population.

METHODS: This retrospective observational study used administrative data from the Veterans Health Administration to identify patients ($N = 484,285$) diagnosed with DM, aged 64 or older with 4 or more A1c tests during a three-year baseline period from 2005 to 2016 and at least one-year of post-baseline data. Hypoglycemia-related hospitalizations were identified by any discharge diagnosis with ICD-9 codes from an algorithm validated by Ginde et al., 2009 and the corresponding ICD-10 codes. The frequency of such events was calculated across gender, race, age groups (64 - 74; 75+), insulin and sulfonylurea use during the baseline period, baseline A1c levels (< 7; 7-7.9; 8-8.9; ≥ 9). χ^2 tests were conducted for significance. The rate of hypoglycemia-related hospitalizations was calculated by dividing the number of hospitalizations for hypoglycemia by the number of overall hospitalizations in the same year among the sample.

RESULTS: A total of 9,020 unique patients had 10,639 hypoglycemia-related hospitalizations from the start date of their baseline period to their date of death or the end of 2016. The rate of hypoglycemia-related hospitalizations declined from 2.3% to 1.8%, the decline being most prominent from 2007 to 2015. The downward trend was similar across most of the sociodemographic and clinical parameters. Among the 9,020 patients, the frequency of patients hospitalized for hypoglycemia increased from 1.2% to 4.7% ($P < 0.0001$) from the lowest to highest baseline A1c range. Among the users of insulin and sulfonylureas, 3.8% and 2.2% were hospitalized for

hypoglycemia compared to non-users at 1.3% and 1.6% ($P < 0.0001$), respectively. African American and Hispanic patients were hospitalized for hypoglycemia at a rate of 4.1%, compared to 1.6% of the remaining sample ($P < 0.0001$). The frequency of patients 75 years or older was 2.0% compared to the 1.8% of younger patients ($P < 0.0001$).

CONCLUSIONS: The rate of hypoglycemia-related hospitalizations in veterans has declined since 2005, although African Americans, older individuals, insulin and sulfonylurea users and those with higher A1c levels remain at greater risk. These findings may inform efforts to individualize A1c target values to prevent potential overtreatment and complications of hypoglycemia.

TRIAL DESIGN FOR INEFFECTIVENESS RESEARCH: A MIXED-METHODS SURVEY

Kevin R. Riggs^{1, 2}; Joshua Richman^{1, 2}; Stefan Kertesz³; Sara J. Knight⁴. ¹University of Alabama at Birmingham, Birmingham, AL; ²Birmingham VA Medical Center, Birmingham, AL; ³Birmingham VA Medical Center & U. Alabama Birmingham, Homewood, AL; ⁴University of Utah, Salt Lake City, UT; ⁵VA Salt Lake City Health System, Salt Lake City, UT. (Control ID #3184284)

BACKGROUND: Many widely used health services may be ineffective. Clarifying the effectiveness of these services could help reduce overuse, but the optimal trial design for evaluating ineffectiveness is uncertain. Some have advocated using equivalence trials (or closely related non-inferiority trials), as demonstrating that placebo or an inactive control is equivalent to an intervention could support the claim that it is ineffective. The objective of this study was to determine whether experienced investigators favor superiority trials or equivalence trials for ineffectiveness research and their reasons for favoring that design.

METHODS: We conducted an online, mixed-methods survey. We crafted a vignette describing researchers planning to conduct a trial of a common intervention they hypothesized was ineffective. We identified experienced investigators by searching clinicaltrials.gov for trials registered March-September 2017 funded by federal sources that included an email address for the principal investigator. We emailed a link to the survey and two reminders to non-responders. Participants answered one multiple-choice question about which study design they favored, and one free-response question describing their reasoning. Participants were randomized to vignettes that varied in two domains: intervention (medication vs. placebo, or surgical procedure vs. sham procedure) and outcome (pain, or morbidity and mortality). We used content analysis to identify related reasons from free-response answers.

RESULTS: 139 participants completed the survey (completion rate 37.5%). Overall, 56.8% favored superiority trials, 27.3% favored equivalence trials, and 15.8% were unsure. Responses did not differ by intervention ($p=0.56$) or outcome ($p=0.74$). 95 participants included a free text response to explain the reason for their selection. Themes identified for favoring superiority trials were: 1) evidence of superiority should be required to justify active treatment, 2) superiority trials are more familiar, 3) placebo should not be the comparator in equivalence trials, and 4) superiority trials require smaller sample sizes. Themes identified for favoring equivalence trials were: 1) negative superiority trials represent a lack of evidence of effectiveness rather than evidence of ineffectiveness, and 2) the research hypothesis should not be the same as the null hypothesis. Many responses were nonspecific or did not address differences between the trial designs, so did not contribute to themes.

CONCLUSIONS: Equivalence trials may have the potential to generate evidence supporting the ineffectiveness of some interventions, but do not appear to be favored by experienced investigators for this purpose at this time. General lack of familiarity with equivalence trials is a contributing factor. Other factors—such as uncertainty about the appropriateness of using placebo as a comparator—may represent misconceptions about equivalence trials. More debate is needed about the optimal design of ineffectiveness research.

TWENTY-YEAR CHANGES IN UNMET HEALTH NEEDS OF NON-ELDERLY ADULT AMERICANS: A NATIONAL STUDY

Laura Hawks^{1, 2}; David Himmelstein³; Stephanie Woolhandler⁴; David Bor¹; Adam Gaffney¹; Danny McCormick⁵. ¹Cambridge Health Alliance, Cambridge, MA; ²Harvard Medical School, Cambridge, MA; ³City University of New York at Hunter College, New York, NY; ⁴Cambridge Hospital, New York, NY; ⁵Harvard Medical School / Cambridge Health Alliance, Cambridge, MA. (Control ID #3185047)

BACKGROUND: Many recent studies have highlighted improvements in coverage and access to care attributable to the Affordable Care Act (ACA). However, a narrow focus on short term pre- to post-ACA changes may distract attention from longer-term trends in Americans' unmet health needs.

METHODS: We analyzed data on persons aged 18-64 from the 1998 and 2017 Behavioral Risk Factor Surveillance System (BRFSS), a telephone-based survey conducted in each US state and Washington D.C. that collects nationally-representative data for the non-institutionalized population. We used two measures of unmet health needs: 1. being unable to see a physician when needed, due to cost; and 2. not having a check-up in the last two years. We assessed changes in insurance coverage and both indicators of unmet health needs from 1998 to 2017 for the overall population as well as for subgroups with specific health conditions. All analyses used weights that allow extrapolation to the US non- institutionalized population, and were also conducted stratified by insurance status. We estimated unadjusted differences (UD) in proportions between 1998 and 2017.

RESULTS: The sample included 105,886 respondents from 1998 and 301,752 from 2017. Between 1998 and 2017 the uninsurance rate among all non-elderly adults decreased from 16.9% to 14.8% (difference: -2.1 [95% CI, 1.6 - 2.5]; however, among young adults (aged 35-44), uninsurance increased by 1.2 percentage points [95% CI, 0.4 to 2.2]. Over the same 2-decade span, the proportion of respondents who reported being unable to see a physician due to cost increased by 4.3% [95% CI, 3.8-4.7], from 11.4% to 15.7%. Among all non-elderly adults this increased by 6.7% [95% CI, 5.1-8.3] in the uninsured, and by 4.5% [95% CI, 4.1-4.9] among the insured. While this measure worsened for all racial/ ethnic groups, inequality persisted. In 2017, 18.8% [95% CI, 17.9-19.7] of black and 21.9% [95% CI, 20.9-22.8] of Hispanic versus 13.3% [95% CI, 13.0-13.6] of white respondents reported this barrier to care. Additionally, 28.5% [95% CI, 27.2-29.7%] of low income, and 39.6% [95% CI, 38.6-40.7] of uninsured respondents could not see a doctor when needed due to cost. This measure worsened to a similar degree among the chronically ill, including those who reported a diagnosis of hypertension, hyperlipidemia, diabetes, obesity, cardiovascular disease, binge drinking and smoking, and among those reporting poor health status. In contrast, the proportion of non-elderly adults who had received a check-up within the past 2 years did not change overall, regardless of coverage status.

CONCLUSIONS: Despite important short-term improvements in coverage and access to care under the ACA, coverage gains were less impressive over the longer term, and the proportion of non-elderly adults with unmet health needs either failed to improve or actually worsened in the last 2 decades. A reform more comprehensive than the ACA will likely be required to more fully address Americans' unmet health needs.

U.S. ADULTS' PERSPECTIVES ON DECISION-MAKING ABOUT HEALTH INSURANCE, HEALTHCARE, AND EMPLOYMENT NEAR RETIREMENT

Renuka Tipimeni^{1, 1}; Erica Solway¹; Preeti Malani^{1, 1}; Jamie Luster¹; Jeffrey T. Kullgren^{1, 1}; Matthias Kirch¹; Dianne Singer^{1, 1}; Aaron M. Scherer². ¹University of Michigan, Ann Arbor, MI; ²University of Iowa Carver College of Medicine, Iowa City, IA. (Control ID #3179040)

BACKGROUND: As U.S. adults approach Medicare eligibility at the age of 65, they face important decisions about health care and employment. Recent legislative, regulatory, and legal challenges to the

Affordable Care Act (ACA) may add new uncertainties to decision-making in this critical period. Our objective was to understand adults' perspectives on health insurance coverage, health care, and employment as they approach retirement age.

METHODS: In October 2018, a cross-sectional online survey was conducted using the Ipsos (formerly GfK) KnowledgePanel®, a large, nationally representative probability-based panel. This survey was conducted as part of the University of Michigan National Poll on Healthy Aging, a recurring online survey of participants age 50-80. The completion rate was 62% among panel members contacted to participate. This study included 1,028 community-dwelling U.S. adults, age 50-64. Analyses report descriptive and bivariate statistics incorporating survey weights. Measures included respondents' plans regarding current and future health insurance, medical care, and retirement decision-making. The margin of error was ±1 to 3 percentage points for questions asked of the full sample, and higher among subgroups.

RESULTS: Nearly half (45%) of adults age 50-64 had little to no confidence in their ability to afford health insurance when they retire, and 27% had little or no confidence in ability to afford health insurance over the next year. Confidence in health insurance affordability during retirement was highest among ages 60-64, males, African-Americans, those with annual household incomes >\$60,000, higher educational attainment, and excellent or very good health. In the past year, 14% of respondents reported keeping a job and 11% delayed or considered delaying retirement specifically to have their employer-sponsored health insurance. 12% thought about or went without health insurance in the past year. 8% stated that they were waiting to get a medical procedure until they have Medicare coverage, and 13% had not gotten medical care in the past year because of cost concerns. More than two-thirds (68%) of respondents were concerned about potential changes to health insurance due to changes in federal policies. Those age 60-64 and with lower incomes (<\$60,000 annually) were more likely to express these concerns.

CONCLUSIONS: Half of adults age 50-64 were worried about their ability to afford health insurance when they retire and most were concerned about how changes in federal policies could affect their insurance. Some even delayed retirement or kept a job to keep their employer-sponsored health insurance. While federal legislative efforts to change the ACA largely failed in 2018, these findings suggest that many adults age 50-64 still worry about potential future changes to their health insurance options. Health care policy solutions are needed to help patients near retirement better understand their coverage options and navigate health care in this critical transition period.

UNDER-DISPENSING OF MEDICINES FOR NON-COMMUNICABLE DISEASES IN UGANDA AND ITS EFFECT ON PATIENTS: A CROSS-SECTIONAL MIXED METHODS STUDY

Jeremy I. Schwartz^{1, 3}; Andrew Tusubira^{3, 2}; Rejoice Ngongoni⁴; Gidio Agaba⁵; Christine Nalwadda^{2, 3}. ¹Yale School of Medicine, New Haven, CT; ²Makerere University College of Health Sciences School of Public Health, Kampala, Uganda; ³Uganda Initiative for Integrated Management of Non-Communicable Diseases, Kampala, Uganda; ⁴Stanford Medicine, Stanford, CA; ⁵Mulago National Referral Hospital, Kampala, Uganda. (Control ID #3185863)

BACKGROUND: The prevalence of non-communicable diseases such as hypertension (HTN) and diabetes (DM) is rising rapidly in low-income countries. Access to medicines for these conditions is low, largely driven by low availability and high cost. Anecdotally, patients often do not receive the medicines prescribed for them at public sector health facilities. But the scale of such under-dispensing and its implications for patients have not been previously defined. In this study, we aimed to characterize the gap between prescribing and dispensing of these medicines in Uganda and to understand the effect of this gap on patients' ability to care for their chronic conditions.

METHODS: We conducted a cross-sectional study at public-sector hospitals throughout Uganda, utilizing a parallel-convergent mixed methods design. We surveyed a convenience sample of patients at 20 hospitals that offer HTN/DM clinics and conducted in-depth interviews and focus group discussions with a purposive sample of patients at six of these clinics. All participants were adults presenting for HTN and/or DM care. Quantitative and qualitative findings were analyzed separately, their results compared and merged for interpretation. Survey data were analyzed using descriptive statistics. We defined the Prescribing-Dispensing Gap as prescribed doses minus dispensed doses divided by prescribed doses x100. Interviews were transcribed and coded and emergent themes were identified using the Framework method.

RESULTS: We surveyed 637 patients and interviewed 164 patients (36 in-depth interviews and 128 in 14 focus group discussions). Surveyed patients were prescribed a total of 82,591 doses, of which 47,300 (57.3%) were not dispensed. 84% of patients (n=535) did not receive all of their prescribed doses and 90 of 253 (36%) patients contacted in follow-up had not obtained any remaining doses elsewhere. Interviewed patients reported medicines being out of stock and being dispensed less than what was prescribed. Patients noted that some medicines, primarily insulin, were often of low quality, leading to distrust and non-adherence. Patients were consistently advised to purchase non-dispensed medicines from private pharmacies, though financial barriers often prevented them from doing so. As a way of mitigating the frequent shortage of medicines, some patients reported organizing themselves to form informal "patient associations", localized to a few hospitals.

CONCLUSIONS: In this study, we found that 57.3% of prescribed doses of HTN and DM medicines are not dispensed at public-sector hospitals in Uganda due to stockouts and rationing and that many patients do not obtain remaining doses from private pharmacies due to financial barriers. This large Prescribing-Dispensing Gap has profound implications for patients' ability to consistently manage their chronic conditions. Future research should focus on improving access to medicines for chronic conditions, including through innovative patient-centered and patient-driven approaches.

UNDERSTANDING GEOGRAPHIC VARIATION IN SYSTEMIC OVERUSE AMONG THE PRIVATELY INSURED

Allison H. Oakes²; Aditi Sen²; Jodi B. Segal^{1,2}. ¹Johns Hopkins University School of Medicine, Baltimore, MD; ²Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD. (Control ID #3184881)

BACKGROUND: Overuse of services contributes importantly to the high spending on health care in the US. Annually, 14-25% of Medicare beneficiaries and 4-8% of commercially-insured adults experience services that can be considered wasteful. We demonstrated that overuse within regions is stable longitudinally, which suggests that there are regional drivers of overuse. We aimed to characterize these drivers to inform interventions.

METHODS: We analyzed commercial insurance claims from 18-64 year olds. We calculated a Johns Hopkins Overuse Index (JHOI) score, semi-annually, for each of the 375 Metropolitan Statistical Areas (MSA) in the U.S. from January 2011 to June 2015. The JHOI is a normalized measure of systemic health care services overuse that can describe overuse across the adult lifespan. To estimate associations between regional characteristics of the health care system and systemic overuse, we fit an OLS regression to model the JHOI as a function of regional characteristics with state and year fixed effects, clustered at the MSA. Regional characteristics were constructed from the Area Health Resource File and the American Hospital Association Survey. Each regional characteristic was conceptualized as describing: 1) resource availability, 2) healthcare services configuration, 3) market competition, or 4) prevailing local clinical practices. We controlled for demand-side covariates using data from the American Community Survey.

RESULTS: Across all years, the normalized JHOI identified 37 regions that were stable, markedly-overusing regions (>2 S.D. above average) and 47 that were > 2 S.D. below the average. Regional characteristics associated with higher JHOI scores, indicating more systemic overuse, included the total number of physicians per 1,000 residents ($p=0.006$) and a higher Medicare malpractice geographic price index, representing higher spending on malpractice insurance ($p<0.001$). Conversely, regions with a higher density of primary care physicians ($p=0.006$) and those with more hospital-based providers ($p=0.029$) had lower JHOI scores, indicating less systemic overuse. Relative to regions with lower competition in the both the hospital and insurance markets, results diverged when there was discordance in market power. Trending toward significance, areas with a competitive hospital market and a less competitive insurer market were associated with a 0.25 point increase in the JHOI ($p=0.072$) while areas with the inverse were associated with a 0.32 point decrease in the JHOI ($p=0.053$).

CONCLUSIONS: Regional variation in the clinician workforce and drivers of "practice culture" are associated with variation in systematic overuse of health care. Additional research is needed to understand the relationship between the JHOI and market competition. The role of primary care doctors in reducing health care overuse deserves further attention; new models of primary care delivery as stimulated by Centers for Medicare and Medicaid Services (CMS) may prove impactful on overuse of resources.

UNDERSTANDING PRIMARY CARE PHYSICIAN'S INFORMATION NEEDS DURING INBOX MESSAGE PROCESSING

Daniel R. Murphy¹; Tyler Satterly¹; Dean F. Sittig²; Hardeep Singh¹. ¹Michael E. DeBakey Veterans Affairs Medical Center and Baylor College of Medicine, Houston, TX; ²University of Texas, Houston, TX. (Control ID #3168062)

BACKGROUND: Primary care physicians spend a sizable portion of each day performing non-face-to-face care. Much of this activity involves processing notifications delivered via Electronic Health Record (EHR)-based inboxes. Improving EHR inbox designs to better match information displays with physician's information needs and workflows can greatly improve the efficiency of notification processing. However, research on this topic is limited. To identify recommendations for future EHR inbox designs, we performed a study to understand the information physicians access and actions physicians take while processing inbox notifications.

METHODS: We conducted a task analysis by directly observing physicians at four large clinical practices as they processed their inbox notifications. During each session, we asked physicians to verbalize what actions they were taking in response to the messages and the rationale for these actions. We additionally recorded the information they viewed in the EHR. During analysis, notification types and actions taken were categorized (e.g., "test results," and "review medication list," respectively). The data was then analyzed to determine the actions most frequently performed while processing alerts.

RESULTS: We observed 25 physicians as they processed 147 notifications in their EHR inboxes. Notifications included 53 test results, 31 messages from staff members, 21 messages from other clinicians, 15 messages from patients, 13 refill requests, 5 system messages that a patient had not read a message sent to them, 4 co-signature requests, 3 inpatient records, and 2 self-reminders. While processing messages, physicians most frequently (10% of messages) performed the following actions: reviewed test results (37%), send patient portal messages (24%), documented in the patient's record (22%), signed existing orders or notes (20%), sent a message to another clinician or staff (18%), called patients (14%), reviewed their last progress note (13%), review lab trends (10%), and reviewed medications (10%). Other activities (e.g., placing new orders), occurred in <10% of messages. Physicians entered the full chart only 12% of the time.

CONCLUSIONS: We found that physicians performed a variety of actions while processing EHR-based notifications in their inboxes,

primarily including review of various clinical data and communication with staff, patients, and other clinicians. When possible, physicians appeared to prefer accessing data within the inbox rather than enter the full record. To improve message processing efficiency for physicians, EHR vendors can ensure this relevant information is directly accessible from within the inbox and allow follow-up actions to be taken without entering the full record. Further research is needed to assess the impact of such changes on processing efficiency.

UNDERSTANDING RISK COMMUNICATION ABOUT FENTANYL USE IN HEALTH CARE SETTINGS: SUCCESSES AND OPPORTUNITIES FOR IMPROVEMENT

Christine Gunn^{1, 2}; Alexander Y. Walley³; Samantha F. Schoenberger¹; Ariel Maschke¹; Sarah Bagley¹. ¹Boston University, Boston, MA; ²Boston University School of Public Health, Boston, MA; ³Boston Univ, Boston, MA. (Control ID #3173498)

BACKGROUND: Deaths due to fentanyl overdose continue to increase. Individuals who use opioids may not understand the risks associated with fentanyl use or know how to minimize their fentanyl overdose risk. Overdose risk communication, a process of information exchange to negotiate better risk-related behaviors and outcomes, has not been examined. This study explored overdose risk communication by assessing patient and care provider experiences in discussing fentanyl risks across 4 dimensions of risk communication.

METHODS: We purposively sampled equal numbers of men and women with past year fentanyl use in Boston for qualitative interviews. We also interviewed health care and community outreach practitioners ("providers"). We conducted a grounded content analysis of professionally transcribed interviews. Codes related to patient-provider risk communication about illicit fentanyl use assessed via 4 risk communication constructs: 1) providing information about the risk; 2) recommending the elimination of risky behavior (abstinence); 3) discussing safer use strategies (harm reduction); and 4) reassuring patients that care will continue regardless of adherence to recommendations. Codes were analyzed to build themes around these dimensions and compare strategies currently employed vs. those desired by each group.

RESULTS: Twenty people who use fentanyl (PWUF) and 7 providers were enrolled. Nineteen PWUF had experienced overdose; most attributed this to fentanyl. PWUF reported wanting information about fentanyl risks, but saw those with a history of addiction as the most credible source, not providers. Risk information was welcomed when it was delivered in a non-judgmental, "kind and courteous" manner, and the person did "not sugar coat it". When providers suggested abstinence, both groups stressed that "personal readiness" was essential for treatment. Yet, PWUF reported that referrals in post-overdose settings were uncommon: "They highly recommend to get into a detox, but they never try to make the effort to get me into a detox." All providers emphasized harm reduction as the main strategy to minimize overdose risk from fentanyl. Although providers expressed a willingness to continue care for patients with ongoing substance use, 14 PWUF had experienced stigma that undermined risk conversations, some being refused care: "One of my primary cares, he told me just to get out of his office. That was a family lifelong doctor. Now he will never see me again."

CONCLUSIONS: PWUF wanted to talk about overdose risks with those who had experienced addiction. While harm reduction messages were emphasized by providers, PWUF indicated that ongoing substance use in primary care is stigmatized. Building the capacity of medical practices to effectively counsel patients who use fentanyl in the midst of the opioid crisis is critical to engaging patients in health care. Partnering and employing peers with experience using illicit fentanyl is a promising strategy to improve fentanyl overdose risk communication.

UNDERSTANDING THE SOCIAL CONTEXT OF PUBLIC HOUSING: SOCIAL NETWORKS OFFER CHALLENGES AND ASSETS FOR CARDIOVASCULAR HEALTH

Benjamin Meza¹; Craig E. Pollack²; Kimberly Gudzune³. ¹Johns Hopkins, Baltimore, MD; ²Johns Hopkins University School of Medicine, Baltimore, MD; ³Johns Hopkins University, Baltimore, MD. (Control ID #3185601)

BACKGROUND: The American Heart Association has identified the "mechanisms by which social networks affect health" as a significant knowledge gap and area for further inquiry because social networks have been shown to impact lifestyle factors such as diet and exercise. Yet little is published regarding the social networks of public housing residents and other low-income urban communities that suffer from a high prevalence of cardiovascular disease. The objective of this study was to describe the social network characteristics of a sample of public housing residents in Baltimore, MD.

METHODS: We used data from a cross-sectional survey of randomly selected households in two public housing complexes in Baltimore, MD from August 2014 to August 2015. Adult survey respondents answered an in-person survey of personal demographics, health, and health behaviors. After delineating up to 21 members of their social network, respondents answered detailed questions about 10 randomly selected members, including attributes of the respondent-member relationship and the frequency of interaction between members. We calculated network measures including network density (i.e., the extent to which all individuals in a respondent's social network are connected to each other) and the proportion of network members who are neighbors, live within Baltimore City, maintain daily contact, share a meal or snack, are family or friends, and provide material or emotional support.

RESULTS: The sample included 266 respondents (response rate 48%). Mean age was 44.5 years, 86.1% were women, 95.5% Black, 66.2% were high school graduates, and 33.5% were unemployed. Respondents nominated a median of 15 network members (range 6-21). Network density was high when considering all nominated relationships (0.57, Standard Deviation [SD] 0.29) and even when selecting only frequent contacts (0.25, SD 0.24). On average, the great majority of nominated members lived within Baltimore City (92%, SD 16%) yet only a small proportion lived within the same housing development (19%, SD 20%). Similarly, nearly all members were known to the respondent for greater than 12 months (96%, SD 12%) and most maintained daily contact (63%, SD 31%) but very few shared a meal or snack with the respondent on a daily basis (8%, SD 13%). The majority of members were family (57%, SD 28%) as compared to friends (33%, SD 26%).

CONCLUSIONS: Our findings provide a social context for developing interventions that are sensitive to the local community. High network density has been shown to potentiate some interventions while hampering others; strong social ties but weak dietary ties could offer a space for a network-based intervention; and the predisposition toward local but minimal neighborhood contacts is critical for understanding how information may not readily diffuse through public housing communities.

UNDERSTANDING VARIATION IN HOSPITALIZATION TRAJECTORY AMONG HIGH COST, HIGH NEED PATIENTS ENROLLED IN THE COMPREHENSIVE CARE PHYSICIAN (CCP) PROGRAM

Veena Sriram¹; Lauren O. Wiklund²; Abbie Klein¹; David Meltzer¹; Joyce W. Tang¹. ¹University of Chicago, Chicago, IL; ²Michigan State University, East Lansing, MI. (Control ID #3184971)

BACKGROUND: Decreasing hospitalization rates for high cost, high need patients is a major goal for practitioners and policymakers; however, existing interventions have had variable impact on utilization within their target groups, raising critical questions regarding what aspects of the intervention are working and for whom. The goal of this study is to explore patient and clinical staff perspectives on the factors underlying

variation in hospitalization trajectories for patients enrolled in the Comprehensive Care Physician (CCP) program, a program which focuses on reducing hospitalization by offering patients care from an interdisciplinary team led by a physician who serves as both the patients' outpatient primary care physician and inpatient hospitalist.

METHODS: This is a qualitative study embedded within a randomized controlled trial (CCP versus usual care). In-depth interviews were conducted with a purposive sample of intervention arm patients experiencing decreasing hospitalization ($n=13$) and persistent hospitalization ($n=9$) and with CCP clinical staff ($n=8$). Data were analyzed by a multi-disciplinary research team using inductive coding following the principles of General Thematic Analysis, and synthesized according to the Socio-ecological Model. All transcripts were coded by at least two team members; common themes were developed through discussion in face-to-face meetings.

RESULTS: Our analysis reveals three key themes. First, while patients tended to focus exclusively on individual-level factors (medical illness, self-care behaviors) influencing their hospitalization trajectory, providers and staff highlighted a more complex, broader range of factors at the individual (mental health, substance use), interpersonal (social support) and societal levels (transportation, housing security). Second, both intervention patients and providers described the importance of program-related factors (coordination of care, continuity of care) in decreasing hospitalization frequency; however, neither patients nor providers described program-level factors as contributing to persistent hospitalization. Third, while providers noted the importance of strong patient-provider relationships in decreasing hospitalizations, patients, regardless of hospitalization frequency, highly valued a positive and trusting relationship with their provider.

CONCLUSIONS: Programs seeking to reduce hospitalization among high cost, high need patients would benefit from emphasizing individual-level interventions for patient-based self-care while simultaneously addressing interpersonal, organizational and societal-level issues. Given the value that patients place on trusting, positive relationships with providers, patients may appreciate a model that prioritizes longitudinal provider continuity over the addition of an increased number of short-term providers and staff as is characteristic of many current care management programs.

UNDIAGNOSED CANCER RISK IN WOMEN UNDERGOING UTERINE ARTERY EMBOLIZATION FOR LEIOMYOMATA

Jackie V. Rodriguez¹; Rebecca Perkins¹; Jake Roberts Morgan¹; Susan O'Horo¹; Eung-Mi Lee¹; Benjamin Matthews¹; Michael K. Paasche-Orlow². ¹Boston University Medical Center, Boston, MA; ²Boston University, Boston, MA. (Control ID #3180355)

BACKGROUND: Symptomatic fibroids were historically treated with hysterectomy. More recently, minimally invasive options for treating fibroids while preserving the uterus have been developed. Uterine artery embolization (UAE) is one of the most common techniques, and allows up to 80% of women to successfully treat their symptoms without hysterectomy. However, retaining the uterus raises the possibility of missing an occult cancer. We examined the likelihood of subsequent gynecologic cancer development in women undergoing UAE.

METHODS: Administrative data from 2007 to 2016 were obtained from MarketScan, a database of diagnostic and treatment data for over 60 million commercially insured individuals in the US. Our analysis was limited to women at least 18 years of age without prior diagnosis of cancer who underwent UAE for treatment of leiomyomata and had on average 4.2 years of follow-up. Records were electronically queried for any inpatient or outpatient diagnostic or procedure codes (ICD-9, ICD-10, and CPT) related to uterine, cervical, tubal, or ovarian malignancies occurring after the procedure date through the end of follow-up. All codes for all charts identified through electronic query were then manually reviewed by a minimum of 3 coders, and discrepancies resolved by consensus. Diagnosis of cancer was defined as having at least two codes for gynecological malignancy submitted at least one week apart and/or

those with malignancy codes linked to tissue pathology results. Descriptive statistics were generated for the final study sample.

RESULTS: Between 2007 and 2016 20,575 women underwent UAE. Fifty-one women met our criteria for exhibiting cancer after undergoing UAE (37/51, 73% uterine cancer; 13/51, 25% ovarian cancer; and, 1/51, 2% cervical cancer). On average, women in our sample exhibited cancer within 2.3 years from the date of UAE with a standard deviation of ± 2.14 years and a range of 17 days to 7.8 years. We estimated that 1 in 403 (95% CI: 1 in 354 to 1 in 469) women undergoing UAE were at risk for developing a gynecological malignancy.

CONCLUSIONS: A small fraction of women undergoing UAE go on to develop gynecologic malignancies—the majority of which may have been avoided with hysterectomy. Women choosing uterine preservation with UAE for symptomatic fibroids should be aware that they might develop gynecologic malignancies in the future that could be prevented with hysterectomy.

UNLOCKING IMPLICIT BIAS: IMPLEMENTATION OF AN IMPLICIT BIAS WORKSHOP TO INCREASE RESIDENT PHYSICIAN AWARENESS OF PERSONAL IMPLICIT BIAS AND ITS EFFECT ON PATIENT CARE.

Vy Pham¹; Jabraan Pasha²; Jacob Murray¹. ¹OU-TU School of Community Medicine, Broken Arrow, OK; ²University of Oklahoma, Tulsa, OK. (Control ID #3178438)

BACKGROUND: Unconscious attitudes, also known as implicit biases are ubiquitous and their effects are wide-ranging. From something as seemingly insignificant as the clutching of a purse in lieu of a passerby to something of potential great consequence such as the lack of a surgical referral, the fingerprints of implicit bias are on many of the decisions we make. However hard it is to conceive, physicians' patient care decisions are not immune to the influence of unconscious beliefs and attitudes, and the data showing the effect of implicit bias on healthcare disparities is growing. Mirroring the societal disparities seen in the criminal justice system and workforce, in healthcare, the divide is just as great. Given the strong data linking implicit bias to healthcare disparities, it is very important to promote awareness of implicit bias in not only healthcare, but also healthcare providers as individuals. Our study looked to increase resident awareness and confidence in managing unconscious attitudes and beliefs that may be affecting patient care.

METHODS: Participants were 53 internal medicine, pediatric and family medicine residents at OU-TU School of Community Medicine. Between August 2018 and October 2018, during Academic Grand Rounds, participants attended a 90-minute implicit bias workshop. The interactive workshop looked to define implicit bias, demonstrate its origins and show its societal impact via lecture, hands-on activities and small group discussion. Via a 7-point Likert scale, a pre and post-workshop questionnaire measured participants' awareness of implicit bias and confidence in discovering and managing implicit attitudes. Data was analyzed via paired T-test analysis.

RESULTS: There was a mean increase of resident physicians' awareness of general, personal implicit bias (mean increase of 0.938, $P<.001$) and awareness of implicit bias toward patients (mean increase 0.698, $P<.001$). The results also reflected an increase in confidence in discovering personal implicit bias (mean increase 0.358, $P<.001$) and in management of implicit attitudes discovered about patients (mean increase 0.321, $P<.001$).

CONCLUSIONS: Our implicit bias workshop proved successful in increasing resident awareness of their vulnerability to unconscious attitudes and in increasing their confidence in recognizing and managing these same attitudes. Although increasing awareness, alone is not an adequate strategy for eliminating implicit bias and discriminatory practices that often follow, it has been shown to be effective in beginning to limit the unconscious bias. Paired with increased confidence in recognizing and managing these biases, this workshop appears to be a practical and effective first step towards combatting implicit bias.

UNMET MATERIAL AND SOCIAL NEEDS AND PRE-EXPOSURE PROPHYLAXIS (PrEP) FOR HIV PREVENTION ADOPTION: WHAT IS THE ASSOCIATION?

Tyler Andriano¹; Minia N. Rios Gutierrez²; Julia H. Arnsten¹; Viraj V. Patel^{1, 2}; Albert Einstein College of Medicine, Bronx, NY; ²Albert Einstein, Bronx, NY. (Control ID #3185146)

BACKGROUND: Young Black/Latinx men who have sex with men (YBLMSM) have the highest rates of new HIV infections but low uptake of pre-exposure prophylaxis (PrEP)-a highly effective HIV prevention tool. While unmet material/social needs are associated with low uptake of biomedical prevention for diverse conditions, this association is unknown for PrEP. We investigated the effects of unmet needs on PrEP adoption in a sample of YBLMSM.

METHODS: We surveyed HIV-negative YBLMSM aged 18-29 in New York City at high-risk of HIV (eg, recent STI) recruited online (n=143). Primary outcomes were 1) intention to use PrEP in the next month and 2) current PrEP use. We used the 17-item Family Resource Scale to measure unmet needs in three domains: basic (housing/food), health/social services, and economic, using a Likert scale ranged from 1=needs never met to 6=needs always met. For the full scale and each domain, we calculated the mean score and used bivariate logistic regression to test associations between outcomes and unmet needs (dichotomizing scores at having any unmet needs vs. needs always met).

RESULTS: Participants' mean age was 24.1(SD±3) years. Most identified as male (87%), gay (76%), and Non-Hispanic Black (63%) or Latinx/Hispanic (37%). Some (19%) had no health insurance and among the insured (79%), 42% had Medicaid. Of those not on PrEP, 48% (69/114) intended to start in the next month; 20% (29/143) were currently on PrEP. In the full scale, 75 participants (52%) had some unmet needs. Among the three domains, 36%(n=52) had unmet basic needs, 59%(n=85) had unmet health/social needs, and 64%(n=92) had unmet economic needs. In bivariate analysis of the scale, participants were more likely to intend to use PrEP if they had more unmet needs in the full scale ($p=0.03$), basic ($p=0.01$), and economic (0.04) domains. Yet, for health/social needs, regardless of the level of unmet needs, participants had similar intentions to use PrEP. Likewise, regardless of unmet need levels overall or in each domain, current PrEP use was similar.

CONCLUSIONS: A high prevalence of unmet material/social needs existed among YBLMSM. Those with more unmet needs had a higher intention to use PrEP, but similar rates of PrEP use as those with met needs. Given the significant interest in PrEP use, reaching YBLMSM with greater unmet needs may help improve PrEP uptake.

| Table. Association of PrEP intention and current PrEP use with unmet needs. | | | |
|--|-----------|-----------|------------------|
| | Mean (SD) | Mean (SD) | OR (95% CI) |
| Intending to take PrEP in next 30 days (N=69) | 4.5 (1.4) | 5.0 (1.0) | 0.7 (0.5, 0.9)* |

UNMET MENTAL HEALTH NEED AMONG CHINESE AND LATINO PATIENTS IN PRIMARY CARE: THE INTERSECTION BETWEEN LANGUAGE, ETHNICITY, AND GENDER

Maria E. Garcia¹; Ladson Hinton³; Steven Gregorich¹; Jennifer Livaudais-Toman¹; Celia P. Kaplan^{2, 1}; Leah S. Karliner^{4, 1}. ¹University of California, San Francisco, Greenwich, CT; ²University of California San Francisco, San Francisco, CA; ³University of California, Davis, Sacramento, CA; ⁴UCSF, San Francisco, CA. (Control ID #3186068)

BACKGROUND: Although racial and ethnic minorities are more likely than whites to seek care for mental health symptoms in primary care, they are less likely to receive depression treatment. While prior studies have studied the independent contributions of race/ethnicity, gender and language on mental health disparities, the intersecting effects of these factors are unknown. This study examines the intersecting contributions of these factors to unmet mental health need among Chinese and Latino patients in primary care.

METHODS: As part of a study of communication and health outcomes in primary care, patients were interviewed via telephone in English, Chinese, or Spanish within 1 week of a visit. Two mental health outcomes were assessed: whether in the past year the patient 1) perceived a need for help with emotional or mental health symptoms ('mental health need'), and 2) had seen a primary care physician or a mental health professional for these symptoms. Among those who reported 'mental health need', we defined 'unmet mental health need' as those who had not used services for their symptoms. Main predictor variables included English proficiency (English proficient [EP] vs limited English proficient [LEP]), race/ethnicity, and gender. Descriptive statistics and chi-square tests estimated the prevalence of outcomes and examined differences by English proficiency and race/ethnicity. Regression models explored interaction effects among English proficiency, race/ethnicity, and gender on the 2 mental health outcomes, controlling for additional patient characteristics.

RESULTS: Among the 1149 participants (62% women; 262 Chinese EP, 532 Chinese LEP, 172 Latino EP and 183 Latino LEP), 33% reported mental health need. Women were more likely to report need than men (aOR 1.35, 1.03-1.79) regardless of race/ethnicity or English proficiency. There was a significant interaction between race/ethnicity and language proficiency. Among Chinese participants, those with LEP were more likely than those with EP to report mental health need (aOR 2.55, 95% CI 1.73-3.76). While there was a trend in the opposite direction among Latinos, it was not statistically significant (aOR 0.64, 0.40-1.04). Among patients reporting mental health need, 41% had unmet mental health need. While there were no racial/ethnic differences in unmet need, there was a significant interaction between English proficiency and gender. Men with LEP, compared to those with EP, were more likely to have unmet need regardless of race/ethnicity (aOR 2.53, 1.06-6.04).

CONCLUSIONS: In a population of Chinese or Latino primary care patients, we found both high levels of mental health symptoms and unmet mental health need. Our results affirm the importance of universal depression screening that is inclusive of all populations and suggest that attention to intersecting patient characteristics can help identify those at highest risk of untreated symptoms (such as men with LEP) who would benefit from targeted interventions to ensure linkage to treatment.

US MEDICAL SCHOOL APPLICANT EXPERIENCES OF BIAS ON THE INTERVIEW TRAIL

Avik Chatterjee^{1, 2}; Charlotte Greif³; Robert Witzburg⁴; Lori Henault⁵; Kristen Goodell⁴; Michael K. Paasche-Orlow⁶. ¹Harvard Medical School, Cambridge, MA; ²Boston Health Care for the Homeless Program, Boston, MA; ³UT Southwestern, Dallas, TX; ⁴Boston University School of Medicine, Boston, MA; ⁵Boston Medical Center, Boston, MA; ⁶Boston University, Boston, MA. (Control ID #3169424)

BACKGROUND: A diverse physician workforce will be necessary to meet the needs of the United States population, but US medical schools

have been unsuccessful in attracting a diverse student body. Implicit bias is pervasive in medicine, including potentially in the medical school admissions process.

METHODS: We invited all 2018-2019 applicants who interviewed at one US medical school to complete the validated 8-item Everyday Discrimination Scale (EDS) asking about experiences of bias during their medical school interview experiences at any institution where they had interviewed. The survey asked participants the number of schools at which they had interviewed, and assessed covariates including their place of birth, race, ethnicity, native language, religious affiliation, sexual orientation, gender identity, disability status, veteran status and socioeconomic status.

RESULTS: Three hundred forty-seven (30%) of 1175 interviewees completed the survey. Respondents reported having had a median of three interviews (range 1-16), and had a mean age of 23 (range 19-32). One hundred ninety (54.8%) respondents reported White/Caucasian race, 83 (23.9%) reported Asian race, 31 (9.0%) reported mixed race, and 14 (4.0%) reported Black or African-American race. Sixty-seven (19.3%) reported Latino, Hispanic or Spanish ethnicity. One hundred ninety-eight (57.1%) reported female gender and 144 (41.5%) were male; 296 (85.3%) reported their sexuality as straight. Most respondents (334, 96.3%) reported having no disability, and 60 (17.3%) reported being from socially disadvantaged backgrounds. Participant demographics matching those of the broader interviewee pool. Seventy-two (20.7%) respondents answered yes to one or more items on the EDS across their interview experiences. Gender, age, race, national origin, religion, and sexual orientation were all sources of discrimination. Among those responding affirmatively to a question on the EDS, 35% reported experiencing bias at more than one institution. Those reporting bias had completed more interviews (5.2 vs. 3.9, P<0.05) and were more likely to be Latino (30.6% vs. 16.4%, P<0.05). Two (14.3%) Black/African-American respondents, 22 (33%) Latino respondents, and 44 (22%) women answered yes to at least one question on the EDS. Only three (4%) reported the incident of bias to the medical school where it occurred—many participants reported telling friends or family members (68%) or doing nothing (30%).

CONCLUSIONS: One in five medical school applicants described experiencing bias during their interview process but very few reported such incidents. Latino ethnicity was associated with a higher likelihood of reporting bias, however, many of our subgroups were too small to allow meaningful subgroup analyses. Further work exploring applicant experiences of bias, how such experiences may affect medical school student body diversity, and how to decrease the frequency of incidents of bias is warranted.

USABILITY OF M-HEALTH APPLICATIONS FOR SAFETY NET POPULATIONS

Shreya Sharma¹; Rebecca G. Mishuris¹; Katherine Gergen-Barnett¹; Jack Maypole²
¹Boston University School of Medicine, Boston, MA; ²Boston University School Of Medicine, Boston, MA. (Control ID #3183095)

BACKGROUND: The number of smartphone users among diverse, low-income communities is growing in the United States. As a result, mobile applications ("apps") are serving as an accessible means for health management. Unfortunately, little is known about how to evaluate health related apps or their usability features for diverse, low-income populations. We sought to define mobile health app features important for the needs of these populations and identify apps in the areas of chronic disease management and medication adherence that best included these features.

METHODS: In June 2018, online databases (PubMed, Embase) were searched to identify articles related to evaluating the usability of mobile applications in health and wellness. App domains evaluated in past studies were assessed to create a list of domains for rating apps relevant to diverse, low-income populations in this research study (Sarkar, Arnhold, Gordon, Stephan, Stowell, Vilardaga, Vu, Wen). The domains were categorized as: Usability, Population focus, Technology, and Clinical Impact. Each domain was given a weight related to importance in the

usefulness of a mobile application by independent coders (RGM,KGB,JM) and a reviewer (SS) then adjudicated these weights. Ten apps in smoking cessation, diabetes management, and medication adherence were chosen to be rated by a coder (SS) in each domain with a score of 0 to 3. Zero was assigned if the specific domain was unavailable, and 3 was assigned if the domain had high usability for the target population. The weight of each domain was incorporated into the domain's rating; the weighted scores across all domains were added to assign each app a final overall score. The apps with the highest overall scores were considered by a local patient advisory board for final recommendation of patient use.

RESULTS: The most important domains for diverse, low income communities include:languages available, literacy, graphics, multimedia, usability, patient centeredness, data entry mode, data exportability, cost, evidence based content, platform, connectivity requirement, social support provided, cultural sensitivity, privacy, updates, and a message or reminder function. Domains such as literacy and language had greater utility value than privacy and data entry. The top weight ranked apps for smoking cessation were Smoke Free- Quit Smoking Now and QuitNow! with an average score of 149.5/201 and 156/201;the apps for diabetes management were Glucosio and MyNetDiary with an average of 147/201 and 146/201;the apps for medication adherence were Medisafe and MyMeds with an average of 137.5/201 and 126/201.

CONCLUSIONS: Our research has shown that app domains relevant to low SES populations can be identified and used to rate and validate apps which specifically address these populations' needs. The next steps of this study are to implement the suite of apps in primary care clinics as "prescriptions" for patients and to determine uptake and impact of these specific mobile apps on health-related behaviors.

USE OF A NATURAL LANGUAGE PROCESSING ALGORITHM TO PREDICT READMISSIONS AT A VETERANS AFFAIRS HOSPITAL

Ryan D. Schulteis²; Joseph E. Lucas³; Joel C. Boggan¹; David L. Sime².
¹Duke University Health System, Durham, NC; ²Durham VAMC and Duke University, Durham, NC; ³Duke University, Durham, NC. (Control ID #3186428)

BACKGROUND: Health systems have sought to predict hospital readmissions, with the hope of reducing readmissions through targeted interventions. The Department of Veterans Affairs (VA) developed an independently validated risk calculator with c-statistic of 0.65 used locally at Durham VA Medical Center (DVAMC) since 2010. We hypothesized including documentation from resident discharge summaries in a natural language processing (NLP) algorithm would improve the predictive accuracy for readmissions.

METHODS: All medicine discharge summaries over two academic years from 7/1/2016 through 6/30/2018 that included a calculated risk of readmission using the VA readmission risk calculator were collected from the VA electronic health record. We then extracted the calculated risk percentage of subsequent readmission within 30 days included within the summary text and excluded patients readmitted in less than 24 hours. Readmission events then were defined as subsequent admission to DVAMC within 30 days. An ROC curve was constructed to test the discriminatory power of predicted readmission risk from the calculator. For NLP, the set of discharge summaries was split into training and test sets. The text of each discharge summary was preprocessed and converted to a list of integer tokens and subsequently passed to a neural network. The network then outputs another predicted probability of readmission based upon the encoding of the discharge summary text - the "NLP Readmission Probability". We measured the predictive power of this NLP Readmission Probability with an additional ROC curve. Finally, logistic regression was used to add NLP prediction to the previous calculated risk to test for improved predictive ability.

RESULTS: Overall, 4,306 discharge summaries were collected over the 2-year period. The performance of the readmission calculator was similar to previous validation with a c-statistic of 0.62. A vocabulary of all words occurring more than once across all summaries was used for NLP, for a total of 31,283 words. Subsequently, 2000 summaries were used to train the neural network iteratively, while 871 were used for validation. An additional 1435 summaries served as the test set. The accuracy of the NLP model for readmission was 82.3%, which, given an overall readmission rate of 17.5%, corresponded to a c-statistic of 0.56. When combined with the calculated risk in a logistic regression model, the NLP algorithm did not add discriminatory power, with combined AUC of 0.62.

CONCLUSIONS: Natural language processing using text from medicine discharge summaries did not provide additional discriminatory power when compared to a previously validated discharge risk prediction tool. The NLP algorithm offered little discriminatory power when used alone, with a AUC of 0.56. As many hyperparameters can be configured for NLP, we cannot rule out that a different combination would have created a model with higher predictive power.

USE OF DIRECT-TO-CONSUMER TELEMEDICINE TO ACCESS MENTAL HEALTH SERVICES

Jessica Hohman¹; Kathryn A. Martinez¹; Mark N. Rood²; Susannah L. Rose¹; Michael B. Rothberg¹. ¹Cleveland Clinic, Cleveland, OH; ²Cleveland Clinic Foundation, Chagrin Falls, OH. (Control ID #3184265)

BACKGROUND: Significant barriers to accessing mental health services exist, including limited insurance coverage, high costs, provider shortages, and long wait times. Direct-to-consumer (DTC) telemedicine connects patients and providers via mobile/web applications 24 hours a day, and insurance is accepted but not required. As such, DTC telemedicine has been proposed as a way to increase access to care for many common conditions, but little is known about its use for mental health care. The objective of this study was to characterize use of a large nationwide DTC telemedicine platform for mental health services.

METHODS: This is a retrospective cross-sectional study of encounters for mental health diagnoses conducted on the AmericanWell DTC telemedicine platform between July 2016 and July 2018. Mental health diagnoses were identified via ICD10-CM codes associated with encounters, and prescriptions were identified via National Drug Codes. Encounter measures included time of day, wait time, visit length, prescription outcome, and referral receipt. Patient measures included age, gender, whether they used a coupon for free or reduced-cost care, and whether they provided insurance information. Patient satisfaction was ascertained at the conclusion of the encounter on scales of 0 to 5 stars. Provider characteristics included type (physician versus not) and specialty.

RESULTS: We examined 19,283 mental health encounters between 6,710 patients and 1,067 providers. Fifty-nine percent of patients were female, mean age was 35 years, 28.4% did not provide insurance information, and 11.8% used a coupon for free or reduced-cost care. Mean wait time was 5.6 minutes. Over 70% of encounters were for anxiety or depression, followed by bipolar disorder (6%), ADHD (4%), nicotine use disorders (2%), alcohol use disorders (2%), and sleep disorders (2%). Schizophrenia and schizoaffective disorders accounted for <1% of visits. Over half of encounters were with a therapist, psychologist, or licensed social worker; 20% were with primary care providers (PCPs) and 20% with psychiatrists. Two percent resulted in referrals. Visit duration varied by provider type; median visit length with PCPs was 6 minutes vs. 16 minutes with psychiatrists and 47 minutes with therapists. Psychiatrists prescribed medication at a higher rate than PCPs (75% vs. 70% of encounters). Patients reported high satisfaction (4.9/5) across all conditions.

CONCLUSIONS: DTC telemedicine provides access to counseling and pharmacotherapy for a diverse range of common mental health conditions, particularly for younger users with mood disorders or ADHD, but the number of visits for other conditions was small. Most patients received prescriptions, and overall satisfaction was high. With growth, DTC telemedicine might facilitate care for patients in underserved areas.

USE OF INTERPRETERS FOR LIMITED ENGLISH PROFICIENCY PATIENTS WITH HIP FRACTURE

Jon Mong¹; Shail Rawal¹; Peter Cram²; Khalid Syed¹. ¹University of Toronto, Toronto, ON, Canada; ²University of Iowa, Iowa City, IA, USA. (Control ID #3179311)

BACKGROUND: Informed consent (IC) is central to patient autonomy. Obtaining IC is difficult in the best of cases, and even more complex in patients with limited English proficiency (LEP). Professional interpreter use is standard of care when communicating with patients with LEP in Canada. Hip fractures are common and require urgent surgical repair for optimal outcomes, but also require that physicians obtain IC before surgery. Thus, obtaining IC in LEP patients with hip fracture could be challenging. We examined interpreter use in obtaining IC for LEP patients with hip fracture in an urban Canadian teaching hospital in a city where 48% of patients have a non-English mother tongue.

METHODS: We identified all patients admitted with hip fracture between January 1 2015-January 1 2018 to Toronto Western Hospital. We reviewed the electronic health record and selected all patients for whom English was not their preferred language. We excluded: 1) patients who had non-operative management of their hip fractures with no consent form; 2) patients for whom chart documentation was incomplete, precluding us from evaluating the measures described below. Using a standardized data abstraction tool we collected information on: whether our hospital consent form was signed; if the consent form was signed by the patient or a substitute decision maker (SDM); if there was documentation of interpreter use on the consent form, and if so, whether the interpreter was a professional employed by the hospital or ad-hoc (e.g., family member or hospital staff); and if an SDM signed the consent document, whether there was documentation that the patient was not capable (defined as documentation of: dementia; cognitive impairment; or delirium as measured by nurse administered Confusion Assessment Method). 10% of charts were independently reviewed in duplicate.

RESULTS: Among 553 patients with hip fracture, we identified 134 (24%) as LEP. 127 patients were included in the final analysis. Among those with LEP, 88 (69%) were female (mean age 84 years). The most common languages were Portuguese (37 patients), Italian (33 patients), and Cantonese (9 patients). Among those who were LEP, 57 (45%) signed their own consent forms, while 70 (55%) had an SDM sign on their behalf. Of the 57 LEP patients who signed their own consent, 33 (58%) lacked evidence of interpreter use, while 24 (42%) had documented interpreter use. Of the 24 patients who had documented interpreter use, 4 (17%) utilized a professional interpreter, while 20 (83%) used ad-hoc interpreters. Of the 70 patients who had an SDM sign on their behalf, 11 (16%) did not have documentation of lack of capacity.

CONCLUSIONS: In a Canadian teaching hospital serving a multicultural urban population we found significant gaps in utilization of interpreters for obtaining IC for patients with hip fracture.

USE OF SOCIAL MEDIA TO IMPROVE CARDIOVASCULAR RISK FACTOR MODIFICATION IN THE CARDIOLOGY OUTPATIENT SETTING

Nina Liu; Zubiya Syed; Allan Chen. University of South Florida, Tampa, FL. (Control ID #3138724)

BACKGROUND: Social media has become omnipresent and is a rapidly growing information source with widespread potential for patient education. There are no studies that examine the use of social media to improve cardiovascular risk factor modification. To address this gap, we studied the use of a social media educational program in an outpatient cardiology setting to improve patient knowledge and behavior related to cardiovascular health.

METHODS: Patients were prospectively enrolled at a single tertiary care center as part of routine outpatient visits. A baseline survey was given that

assessed their knowledge and behaviors related to diet (including the Rapid Eating Assessment for Participants (REAPS) survey), exercise, risk factors and medication adherence. Patients elected to receive regular cardiovascular health related educational tips and resources either through a private Facebook group or email. The same survey was given after the follow-up period to assess changes in behavior and knowledge.

RESULTS: 51 patients were enrolled with mean follow-up period of 7.9 weeks. 31.4% were male with mean age of 55.8 years. There was a trend towards significant improvement in the REAPS score from baseline to follow-up ($p=0.05$). Significant improvement was seen in knowledge related to weight/body mass index ($p=0.04$). In subgroup analyses, males rated their importance of personal exercise/fitness significantly higher after the follow-up period ($p=0.02$). Patients aged 60 years and older demonstrated a significant reduction from 5.7 to 3.6 hours/day of sitting/reclining from baseline to follow-up ($p=0.01$). No change was seen in medication adherence. At follow-up, 100% of participants reported learning from the program, 93% reported perceived improvement in health, and 96% stated they would continue the program if available.

CONCLUSIONS: As the first of its kind, this study demonstrated that an educational program via a social media platform may improve patient behavior and knowledge related to risk factor modification in an outpatient cardiology setting. Further studies are needed to evaluate the potential of this adjunctive tool that requires little additional cost and resources.

USER-CENTERED DESIGN AND USABILITY OF AN ELECTRONIC TOOL TO IMPROVE DEPRESSION TREATMENT IN PATIENTS WITH CORONARY HEART DISEASE.

Jennifer Mizhquiri Barbecho¹; Rachel Monane¹; Martin McElhiney³; Luis Blanco¹; Fereshte N. Kharazmi¹; Emily M. Callanan¹; Monica Polanco²; Drew Rabidoux²; Ian Kronish¹; Siqin Ye¹; Nathalie Moise¹. ¹Columbia University Medical Center, Brooklyn, NY; ²New York Presbyterian, New York, NY; ³Columbia University Medical Center, New York, NY. (Control ID #3182556)

BACKGROUND: Depressive symptoms in coronary heart disease (CHD) patients are common and associated with recurrent cardiovascular disease events and mortality. However, only 30% of depressed CHD patients are treated. Informed by behavior change theory and a user-centered design process, we explored treatment barriers and designed and conducted usability testing of a web-based tablet-delivered tool to enhance depression screening, referral and treatment initiation in CHD patients.

METHODS: An implementation team of physicians, patients, nurses, and administrators identified system requirements based on a national survey of 1500 CHD patients and then designed and revised a patient-facing tablet interface of depression screening Patient Health Questionnaire-9 (PHQ-9), preference and barriers assessment, and video-assisted patient activation. We recruited 10 patients with documented CHD from hospital discharge and clinic codes to conduct usability testing. A research coordinator observed, recorded and guided participants through a usability protocol in which participants completed goal-oriented tasks and a think-aloud protocol that assessed depression treatment attitudes and barriers and satisfaction with the tool using retrospective interview probing techniques. We employed descriptive statistics for quantitative responses and content analysis to code qualitative responses for acceptability and themes while iteratively refining the tool.

RESULTS: The average age of 10 participants was 62.7 ± 7.5 years; 60% were male, 50% Hispanic/Latino, 30% Black/African American; 60% had at least mildly elevated depressive symptoms. All participants found the tool highly acceptable. Treatment barriers included stigma/privacy, gender/cultural norms, fear of medications, lack of knowledge, and opportunities (transportation, insurance, time). Half remarked that worry, fear of death and changes in lifestyle, all exacerbated by fear-laden patient-physician communication, contributed to depressive symptoms. Tool facilitators included provision of information on the link between depression and heart disease

and non-pharmacologic treatment options (e. g., cardiac rehab), normalization, depression treatment success stories, personalization, as well as coupling the tool with pamphlets and physician-initiated discussion about stress. The think-aloud protocol informed iterative updates to the tool, including addition of percent completion indicators, voiceover functionality, iconography, tailoring, and decision support.

CONCLUSIONS: We demonstrate how a multidisciplinary implementation team can use a theory-informed user-centered design process to yield a better understanding of participants' technology preferences. We contribute a novel interface to enhance CHD patient engagement in depression treatment. We will next test the effectiveness of this tool on depression screening and treatment in CHD patients in a stepped-wedge trial across 8 cardiology and primary care clinics.

USING BILLING DATA TO COMPARE MEDICAL NEEDS AND UTILIZATION COSTS OF HOMELESS VS. NON-HOMELESS PATIENTS

Benjamin Bovell-Ammon¹; Allison Bovell-Ammon¹; David Ko¹; Christine A. Pace^{2,3}; Thea James³; Megan Sandel¹. ¹Boston Medical Center, Boston, MA; ²Boston University School of Medicine, Boston, MA; ³Boston Medical Center, Cambridge, MA. (Control ID #3185808)

BACKGROUND: Homelessness is associated with adverse health outcomes across the life course and complicates effective delivery of medical and behavioral health services. The growing share of value-based payment models increasingly incentivizes and creates opportunities for hospitals & health systems to identify and intervene upon social determinants of health, including homelessness. The differences in healthcare utilization and costs between homeless patients vs. low-income non-homeless patients and the extent to which such differences might be impactful is understudied. This study aims to develop an easily replicable method for comparing prevalent health conditions and costs between homeless and non-homeless Medicaid-covered patients in a hospital's billing data.

METHODS: Hospital billing data from Boston Medical Center (BMC), New England's largest safety-net hospital, were acquired for patients in the Boston Accountable Care Organization (BACO, a Medicaid ACO) for any ambulatory, emergency department, and inpatient care at BMC between September 1, 2017-August 31, 2018. Patients were identified as homeless if they met at least one of the following criteria: had the ICD-10 code for homelessness (Z.59.0) in their billing record, receive primary care at Boston Healthcare for the Homeless, listed their primary address as a known homeless shelter or BMC. Socio-demographic factors, diagnoses, and costs were characterized and compared between homeless and non-homeless patients.

RESULTS: Among 20,640 patients enrolled in BACO who received health care services at BMC, 13.7% were homeless. Compared to non-homeless patients, homeless patients in the study did not differ in age (avg 41.6y, s.d. 13.3y), but they were significantly ($p<0.01$) more likely to be male (61.9% vs. 37.3%), white (38.1% vs 19.8%), and single/never married (80.9% vs 72.3%) and had significantly ($p<0.01$) higher rates of vascular disease (30.9% vs 18%), CHF (4.7% vs 2%), diabetes (16.3% vs 14.6%), COPD (10.3% vs 3.6%), CKD (7.8% vs 5.9%), schizophrenia (13% vs 3.3%), bipolar disorder (19.5 vs 5.2%), and substance use disorder (65.8% vs 18.7%). Homeless patients had on average \$28,657 of health care costs per patient in the 12 month period while non-homeless patients had \$14,566 ($p<0.01$).

CONCLUSIONS: Among patients in a Medicaid ACO that received services at a major urban safety-net hospital, homeless patients had higher rates of major medical and behavioral health conditions and greater utilization of high cost services. This study demonstrates an easily replicable method by which a health care organization can define the scope of homelessness in their patient population and begin to estimate the excess health care costs that might be attributable to homelessness. Research that may help identify opportunities for developing interventions to stabilize this population, decrease cost and improve clinical outcomes.

USING COMMUNITY ENGAGEMENT TO ADAPT AND IMPLEMENT AN EVIDENCE-BASED CVD INTERVENTION IN RURAL AFRICAN AMERICAN COMMUNITIES

Gaurav Dave^{1, 1}; Stephanie Hoover¹; Leah Frerichs^{2, 1}; Madeline Hamilton¹; Kiana Bess^{1, 3}; Hilary R. Jessup¹; Brenda Boone⁴; Mysha Wynn⁵; Shirley McFarlin⁴; Project GRACE Steering Committee⁶; Giselle M. Corbie-Smith^{1, 1}. ¹University of North Carolina School of Medicine, Chapel Hill, NC; ²Gillings School of Global Public Health, Chapel Hill, NC; ³University of Michigan, Ann Arbor, MI; ⁴James McFarlin Community Development, Rocky Mount, NC; ⁵Project Momentum Inc., Rocky Mount, NC; ⁶Project GRACE, Rocky Mount, NC. (Control ID #3184892)

BACKGROUND: Well known racial and geographic disparities in cardiovascular (CV) risk have led to terms such as a "stroke belt" and "mortality penalty" to describe the southeast US. While there has been improved overall CV mortality, these improvements have not been enjoyed by rural African Americans (AAs); in part because interventions have not addressed unique contextual and social factors that drive health disparities in rural minority communities. Using a Community-Based Participatory Research approach, we adapted PREMIER to Heart Matters, an evidence-based intervention to reduce CV risk, for rural AA communities in North Carolina. This abstract presents clinical and behavioral outcomes of a randomized controlled study at 6 months—the intensive intervention period.

METHODS: We recruited 143 AAs who resided in Edgecombe or Nash counties, had at least one risk factor for CVD, were 21 years or older, and consented to participate. Participants were recruited in clusters, each cluster representing a community- or faith-based organization, that were randomized into intervention ($n=71$) and 6-month delayed intervention control groups ($n=72$). Data on clinical measures (e.g. blood pressure (BP)), self-reported behaviors (e.g. physical activity) and demographics were collected at baseline, 6, and 12 months. Multivariate mixed model and regression analyses were used to estimate treatment effects. We controlled for clustering, age, and use of medications. The primary outcomes are change in systolic BP or diastolic BP, combined hypertension status, BMI, and HbA1c. The secondary outcomes are dietary and physical activity self-efficacy, social support, and vigorous physical activity.

RESULTS: Approximately three-fourths (72.7%, $n=104$) of the sample were female, with a mean age of 57.3 years. We found a statistically significant difference in BP status in the intervention group compared to the control group ($=0.38$, 95% CI [0.05, 0.71]) at 6 months. While diastolic BP increased in both groups, the mean difference from baseline was statistically significant between the intervention (1.93mmHg) and control groups (5.9mmHg) at 6 months ($p=0.01$). Self-efficacy to reduce salt increased significantly in the intervention group ($=0.31$, 95% CI [0.09, 0.53]). Similarly, the intervention group reported increased vigorous physical activity and increased social support for physical activity by friends and families ($p<0.05$).

CONCLUSIONS: The improvements in BP, reported physical activity, and sodium intake represent a meaningful reduction in major risk factors for CVD. More importantly, these findings build evidence regarding the importance of adapted interventions to address the complex aggregate of risk factors that contribute to CVD in rural minority communities. This work advances research on the implementation of evidence-based CVD interventions through community engagement.

USING EXPERIENCE SAMPLING METHOD TO INVESTIGATE ENGAGEMENT OF TALENTED MINORITY URBAN YOUTH IN SCIENTIFIC RESEARCH PIPELINE PROGRAMS

Jhonatan Marte⁴; John Cursio¹; Samantha Ngooi²; Laura Ruth Venable³; Christianah Ogunleye⁴; Tyler Raclin³; Barbara Schneider⁵; David Meltzer²; Vineet M. Arora⁶. ¹The University of Chicago, Chicago, IL; ²University of Chicago, Chicago, IL; ³University of Chicago, Chicago,

IL; ⁴University of Chicago Pritzker School of Medicine, Chicago, IL; ⁵Michigan State University, East Lansing, MI; ⁶University of Chicago Medical Center, Chicago, IL. (Control ID #3184270)

BACKGROUND: Pipeline programs that promote equity by engaging minority youth to consider scientific careers are increasing, but novel evidence-based approaches for program evaluation are lacking. Experience Sampling Method (ESM) is a valid method to measure real-time engagement of teens in science classrooms that has not been applied to pipeline programs. We used ESM to compare engagement of minority youth participating in a hospital-based clinical research experience versus a traditional science program, and examine whether an ESM measure of engagement is associated with perceiving one's activities as related to future goals.

METHODS: Talented Chicago high school juniors were blocked randomized by sex and race to either the 6-week hospital-based program or a traditional science program. The hospital program included realistic research activities (patient interviews, chart reviews, team meetings). The traditional program offered lectures, labs, and field trips to science museums. Students were given watches that alerted them to complete a 40-item ESM survey from the Sloan Study of Youth and Social Development. Students were alerted 5 times per day, Monday through Friday, during weeks 1 and 3. The survey asked what students were doing and thinking (open-ended) and 3 Likert items that constitute an "optimal learning moment" (OLM), a valid ESM measure of engagement. We used a hierarchical linear model to test associations between program group and OLMs, controlling for year, week, gender, and race. We also examined the association between OLMs and perceiving one's activity as important to future goals.

RESULTS: From 2005-2015, we randomized 195 students to either the hospital (108) or traditional program (87) who completed 66.7% of alerts (7820/11680). Two-thirds were URM in medicine; over half (62%) were female. Race, ethnicity, and gender did not differ significantly between groups. OLMs comprised 27.2% of alerts. In 54% of alerts, students reported being engaged in activities related to future goals. Assignment to the hospital-based program was associated with lower odds of OLMs during week 1 (OR=0.50, 95% CI=0.31-0.76, $p<0.001$), but with greater odds in week 3 (OR=1.29, 95% CI=1.01-1.63, $p=0.036$). Males had greater odds of OLMs (OR=1.52, 95% CI=0.74-1.46, $p=0.015$) and Hispanics had lower odds of OLMs (OR=0.52, 95% CI=0.68-1.98, $p=0.014$). Regardless, OLMs were strongly associated with perceiving activity as important to future goals (OR=4.86, 95% CI=4.17-5.66, $p<0.001$).

CONCLUSIONS: Although engagement was initially lower, students in the hospital-based research program were more engaged by week 3, highlighting the need for minority youth to acclimate to research environments. Efforts to improve engagement for females and Hispanics are warranted. Given that an ESM measure of engagement is associated with perceiving activities as important to future goals, ESM can be a relevant short-term outcome for evaluating pipeline programs.

USING HUMAN-CENTERED DESIGN TO DEVELOP PRACTICAL, EVIDENCE-BASED INTERVENTIONS IN PRIMARY CARE

Dani L. Zions¹; Cati Brown-Johnson¹; Nadia Safaeinili¹; Jonathan G. Shaw¹; Lucie Richter²; Svava M. Atladóttir²; Donna M. Zulman^{1, 3}.

¹Stanford University, Stanford, CA; ²Future Medical Systems, Sunnyvale, CA; ³VA Palo Alto Health Care System, Menlo Park, CA. (Control ID #3185534)

BACKGROUND: Though many are working to address the wellness crisis resulting in record levels of physician burnout and patient dissatisfaction, it still takes >15 years for evidence-based innovations to integrate into practice. We sought to determine whether an evidence-based Human-Centered Design (HCD) methodology could be used to rapidly design a scalable solution to enhance provider presence and improve connection with patients.

METHODS: HCD is a flexible, complex process utilizing evidence, intuition, and rapid, iterative prototyping to develop creative products and interventions. To approximate HCD in an academic setting while maintaining rigorous scientific standards, we leveraged a 3-stage HCD approach: Stage 1. Inspiration: a) Secondary research via a systematic review of interpersonal interventions in health care (n=77 studies); b) interviews and observations of diverse primary care encounters (29 observations across 3 clinics); c) interviews with professionals in non-medical fields to provide analogous inspiration (n=30). Stage 2. Ideation: a) Delphi panel of 14 national experts to gather additional input on our "inspiration" output; b) journey mapping and framework development to scope design principles and opportunities (e.g., daily clinic flow from patient/provider lens); c) co-creation sessions with 10 physicians to develop initial prototypes. Stage 3. Implementation: a) User feedback sessions with diverse providers inside and outside of clinic to test the feasibility and acceptability of preliminary intervention designs; b) live prototyping in varied clinics to assess implementation and maintenance metrics.

RESULTS: Over 16 months, we completed preliminary design work to develop an intervention focused on primary care. Stage 1 yielded evidence-based practices that influence patient and clinician experience. Provider interviews highlighted the importance of consistent meaningful connections with patients without extending clinic visit time. Interviews with non-medical professionals illustrated universal approaches to protecting joy of practice in intense interpersonal interactions. Stage 2 highlighted key time points where intervening might positively impact connection in outpatient care, while also accommodating acutely busy periods such as just before a provider enters the room. It also surfaced the lack of opportunity for providers to exchange strategies to connect with patients. In Stage 3, HCD permitted ultra-rapid cycles of creation, piloting, evaluation, and iteration, surfacing ideas and determining feasibility of design prototypes with physician stakeholders in a matter of weeks.

CONCLUSIONS: We found that a design approach combining HCD methodology with a systematic literature review and Delphi process resulted in practical, acceptable, evidence-based intervention prototypes in less than 18 months. In the final stage of this project, the pilot intervention will be implemented and evaluated across multiple settings to determine the effect on patient and clinician experience.

USING SIGNATURE INFORMED CONSENT TO IMPROVE PRESCRIBING LONG-TERM OPIOID THERAPY FOR CANCER PAIN: PERSPECTIVES OF PATIENTS AND INTERDISCIPLINARY PROVIDERS

Soraya Fereydooni^{2, 1}; Karleen Giannitrapani^{2, 9}; Azin Azarfarr²; Peter Glassman^{3, 7}; Maria J. Silveira^{4, 8}; Amanda Midboe⁵; Maria Zenoni^{6, 10}; Robert Pearlman^{11, 12}; William Becker^{6, 10}; Karl Lorenz^{2, 9}. ¹Stanford University, Stanford, CA; ²VA Palo Alto Health Care System, San Jose, CA; ³VA Greater Los Angeles HCS, Los Angeles, CA; ⁴Ann Arbor VAMC HSRD, Ann Arbor, MI; ⁵VA Palo Alto Health Care System, Menlo Park, CA; ⁶VA Connecticut Healthcare System, West Haven, CT; ⁷University of California Los Angeles, Los Angeles, CA; ⁸University of Michigan, Ann Arbor, MI; ⁹Stanford University School of Medicine, Stanford, CA; ¹⁰Yale School of Medicine, New Haven, CT; ¹¹Seattle VA Puget Sound Health Care System, Seattle, WA; ¹²University of Washington, Seattle, WA. (Control ID #3185984)

BACKGROUND: Long-term opioids therapy (LTOT) for cancer pain is accompanied with numerous potential risks. As cancer survival becomes more common, the extension of written signature informed consent (SIC) for LTOT gains relevance. Our objective is to understand provider and patient perspectives on using SIC for LTOT in cancer patients.

METHODS: *Design:* Semi-structured interviews. *Population:* 20 interdisciplinary providers (primary care providers including general internists, oncologists, and advanced practice nurses) and 20 patients from two academically-affiliated Veteran Health Administration Medical

Centers. *Analysis:* Using *a priori* code from the bioethics literature, we employed deductive content analysis to understand provider perspectives and inductive constant comparison to understand patient perspectives.

RESULTS: Providers believed: 1) Autonomy: SIC is an educational tool "to get the patient involved in the decision." However, it may be perceived as a restriction on autonomy when "patients have to sign this form and agree or they're not going to get opioids." 2) Beneficence: SIC can promote patient-centered care by "setting the goals and the expectations right off the bat" to effectively and safely treat pain. 3) Non-maleficence: SIC can prevent potential harm by warning patients against potential adverse effects, divergence, and misuse. Conversely, it may divert providers' focus away from cancer-related issues and damage trust by "spending a lot of time on things that don't make sense to cancer patient," distress patients by "making them feel like criminals," and delay the process "because prescribers just don't feel like doing the work" of SIC. 4) Justice: Provider may reflect their biases by "Jump[ing] right into the consent with someone who's a past drug abuser" or has had "a history of suicide attempts or thinking." Global SIC requirement may minimize "patients thinking that you're singling them out" and ease the introduction of SIC in oncology clinics when "it's part of the clinical practice." 5) Dignity: Despite agreeing that SIC should "be demanded as an educational process," providers worried about SIC as a "one size fits all" approach that is "not designed for cancer patients." Emergent themes from patient data indicated that they want SIC: 1) to explain substance use disorder in simple language 2) to cover consequences of tapering and not tapering 3) to designate someone they can contact with questions 4) to provide simple parameters 5) to have written SIC information to be verbally explained 6) to warn against sensations of euphoria and potential triggers for overuse.

CONCLUSIONS: Having SIC as a standardized process for LTOT in patients with cancer may normalize SIC conversations; however, it is important to allow some room for clinician's autonomy to do what they perceive as best for patients. A systematic requirement of SIC for all patients is a complex proposition, and SIC needs to be tailored for patients with cancer pain on long-term opioid therapy.

USING SIMULATION TO ASSESS COMPETENCY IN MEDICAL EDUCATION: OBSERVATIONS FROM AN INTERNATIONAL EXPERIENCE AT THE UNIVERSITAT INTERNACIONAL DE CATALUNYA

Juan M. Salgado¹; Tiffany E. Schwasinger-Schmidt²; Montserrat Virumbrales Cancio³. ¹University of Kansas School of Medicine, Wichita, KS; ²University of Kansas School of Medicine, Andover, KS; ³Universitat Internacional de Catalunya, Barcelona, Spain. (Control ID #3181873)

BACKGROUND: In 2014 the AAMC published new guidelines for the expectations for medical graduates to include the core Entrustable Professional Activities (EPAs). The goal of EPAs was to establish a mechanism to address competency assessment in medical education and help decrease an emerging gap in student readiness to transition from medical school into residency training. Simulation offers a unique, integrated approach for educators to be able to assess medical student competence in clinical scenarios. At the Universitat Internacional de Catalunya (UIC) in Barcelona, Spain, the medical school has utilized the Comprehensive Centre for Advanced Simulation (CISA) to formulate a competency assessment for their Objective Structured Clinical Exam (OSCE) at the completion of medical school.

METHODS: The OSCE at UIC was analyzed as a case study from a student's perspective during a month long international medical experience in June 2017. Participants included CISA educators and technical staff, standardized patients, OSCE evaluators, and medical students. Core medical competencies included taking a medical history, physical examination skills, formulation of an appropriate assessment and plan, technical procedural skills, interprofessional interactions, communication skills,

implementation of preventative medicine, and medical ethics. This exam comprised 50% of the medical students' grade in his or her final year of medical school. Assessment of student competency was evaluated by a review of student performance assessed by standardized checklists on the 20 different OSCE cases.

RESULTS: UIC has utilized the OSCE as a method of competency-based assessment since the 2013-2014 academic year. Overall class averages on the OSCE from 2014 to 2018 were 79%, 74%, 73%, 71%, and 74%, respectively. Assessment and Plan scores were 81%, 63%, 73%, 77%, and 76%, respectively. Medical Ethics scores were 58%, 81%, 82%, 85%, and 67%, respectively. Interprofessional Interaction scores were 72%, 84%, 65%, 62%, and 70%, respectively. A standardized overall OSCE score determined by the Medical Simulation director was used as a metric to determine competency.

CONCLUSIONS: This observational case study highlights the power of simulation to assess student competency with regards to skills necessary for residency training. As medical schools transition to EPA based assessments, the need for standardized measures to determine competency will become essential. The lessons learned from this case study of UIC's utilization of the OSCE at the completion of medical school can serve as a template for measuring medical students readiness for residency. Educators can track student performance and implement changes to curriculum to enhance student performance and ease the transition to clinical practice. From a student's perspective, simulation affords one the opportunity to translate classroom knowledge into clinical practice, and confidence can be instilled upon completion of competencies prior to entering residency training.

UTILITY OF POINT-OF-CARE ULTRASOUND AS A TOOL FOR MEDICAL DECISION MAKING IN A RESOURCE-LIMITED SETTING

Michelle Fleshner¹; Ayako W. Fujita²; DIVYA BHAMIDIPATI¹; Steven Fox¹; Thuy Bui³. ¹UPMC, Pittsburgh, PA; ²University of Pittsburgh Medical Center, PITTSBURGH, PA; ³University of Pittsburgh, Pittsburgh, PA. (Control ID #3185226)

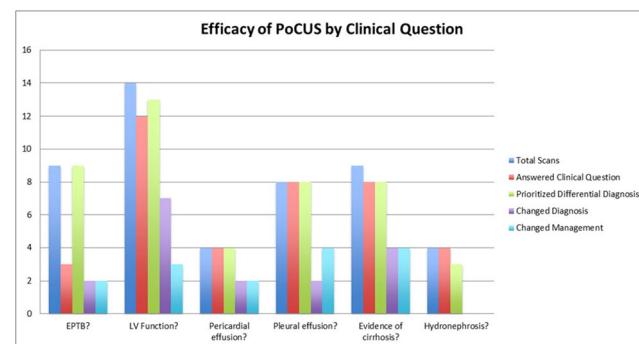

BACKGROUND: Point-of-care ultrasound (PoCUS) is a quick, inexpensive, and noninvasive tool for bedside diagnosis that is most effective when used to answer a specific clinical question. Few studies have looked at the effect of PoCUS on clinical diagnosis in resource-limited settings. This study investigated the ability of PoCUS to assist with medical decision making when used by Internal Medicine trainees in resource-limited settings.

METHODS: This was a retrospective analysis of PoCUS studies conducted at a global health site through the University of Pittsburgh Medical Center (UPMC) Internal Medicine Residency program. A pilot study was performed in March of 2018 and a formal study is forthcoming in January - April 2019. Residents underwent a week-long intensive ultrasound training course prior to traveling abroad and were then required to record and interpret ultrasound clips used in clinical practice. Equipment included Phillips Lumify cardiac and linear transducers. Prior to performing each scan, residents documented the "pre-PoCUS" diagnosis and clinical question. Afterwards, they recorded the "post-PoCUS" diagnosis and the ability of PoCUS to answer the clinical question and prioritize the differential diagnosis. Change in management was a secondary outcome. Expert and peer review of image acquisition and interpretation will be utilized for quality assurance. Data were analyzed using Microsoft Excel.

RESULTS: During the pilot study, a total of 58 studies were performed by 3 residents over 4 weeks. Twenty-five (43%) were abdominal ultrasounds, 24 (41%) were cardiac, and 9 (16%) were pleural. Ultrasound scans answered the clinical question in 46 (79%) studies, helped to prioritize the differential diagnosis in 51 (88%) studies, and changed the diagnosis in 21 (36%) studies. Finally, eighteen (31%) ultrasound scans changed

management, mostly by adding or removing medications. Efficacy of PoCUS scans was stratified by clinical question (Image 1). Data collection is ongoing through April 2019.

CONCLUSIONS: PoCUS is underutilized and has the potential to be extremely useful for medical decision making in areas with limited resources. PoCUS curricula for residents should focus on answering patient-specific clinical questions. Future directions include creating a peer-to-peer network for securely sharing and discussing PoCUS images and expanding this analysis to higher-resource settings in an internal medicine context.

UTILIZATION OF ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION IN NEW YORK STATE, USA AND ONTARIO, CANADA

Samantha Hershenfeld¹; Vicki Ling²; John J. Matelski¹; Matthew Cheung¹; Michael Paterson²; Peter Cram³. ¹University of Toronto, Toronto, ON, Canada; ²Institute for Clinical Evaluative Sciences, Toronto, ON, Canada; ³University of Iowa, Iowa City, IA, USA. (Control ID #3184706)

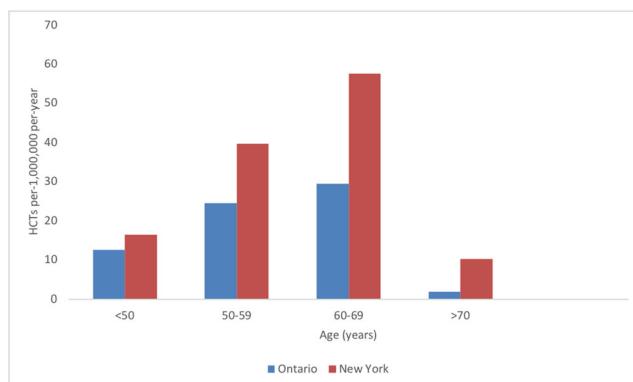

BACKGROUND: Hematopoietic Cell Transplantation (HCT) is a potentially curative treatment for multiple hematological and oncologic diseases. However, HCT is costly and resource-intensive. There is a general perception that the United States (US) offers improved access to many advanced therapies such as HCT, but also suffers from overtreatment. Alternatively, Canada is thought to suffer from protracted wait times and treatment delays, with advantages of greater equity and reduced disparities. Canada and the US share close geopolitical relationships and similar HCT indications. There have been no studies to our knowledge comparing utilization of HCT in the US and Canada.

METHODS: We used population level administrative health data from New York State (NY) and Ontario (ON) to identify all adults (>18 years) who underwent inpatient allogeneic HCT between 2012-2015 using ICD9CM codes (NY) and CCI codes (ON). We compared ON and NY with respect to patient demographic characteristics, patient neighborhood income quintile (based on postal code of residence), and hospital characteristics using univariate techniques. We examined indications for HCT in NY and ON using ICD9 and ICD10 diagnosis codes. We compared HCT utilization rates in NY and ON.

RESULTS: We identified 1361 HCT procedures performed in NY and 593 procedures in ON. HCT recipients in NY were older than ON (mean age 51.5 vs 49.0 years; p<0.001). A significantly higher percentage of HCTs in NY were repeat procedures relative to ON. The most common indication for HCT in ON and NY was acute myeloid leukemia (41.2% and 22.3%). A higher percentage of HCT recipients in NY resided in affluent neighborhoods (defined as neighborhoods in the highest income quintile) compared to ON (32.0% vs 26.9%; p=0.026). Mean hospital HCT volumes were similar in NY and ON (34.8 vs 32.4 HCTs per-year;

$p=0.48$). Utilization of HCT was 25.2 per-1 million population per-year in NY and 16.4 per-1 million per-year in ON ($p<0.001$). The magnitude of the NY-ON difference in utilization was larger for older patients.

CONCLUSIONS: We found significantly lower utilization of HCT in ON compared to NY. HCT recipients in NY also were significantly older and more likely to reside in high-income neighborhoods compared to ON HCT recipients. These differences should inform HCT policy in both jurisdictions.

HCT utilization in ON and NY stratified by patient age

UTILIZATION PATTERNS, EXPENDITURES, AND ESTIMATED SAVINGS ASSOCIATED WITH ANALOG OR HUMAN INSULIN PRODUCTS IN THE MEDICARE PART D PROGRAM.

Jing Luo; Aaron Kesselheim. Brigham and Women, Boston, MA. (Control ID #3185059)

BACKGROUND: High cost insulin analogs (e.g. glargine) are frequently used to treat patients with type 2 diabetes in the US. Recent evidence shows that switching older adults with type 2 diabetes from analog to lower cost human insulin (e.g. NPH or human premixed 70/30) is not associated with worsened glycemic control or increased risk of hypoglycemia and may result in cost savings for payors and patients. We sought to describe utilization patterns and expenditures for analog and human insulins separately in the Medicare drug benefit program and to estimate potential savings under 3 counterfactual scenarios between 2012 and 2016.

METHODS: We used the Medicare Part D Spending Dashboard, which summarizes data available the Part D Prescription Drug Event (PDE) data to tabulate volume (where 1 dosage unit = 1 ml = 100 IU insulin) and expenditures for human or analog insulin products from 2012 to 2016. We included all standard strength insulin formulations except inhaled insulin. To estimate potential savings and informed by literature, we considered 3 counterfactual scenarios: 1) optimistic, where utilization in Part D was 70% human and 30% analog, 2) moderate, where utilization was 50% human and 50% analog and 3) pessimistic, where the overall proportion represented by analogs was 10% less than observed each calendar year. We report gross and net expenditures for the observed and counterfactual scenarios, after accounting for a class-specific 25% rebate. We inflated all dollars to 2016 using the CPI-U.

RESULTS: Our sample included 8 human and 19 analog insulin products. The number of beneficiaries increased from 4.1 million in 2012 to 5.2 million in 2016. Similarly, the volume of insulin dispensed increased from 389 million units to 486 million units. The mean units dispensed/beneficiary was 94.8 (range 92.8 to 96.1). The proportion of insulin dispensed as analogs increased from 78% in 2012 to 83.6% in 2016. Gross expenditures for all insulin products increased from \$4.9 billion in

2012 to \$11.9 billion in 2016, a cumulative total of \$43.7 billion. The estimated 5-year savings under optimistic, moderate, and pessimistic counterfactual scenarios, inclusive of rebates, would have been \$11.6 billion, \$7.2 billion and \$2.2 billion, respectively.

CONCLUSIONS: Most insulins dispensed in the US Medicare drug benefit program were for analog products. Where it may be clinically appropriate, increased utilization of comparable human insulin products may result in substantial savings for Medicare.

UTILIZING A NOVEL ADAPTIVE E-LEARNING PRODUCT WITHIN A LARGE INTERNAL MEDICINE RESIDENCY TRAINING PROGRAM

Michael Healy^{1, 2}; Emil R. Petrusa¹; Craig Noronha³; Carl Gustaf Stefan Axelsson¹; Ole-Petter R. Hamnvik^{4, 2}; Melissa Elmore²; Leokadia Marchwinski²; Matthew O'Rourke²; Roy Phitayakorn^{1, 2}. ¹Massachusetts General Hospital, Harvard Medical School, Boston, MA; ²NEJM Group, Waltham, MA; ³Boston Medical Center, Boston University School of Medicine, Boston, MA; ⁴Brigham and Women's Hospital, Harvard Medical School, Boston, MA. (Control ID #3176864)

BACKGROUND: There is limited research about the impact of test preparation tools on subsequent resident performance on formal assessments. Question banks are a popular and widely used form of test preparation, and some studies suggest that question banks help learners reinforce knowledge and assess their individual learning needs. However, it is unclear how learners should use question banks to best maximize their knowledge retention. The objective of this pilot study was to examine how internal medicine residents utilized the NEJM Knowledge+ Internal Medicine Board Review (NEJM Knowledge+) product as an examination preparation tool and to measure their resulting performance on subsequent quizzes and exams.

METHODS: Participants were 69 residents (29 interns, 29 second-year residents, 10 third-year residents, and 1 chief resident) from a single internal medicine residency program. As compensation for participation, these residents were provided access to NEJM Knowledge+ starting in the beginning of the 2018 academic year to use independently for one year. Resident demographics, performance on a locally developed 60 question pre-test, and performance on the 300 question 2018 ACP Internal Medicine In-Training Examination were collected. Usage of NEJM Knowledge+ was monitored based upon the percent of progress made within the product. A correlation was computed between scores on the local test and the in-training exam. Finally, differences in the percent of progress made within NEJM Knowledge+ were calculated.

RESULTS: The correlation between performance on the local pre-test and the in-training exam was 0.53 ($p<0.0001$), indicating a moderately positive relationship. Collectively, 48 residents (69.6%) made progress within NEJM Knowledge+. Question sets in each of the 18 topics were completed, with the highest number of residents answering question sets correctly in cardiology (n=43, 62.3%), while the topic with the fewest was otolaryngology (n=4, 5.8%). There were no significant differences in progress within NEJM Knowledge+ between training years via the total number of question sets or the number of topic-specific question sets answered correctly.

CONCLUSIONS: The NEJM Knowledge+ product was used by a majority of the residents in this pilot study. Pre-test performance correlated with in-training examination scores, which opens the possibility of using the pre-test results to coach residents on effectively using the NEJM Knowledge+ product to address their existing knowledge gaps.

UTILIZING GEOSPATIAL MODELS FOR IDENTIFICATION OF PATIENTS AT RISK FOR HEPATITIS C INFECTION

Thomas Ludden¹; Lindsay Shade¹; Jeremy Thomas¹; Brisa Hernandez¹; Sveta Mohanan¹; Michael Leonard¹; Mark Russo²; Jewell Carr¹; Philippe Zamor²; Hazel Tapp¹. ¹Atrium Health, Charlotte, NC; ²CHS, Charlotte, NC. (Control ID #3161058)

BACKGROUND: Increased screening and the development of effective antiviral treatments have led to marked improvement in Hepatitis C (HCV) patient outcomes. However, many people in the US are believed to have undiagnosed HCV. Geospatial modelling using multiple high-risk variables including social determinants of health, age, and HCV prevalence provides an opportunity to identify at-risk populations in need of screening and linkage-to-care for HCV.

METHODS: We conducted a literature review to identify variables associated with patients at-risk for HCV infection. We separated the variables into two groups: HCV Prevalence and Social Determinants of Health. We collected data from publicly available sources and Atrium Health (formerly Carolinas HealthCare System), an integrated healthcare system based in Charlotte, NC with over 12 million patient encounters per year. We standardized the variables in the two groups and mapped out the overall combined index scores of each group at the census tract level in Mecklenburg County, NC.

RESULTS: 12 social determinants of health variables and 4 prevalence of HCV variables were identified. Between the two indexes, we identified 21 high risk census tracts that scored at least 2 standard deviations above the mean. Two census tracts overlapped between the two indexes; 11 were uniquely identified as high risk for prevalence of HCV and 8 were uniquely identified as priority tracts for social determinants of health.

CONCLUSIONS: Geospatial models identified a selection of census tracts that can be used to map high risk HCV populations. This will allow future targeted screening and linkage-to-care interventions for patients at high risk of HCV.

UTILIZING STAKEHOLDER PERSPECTIVES TO INFORM THE USER-CENTERED DESIGN OF THE RESOURCE ACCESS MAPPING PROJECT (RAMP), A MOBILE PHONE-BASED INTERVENTION TO IMPROVE ACCESS TO SOCIAL SERVICES
Ashley Odai-Afotey¹; Chaarushi Ahuja¹; Trucmai Ton²; Danya Keene²; Mona Sharifi³. ¹Yale School of Medicine, New Haven, CT; ²Yale School of Public Health, New Haven, CT; ³Yale New Haven Hospital, New Haven, CT. (Control ID #3168500)

BACKGROUND: Low-income and marginalized populations experience poorer health outcomes and lower access to health-promoting resources. The wide adoption of mobile phones in these populations could serve as a means to address systematic barriers to healthcare and resource access. In this study, we aim to explore resource needs and barriers to accessing services for social determinants of health among marginalized communities to inform the user-centered design of a mobile intervention.

METHODS: Participants were purposefully recruited to participate in focus groups from low-income and marginalized populations through partnerships with three local community organization addressing mental health, food insecurity, and youth homelessness in New Haven, CT. We conducted focus groups located at these community-based organizations using a semi-structured moderator's guide. This guide was developed and iteratively refined by our qualitative research team to explore: (1) how participants navigate community resources, (2) barriers to resource access, and (3) perspectives on key requirements to optimize the usability and usefulness of a mobile application to improve resource access. We also reviewed prototypes of the mobile application to obtain more specific feedback. All focus groups were recorded, transcribed verbatim, and analyzed using a grounded theory approach.

RESULTS: To date, we have completed three focus groups with 20 participants (4-8/group) ages 19-64 years. Participants were 47% male, 63% African-American, 42% had completed high school or less, 90% reported having access to a smartphone and out of those, 94% used "apps". Participants identified the primary sources of information on community resources as: disorganized and frequently inaccurate electronic resources, advertising at local community programs, and word of mouth. Barriers to resource access included lack of awareness, lack of

centralized resources and outdated information, and distrust towards organizations and staff. Participants expressed that a mobile application to improve resource access should include comprehensive, up-to-date information, facilitate peer-to-peer communication and advocacy, and provide resources tailored to an individual's unique needs.

CONCLUSIONS: Engaging target end-users in the development of interventions is more likely to yield a design that will be effective and highly adopted. Focus group participants from marginalized populations described an existing resource system that is disorganized and information-limited and defined several modifiable barriers to accessing resources to address social determinants of health. A centralized mobile application could introduce standardization, improve the reliability and accuracy of information, capitalize on and expand existing social networks and forms of information sharing, and facilitate tailored resource recommendations.

UTILIZING STANDARDIZED DOCUMENTATION TO IMPROVE THE CLARITY AND EFFICIENCY OF PERIPROCEDURAL COMMUNICATION FOR INPATIENT VASCULAR INTERVENTIONAL RADIOLOGY PROCEDURES

Emma Simon; Erin McCaffrey; Masha Kuznetsova; Leora I. Horwitz; Eric Aaltonen. NYU School of Medicine, New York, NY. (Control ID #3184932)

BACKGROUND: Hospitalized patients often undergo interventional radiology (IR) procedures, many of which require individualized pre-procedure preparation and post-procedure care. Internists caring for these patients may not be familiar with requirements for these patients, causing procedural delays or periprocedural adverse events. Clear communication between IR and internal medicine is therefore necessary, but is often lacking.

METHODS: We conducted qualitative interviews with hospitalists, house staff, nurses and IR staff to identify common breakdowns in periprocedural communication between IR and referring medicine units. Utilizing insights from these interviews, we identified essential elements for pre-procedure and post-procedure communication. These elements were added as fields in templated pre- and post-procedure IR notes (Table 1). Each standardized template contains 16 elements. Outcome measures included proportion of key elements included in IR notes, inpatient provider satisfaction, and frequency of phone calls into and out of IR before and after the intervention.

RESULTS: Before implementation of the standardized templates, pre-procedure consult notes (N=25) contained an average of 3.5 key elements (typically a brief medical history, assessment and plan), while post-implementation (N=50), these notes contained an average of 15.3 elements ($p<0.001$). Similarly, post-procedure notes (N=25) contained an average of 4.7 elements (typically the names of the IR providers, a brief procedure description and patient condition) pre-intervention versus a mean of 15.0 elements post-intervention (N=50) ($p<0.001$). Surveys of hospitalists pre- (N=17) and post-intervention (N=10) showed no significant difference in lack of confidence in preparing patients for IR procedures (52.9% vs. 30.0%, $p=0.40$), ineffective collaboration with IR (11.8% vs. 0%, $p=0.44$), and not receiving clear recommendations (35.3% vs. 10%, $p=0.67$); however analyses were underpowered. Total calls into and out of VIR decreased 15.6% overall (mean decrease of 7.7 calls/weekday and 24.5 calls/weekend, $p=0.006$).

CONCLUSIONS: Standardizing pre- and post-procedure documentation can effectively increase the inclusion of key content, and this content may reduce internal medicine physician questions and concerns regarding periprocedural patient care.

VALIDATING HOMELESS DATA FROM THE VETERANS HEALTH ADMINISTRATION ELECTRONIC HEALTH RECORD

Kathleen A. McGinnis¹; Melissa Skanderson¹; Emily A. Wang²; Kathleen M. Akgün³; Mona Duggal¹; Adam Gordon⁸; Vincent Marconi⁷; Keith

McInnes⁴; Christopher T. Rentsch⁵; Amy C. Justice⁶. ¹VA Pittsburgh Healthcare System, West Haven, CT; ²Yale School of Medicine, New Haven, CT; ³Yale University, VACT West Haven, New Haven, CT; ⁴Dept Veterans Affairs, Bedford, MA; ⁵London School of Hygiene & Tropical Medicine, London, United Kingdom; ⁶Yale University, West Haven, CT; ⁷Emory University, Atlanta, GA; ⁸The University of Utah, Salt Lake City, UT. (Control ID #3184134)

BACKGROUND: Homelessness is especially prevalent among veterans and the Veterans Health Administration (VA) electronic health records (EHR) can be used as a research tool for understanding modifiable mediators of homelessness. We sought to validate homeless data in the VA EHR by comparing it with self-reported data from the Veterans Aging Cohort Study (VACS) survey, a confidential, self-administered survey of HIV+ and uninfected veterans.

METHODS: Using VACS survey items, we created two homeless variables - ever (prior to survey) and recent (w/in 4 weeks prior to survey) based on self-report of having "been without a permanent address that you call home" or "stayed one or more nights in a shelter, on the street, in the park, or in an abandoned building". We also created two EHR homeless variables using the ICD-9 code v60.0 for "lack of housing": 1) homelessness any time prior to the survey, and 2) recent homelessness - within 30 days prior to or up to one week after the survey date. Agreement between survey and EHR variables were assessed using sensitivity and specificity, assuming the survey as the reference standard, and Cohen's kappa statistics. Positive predictive value (PPV) and negative predictive value (NPV) were also calculated.

RESULTS: There were 3734 HIV+ and 3791 uninfected VACS participants enrolled in VACS from 2000 to 2012, mean age was 50 years ($sd=9.4$), 95% were male, and 65% were African-American. Ever and recent homelessness were reported by 47% and 17% on the survey, respectively. In the EHR, we identified 30% as ever homeless and 6% as recently homeless. Compared with self-report, using ICD-9 codes, sensitivity is low (53%) but specificity is good (92%) for EHR ever homeless (PPV=85%, NPV=69%, kappa = 0.46); similarly, sensitivity is low (26%) and specificity is good (97%) for EHR recent homelessness (PPV=68%, NPV=87%, kappa = 0.31).

CONCLUSIONS: Agreement between EHR and survey homelessness is fair to moderate with good specificity. Although we can be confident that those identified as homeless are correctly identified, a large proportion of those who have experienced homelessness are not identified in the EHR. This work will be extended to incorporate evaluating other VA EHR sources of homeless information such as ICD-10 codes, clinic stop codes, and data collected using clinical reminders at clinic visits in order to develop and validate a robust measure for homelessness nationally across the VA. Identification of homelessness within the VA can be used in future studies to identify those at risk and to adjust for homelessness in research.

VALIDATION OF OUR UNIQUELY DEVELOPED PREDICTION FORMULA OF FALL USING DIFFERENT POPULATION FROM ORIGINAL ONE USED IN ITS DEVELOPMENT: A SECOND REPORT

Masaki Tago; Naoko E. Katsuki; Yoshimasa Oda; Hidetoshi Aihara; Shuichi Yamashita. Saga University Hospital, Saga, Japan. (Control ID #3138735)

BACKGROUND: Previous studies have identified many risk factors for falls and several predictive formulae for falls have been developed. Hendrich II Fall Risk Model has been reported to be the most appropriate predictive formula with sensitivity of 70% and specificity of 61%. They require examinations and techniques seldom used in routine clinical settings, as well as time-consuming assessment items, which poses a serious impediment to its use. Therefore, we have developed a simpler predictive formula using a regression coefficient acquired from the results of the multivariate analysis. We used two scales, the Japan Ministry of Health, Labour and Welfare (MHLW) bedriddenness rank and cognitive function score, which are both commonly used evaluation tools in Japan.

The formula was as follows: $y = (75 \text{ years or older}) \times 6 + (\text{male}) \times 4 + (\text{emergency admission}) \times 5 + (\text{hypnotic}) \times 4 + (\text{history of falls}) \times 3 + (\text{bedriddenness rank of J}) \times 12 + (\text{bedriddenness rank of A}) \times 18 + (\text{bedriddenness rank of B}) \times 20 + (\text{bedriddenness rank of C}) \times 17 + (\text{cognitive function score of 2}) \times 4$. We validated the accuracy of our unique formula which we presented at the SGIM17, using other group setting than the one we originally used in its development.

METHODS: We retrospectively analyzed inpatients over 20 years old who were admitted to an acute care hospital in Japan, between April 2015 and March 2018. The data (including age, sex, the department to which the patient was admitted, emergency admission or not, whether the patient was transferred by ambulance, admission with a referral letter or not, taking hypnotics or not, bedriddenness rank and cognitive function score on admission, visual impairment and history of falls and strokes) were derived from the charts. We performed Receiver Operating Characteristic (ROC) analysis and the calculation of the likelihood ratio using our predictive formula and the data acquired in our study of falls of inpatients.

RESULTS: During the study period, 9344 patients were admitted, of whom 8967 were over 20 years old without unavailable data. The median age of 8967 inpatients was 77 years, 49.3% were men, and the median length of hospital stay was 9 days. The median calculated predictive score was 17. A total of 274 suffered falls, whose median age was 84 and median length of hospital stay was 25 days. The test of goodness of fit of the predictive formula using ROC curve analysis showed Area Under the Curve (AUC) of 0.766 (95%CI: 0.744-0.789, $P < 0.001$), and sensitivity of 83.2% and specificity of 60.9% with the setting of cut-off point of 24. The negative likelihood ratios with the cut-off points of 6 (the first quartile) and 10 were 0.04 and 0.10, respectively.

CONCLUSIONS: We herein validated the accuracy of our previously reported predictive formula of falls of adult inpatients using bedriddenness rank and cognitive function scores, with different group setting from the one we originally used in its development showing higher accuracy of our formula than previously reported ones.

VARIATION IN PRIMARY CARE SPENDING FOR MEDICARE PATIENTS IN AND OUT OF HEALTH SYSTEMS

Rachel O. Reid^{1, 2}; Cheryl Damberg³; Mark W. Friedberg^{1, 2}. ¹RAND Corporation, Boston, MA; ²Brigham and Women's Hospital, Boston, MA; ³RAND Corporation, Santa Monica, CA. (Control ID #3185427)

BACKGROUND: Greater orientation toward primary care has been associated with better quality and lower costs of care. Health systems are growing in the United States and increasingly shape care delivery. In this study, we explore variation in primary care spending as a proportion of total spending among Medicare fee-for-service beneficiaries who seek care from health system-affiliated provider organizations (POs) versus unaffiliated POs, as well as across health systems.

METHODS: Using 100% 2015 Medicare claims, enrollment, and provider data, we attributed 6,602,562 beneficiaries to 10,863 health system POs and 9,902,449 beneficiaries to non-health system 88,600 POs, attributing beneficiaries to POs (identified by TIN) responsible for at least 30% of their evaluation and management service and identifying system-affiliated POs using the SK&A provider database. We then assessed the percentage of their total medical and prescription drug spending on primary care. We defined primary care spending according to narrow and broad definitions of primary care providers (PCPs) and services. The narrow PCP definition included Family Practice, Internal Medicine, Pediatrics, and General Practice. The broad definition also included Nurse Practitioners, Physician Assistants, Geriatric Medicine, and Gynecology. Both excluded hospitalists. The narrow services definition included evaluation and management visits, preventive visits, care transition or coordination services, and in-office preventive services, screening, and counseling. The broad definition included all professional services billed by PCPs.

RESULTS: Beneficiaries attributed to health system POs had less spending on primary care than those attributed to non-health system POs (e.g., 2.5% versus 3.3% for the narrow PCP and service definition). Among health systems, the primary care spending percentage varied according to the definition used (from 2.5% of total spending for the narrow PCP and service definition to 6.0% for the broad definitions), did not vary with the number of physicians in a system, and increased with the percentage of system physicians who were PCPs (ranging from 1.7% of spending for systems with less than 25% PCPs to 3.3% for systems with at least 75% PCPs, for the narrow PCP and service definition).

CONCLUSIONS: Compared to health system POs, non-health system POs have lower proportions of total spending on primary care. Health systems with greater primary care specialty composition have higher proportion of medical spending on primary care. As state policymakers working to establish minimum thresholds for the proportion of health care spending on primary care can be informed by information about the variation in primary care spending among health systems. Describing the proportion of spending devoted to primary care among POs can enable future research examining the relationship between primary care spending and the quality and efficiency of care.

VARIATIONS IN THE USE OF SAFETY MEASURES AMONG HARVARD-AFFILIATED HOSPITALS

Hojjat Salmasian¹; Laura C. Myers²; Merranda Logan²; David M. Levine¹; Christopher Roy³; Michelle Frits¹; Lynn A. Volk⁴; Ruth Akindele¹; Juliette Randazza¹; Sevan Dulgarian¹; David Shahian²; Elizabeth Mort²; David W. Bates¹. ¹Brigham and Women's Hospital, Boston, MA; ²Massachusetts General Hospital, Boston, MA; ³Mount Auburn Hospital, Cambridge, MA; ⁴Partners HealthCare, Wellesley, MA. (Control ID #3178489)

BACKGROUND: The field of safety reporting has evolved since the Harvard Medical Practice Study was performed decades ago. As part of the new Harvard Safe Care Study, which is designed to emulate and expand upon that seminal study, one aim was to catalog the measures and triggers different Harvard-affiliated hospitals use to identify and monitor safety events, and to study variations in these processes by organization characteristics.

METHODS: Electronic surveys were sent to the designated quality/safety leaders of 10 Harvard-affiliated hospitals that deliver both inpatient and outpatient care. The surveys asked if and how they collect and monitor an extensive list of 134 safety measures endorsed by regulatory bodies, expert groups, specialty boards, and/or the National Quality Forum. The measures were grouped by clinical domain into adverse drug events, critical care, deep vein thrombosis/pulmonary embolus, falls, general inpatient, general outpatient, hospital-acquired infections, maternal/perinatal, pressure injuries, surgical, and transitions in care. We analyzed within- and between-group agreement using Fleiss' kappa (using 0.3 and 0.6 as cutoffs for moderate and high agreement), stratifying sites based on hospital size (>400 beds vs <400 beds) and academic status (non-teaching, graduate teaching, and major teaching). The consensus method was used for the between-group comparison. We also performed subgroup analysis of measures that are "required" to be reported to a regulatory agency such as the Center for Medicare and Medicaid Services (CMS) or a specialty board.

RESULTS: Overall, agreement among sites for measures they collected was low ($=0.148$). Highest agreement was observed for measures related to pressure injury ($=0.554$) and hospital-acquired infections ($=0.382$). Lowest agreement was observed among maternal/peripartum ($=0.040$) and surgical measures (0.048). Agreement was weak but larger within the group of large hospitals ($=0.272$) and within the subgroup of major teaching hospitals ($=0.265$). Of the 23 measures reported to governing agencies other than the CMS, sites reported that they actively collect an average of only 77% (range = 48-100%, $=0.006$, p-value = 0.40).

CONCLUSIONS: We observed high variation among the studied Harvard-affiliated hospitals regarding which safety measures they collect, including those reported to governing agencies, which could not be simply explained based on hospital size and teaching status. This could be due to different monitoring needs and priorities at different sites, different institutional goals at the time of the survey, or disagreements about the usefulness of various measures. Notwithstanding the measures required by all payors and regulatory agencies, hospitals vary in the scope of metrics used to advance quality and safety in their institutions. Understanding the reasons behind the difference may inform the approach to improvement across sites.

VETERAN PERSPECTIVES ON CANCER CARE COORDINATION

Willi L. Tarver; Edward J. Miech; David Haggstrom. Roudebush VA Medical Center, Indianapolis, IN. (Control ID #3186391)

BACKGROUND: Coordinating cancer care can prove especially challenging because of the complexity of both the disease and its treatment. Typically, the care of cancer patients involves multiple types of therapies and providers (surgery, radiation therapy, chemotherapy) and ongoing treatment of cancer and other health conditions. Cancer care coordination depends upon effective, regular communication among physicians, support staff, and the patient. The objective of this study is to explore Veteran patients' experiences of cancer care coordination in order to develop a deeper understanding of the issues Veterans consider important and actionable.

METHODS: Semi-structured interviews were conducted among patients diagnosed with cancer types and stages that commonly receive interdisciplinary care (e.g., colorectal [stage II and up], prostate [high risk], head and neck [all stages], and lung [all stages] cancer) were eligible to participate in the study. The constant comparison technique was used to identify emerging themes in the data.

RESULTS: Twenty-five Veteran cancer patients participated in this study. Our analysis identified four general categories representing different parts of the trajectory of the patient cancer care experience in need of coordination. Each phase had a distinct set of needs and challenges. Diagnosis: After receiving a diagnosis of cancer, Veterans reported initial feelings of shock and fear. Pre-Treatment: This phase was characterized as busy and chaotic, consisting of many appointments in different locations, and ultimately left many Veterans feeling a lack of control. Veterans repeatedly expressed an interest in having an early explicit understanding of their care, including the next steps and expectations. Onset of Treatment: Uncertainty about what to expect when receiving advanced treatments, like radiation and chemotherapy, was often exacerbated by poor provider-provider communication issues. Some participants identified novel solutions, such as proactively viewing the treatment area in advance. Ongoing Treatment: As treatment progressed, many Veterans experienced a growing familiarity with their routine, and simultaneously, began to regain a sense of control. Care Team: Nurse navigators were considered vital to cancer care coordination. This also marked a shift where many Veterans experienced a decrease in anxiety and worry. Veterans valued honesty and transparency from their providers which built a sense of trust.

CONCLUSIONS: Veterans expressed a need to have care coordination needs and steps more explicitly addressed early, as well as active mechanisms to meet those needs. The patient experience of coordination gradually improved over the course of the care trajectory, often facilitated by relationships fostered with members of the healthcare team. Exploring the perspectives of Veteran cancer patients can offer invaluable insight to aid cancer care providers and policy makers in developing programs to improve care coordination.

VIDEO INTERVENTION TO IMPROVE INCIDENT REPORTING AMONG MEDICAL TRAINEES

Jose R. Valery; Haythem Helmi; Aaron Spaulding; Xinxiang Che; Gabriel Prada; Natalia Chamorro Pareja; Pablo Moreno Franco; Fernando Stancampiano. Mayo Clinic Florida, Jacksonville, FL. (Control ID #3184649)

BACKGROUND: Efforts are being made across teaching hospitals to improve trainee involvement with incident reporting systems. Studies suggest that understanding barriers to incident reporting is essential in developing successful educational interventions. We previously reported on barriers to incident reporting within our institution which were lack of knowledge of how to report, concern about negative repercussions after reporting, lack of time to report and the belief that reporting is futile. This study was designed to address these specific barriers with a patient safety video distributed via email. Barriers were assessed using baseline and post-video surveys.

METHODS: The study was conducted after IRB approval. A 5-minute video was produced aiming to address the barriers noted above. Baseline and post-video surveys were developed after a literature review of similar surveys, review with a panel of patient safety experts, and pre-testing with a group of trainees. The surveys and video were distributed via email to 1144 trainees. Participation was anonymous and voluntary. T-tests assuming unequal variances were used to determine significance. A p-value of < 0.05 was interpreted as significant.

RESULTS: The response rate to the baseline survey and video was 6.1%. 41.4% of trainees who viewed the video responded to the follow up survey. Baseline and post-video survey results are shown in Table 1. Trainees indicating having knowledge to create an incident report increased from a baseline of 48.6% to 72.4% which was significant (p-value of 0.013). Otherwise, there was no significant change in attitudes about incident reporting.

CONCLUSIONS: Using email to distribute a patient safety video targeting specific barriers to incident reporting with anonymous and voluntary participation yielded a low response rate. Although there was improvement in perceived knowledge among participants, there was no measured improvement in other attitudes measured about incident reporting. The same video delivered during an in-person, required, educational conference was previously studied where knowledge and attitudes about incident reporting significantly improved (manuscript in progress). Our data suggests that although email distribution is a practical way to deliver patient safety education, the impact is low if participation is voluntary and anonymous.

VITAL-AF: A PRAGMATIC TRIAL INTEGRATING ROUTINE SCREENING FOR ATRIAL FIBRILLATION DURING PRIMARY CARE VISITS

Steven J. Atlas¹; Jeffrey M. Ashburner¹; David D. McManus²; Yuchiao Chang¹; Ana T. Trisini Lipsanopoulos¹; Leila H. Borowsky¹; Wylieana Guan¹; Wei He¹; Patrick T. Ellinor¹; Steven A. Lubitz¹; Daniel E. Singer¹.

¹Massachusetts General Hospital, Boston, MA; ²University of Massachusetts Medical School, Worcester, MA. (Control ID #3185071)

BACKGROUND: Atrial fibrillation (AF) is a common age-related arrhythmia associated with increased risk of ischemic stroke. Novel technology may permit efficient and effective AF screening among undiagnosed, at-risk individuals to reduce ischemic stroke through use of guideline-indicated oral anticoagulants (OAC). We designed VITAL-AF ([ClinicalTrials.gov](#) NCT03515057) as a pragmatic cluster-randomized trial in a large primary care network in the United States, with the primary objective of assessing the benefit of population-based screening for AF in older patients using a single-lead ECG as part of routine care.

METHODS: VITAL-AF was designed to be generalizable, implementable, and pragmatic. VITAL-AF includes all patients 65 years of age attending an outpatient visit in a participating site (including hospital-, community- and health center-based practices) with a physician or nurse practitioner, embeds screening as part of routine assessment of vital signs at each encounter, utilizes clinic medical assistants rather than research personnel to conduct screening, and assesses outcomes using electronic health record data. Practices were randomized to the screening intervention or control arm. Control practices continue with true usual

care that may include pulse palpation and rhythm assessment based upon physician standard practice. Here we present historical data from the network about the size, visit patterns, and characteristics of the eligible population prior to trial enrollment starting July 31, 2018.

RESULTS: Overall, 142,291 patients were seen in network practices in the prior 3 years. There were 35,856 (25%) eligible patients 65 years of age seen in 16 participating study sites (hospital, community and health center clinics) including 4,704 (13%) patients with known AF. In 2017, 93% of eligible patients 65 years completed at least one primary care outpatient visit, with 67% completing multiple visits. This population has many risk factors for AF including: 41% 75 years of age, 43% male, 70% with hypertension, 19% with coronary artery disease, 18% with diabetes, and 8% with heart failure. Among those without prevalent AF on OAC, 93% had a CHA2DS2-VASc score 2 with 40% having a score 4. The trial is in progress and subject accrual is expected to be complete as of late fall 2019.

CONCLUSIONS: VITAL-AF is a pragmatic, population-based trial of a screening program for undiagnosed AF in older at-risk patients within a primary care network. To emphasize generalizability, ease of implementation, and to facilitate screening uptake across a range of primary care clinics, VITAL-AF uses a single, age-based eligibility criterion. A small percentage of patients with low CHA2DS2-VASc score or with prevalent AF will be screened. Outcome assessment will evaluate rates of new AF detection and appropriate use of OACs among all patients 65 years of age seen in a participating clinic.

VOLUNTARY BUNDLED PAYMENT FOR CORONARY ARTERY BYPASS SURGERY: DO EFFECTS FOR JOINT REPLACEMENT EXTEND TO OTHER SURGICAL CONDITIONS?

Joshua Rolnick²; Joshua M. Liao^{1, 2}; Xinshuo Ma²; Ezekiel J. Emanuel²; Eric Z. Shan²; Jingsan Zhu²; Erkuan Wang²; Qian Huang²; Amol S. Navathe^{2, 3}. ¹University of Washington, Seattle, WA; ²University of Pennsylvania, Philadelphia, PA; ³CMC VA Medical Center, Philadelphia, PA. (Control ID #3182898)

BACKGROUND: Episode-based payment is an increasingly common strategy to reduce spending. Medicare's voluntary Bundled Payments for Care Improvement (BPCI) program tested the impact for several surgical conditions. However, while evidence shows savings with BPCI for knee and hip replacement surgery, less is known about CABG, despite CMS's recent decision to reconsider a mandatory bundles program for CABG.

METHODS: We performed a difference-in-differences comparison using 2011-2016 Medicare claims. Episodes attributed to BPCI physician groups were excluded. CABG participants were propensity-matched with up to 15 non-participants. The primary outcome was standardized total episode spending. Secondary outcomes were changes in utilization and spending by category. Models were adjusted for patient characteristics, time-varying market characteristics, and hospital and quarter fixed effects. Ordinary least squares models were used for utilization and spending by category. A generalized linear model with a log-link function and gamma distribution was used for total spending.

RESULTS: From October 2013–October 2015, 49 hospitals enrolled in CABG. 43 participants (10,125 episodes baseline period, 4,688 treatment) were matched with 548 non-BPCI hospitals (30,133 episodes baseline, 29,273 treatment). Mean BPCI follow up was 24 months. There were no baseline differences in age or Elixhauser index. Baseline episode spending was \$48,258 BPCI group vs. \$47,417 controls (p<0.001) and spending for post-acute institutional care was \$5,366 BPCI vs. \$4,435 controls (p<0.001). The parallel trends assumption was met for all outcomes. Difference-in-differences analysis showed BPCI participation was associated with a non-significant 1.9% increase (95% CI -4.7%-8.9%, p-value=0.588) in risk-adjusted total spending. Proportion of spending on physician fees decreased 5.1% (95% CI 6.3%-3.9%, p-value<0.001) and SNF spending showed a non-significant 1.3% decrease (95% CI -1.2%-3.7%, p-value=0.31). Proportion of spending on post-acute institutional

care significantly increased 5.1% (95% CI 1.9%-8.3%, p-value = 0.002). There were no significant changes in readmission rate, ER visit rate, or mortality. However, discharge to post-acute institutional care increased 17.9% (95% CI 6.0%-29.8%, p-value=0.003)

CONCLUSIONS: BPCI participation was associated with shifts in spending by category but no significant total spending change. Utilization of post-acute institutional care after index hospitalization increased, but ER visits and readmissions did not change. Bundled payments in their current form may not produce savings for all conditions, raising questions about the likely impact of mandating bundled CABG payments.

WASTE IN THE MEDICARE PROGRAM: 2015 NATIONAL ESTIMATES OF LOW-VALUE SERVICE USE AND SPENDING

Rachel O. Reid^{1, 2}; John N. Maf^{3, 4}; Cheryl Damberg⁴. ¹RAND Corporation, Boston, MA; ²Brigham and Women's Hospital, Boston, MA; ³David Geffen School of Medicine at UCLA, Los Angeles, CA; ⁴RAND Corporation, Santa Monica, CA. (Control ID #3185307)

BACKGROUND: Low-value health care services that offer no clinical benefit but expose patients to risk and expense are common in the US health care system. The Choosing Wisely campaign and other efforts have focused attention on waste since low-value service use and spending were last estimated in Medicare nationally. In this study, we provide updated national estimates of low-value service use and spending in the Medicare population using a broad set of low-value care measures.

METHODS: We included 100% of fee-for-service Medicare beneficiaries aged 65 and older who were continuously enrolled in Parts A, B, and D for at least 2 years in 2015: 14,024,927 beneficiaries. Using Medicare enrollment, medical claims, and prescription drug event data, we used the Milliman MedInsight Waste Calculator to assess 36 claims-based measures of low-value services applicable to the Medicare population, reflecting recommendations from the Choosing Wisely Campaign, the USPSTF, and other professional guidelines. We defined as low-value those services deemed "wasteful" or "likely wasteful" based on a sufficient claims history without a clinical rationale for the service, and calculated wasteful spending on those low-value services as the total allowed amount for the claim for that service.

RESULTS: Among included beneficiaries, 11,554,997 (82.4%) had at least one service that could be considered potentially low-value (45.9 million services, 4.0 per capita). Of these, 6,307,792 (54.6%) had at least one service ultimately deemed low-value, accounting for 13.5 million distinct services (2.1 per capita) and \$4.7 billion in wasteful spending (\$740 per capita). The 3 low-value services most frequently received were: eye imaging testing without significant eye disease (3.4 million services, 25.5% of low-value services), baseline laboratory studies before elective low-risk surgery (2.8 million services, 21.1% of low-value services), and opioids for acute back pain (2.5 million services, 18.4% of low-value services) - comprising nearly two-thirds of wasteful services (64.9%). The 3 services representing the greatest fraction of wasteful spending were: eye imaging testing without significant eye disease (\$1.5 billion, 32.5% of wasteful spending), baseline laboratory studies before elective low-risk surgery (\$1.1 billion, 24.0% of wasteful spending), and renal artery revascularization (\$528 million, 11.3% of wasteful spending) - comprising more than two-thirds of wasteful spending (67.8%).

CONCLUSIONS: Delivery of low-value services remains common and costly in Medicare: most beneficiaries received at least one low-value service. However, utilization and spending are concentrated among a small subset of the measures assessed, suggesting targeted opportunities for waste-reduction. These findings suggest that targeted interventions to reduce this subset of low-value services could substantially reduce waste in Medicare and highlight the need for understanding of how best to design and implement such interventions.

WELLNESS BEHAVIOR PROFILES OF INTERNAL MEDICINE AND PSYCHIATRY RESIDENTS

Milad Memari; Margaret S. Chisolm; Sean Tackett; Anne Ruble; Scott Wright. Johns Hopkins Bayview Medical Center, Baltimore, MD. (Control ID #3181174)

BACKGROUND: The ACGME requires that residency training programs (RTP) establish or bolster interventions that facilitate resident well-being, promote resilience, and guard against burnout. There is, however, limited data characterizing residents' participation or engagement in wellness promoting behaviors during their training to guide these initiatives.

METHODS: We surveyed a cohort of internal medicine and psychiatry residents regarding 16 self-care or wellness promoting behaviors over the preceding 30-days in December of 2017, dividing them into those done alone and those involving others.

RESULTS: 101 residents were invited to share their behavioral profiles, and most residents completed the entirety of the survey (86%, n=87). Getting a good night's sleep (sleeping >7 hours consecutively) was the most frequent wellness supporting behavior that did not require others (averaged 14 times in prior 30 days). The most frequent wellness activities involving others included "cuddling" with another adult (16 times), calling family members (13 times), and sharing a meal with friends or family (11 times). Of the 16 behaviors studied, 13 were performed more frequently among residents compared to interns; two of these reaching statistical significance (sleeping >7 hours consecutively and attending a special event [e.g. sporting event, play, concert...], both P < 0.05).

CONCLUSIONS: This study offers a glimpse into the midyear self-care activities of interns and residents in 2 training programs. The wellness behaviors that were most commonly endorsed necessitated the involvement of friends and family. These basic wellness behavioral profiles of interns and residents may serve to inform the development of curricula and guidance from RTPs as mandated by the ACGME.

WERE THE 2015 HYPERTENSION SCREENING RECOMMENDATIONS TAKEN WITH A GRAIN OF SALT? A RETROSPECTIVE STUDY ON CHANGES IN PHYSICIAN BEHAVIOR BEFORE AND AFTER THE UPDATE TO THE 2015 USPSTF HYPER TENSION GUIDELINES

Deborah Fung¹; Amani Allen²; Rosio Ramos³; Erica Phillips³; Nathalie Moise⁴; Jacob Julian⁴; Ian Kronish⁴. ¹New York Presbyterian Weill Cornell, New York, NY; ²Cornell University, Ithaca, NY; ³Weill Cornell Medical College, New York, NY; ⁴Columbia University Medical Center, New York, NY. (Control ID #3179309)

BACKGROUND: Hypertension (HTN) is a major modifiable risk factor for cardiovascular disease (CVD) and is highly prevalent in the United States. Traditionally, two elevated office blood pressure (BP) measurements have been the mainstay of diagnosing HTN; however, many patients with elevated office BP do not have elevated out-of-office BPs. This phenomenon, known as white-coat HTN, confers lower risk of CVD, may lead to over-diagnosis of HTN, increased stress and anxiety for patients now labeled with a chronic illness, and unnecessary healthcare costs. In 2015, the U.S. Preventive Services Task Force (USPSTF) updated its HTN screening recommendations to emphasize the importance of ruling out white-coat HTN by obtaining ambulatory BP monitoring (ABPM) or home BP monitoring (HBPM) in adults with elevated office BP. The goal of this study is to evaluate the utilization of out-of-office BP monitoring via ABPM or HBPM by primary care providers before and after this update.

METHODS: We conducted a retrospective electronic health record review of scheduled visits between primary care providers from three diverse, urban academic-based clinical practices involving adult patients with elevated office BP but no prior diagnosis or treatment for HTN. Patient inclusion criteria were: age 18, office systolic BP 140 mmHg and/or diastolic BP 90 mmHg, and no prior history of HTN or white-coat HTN. Exclusion criteria were:

severely elevated BP 180/110 mmHg, history of stroke, coronary artery disease, peripheral artery disease, heart failure, left ventricular hypertrophy by echo, atrial fibrillation, and chronic kidney disease. Data pertaining to the patient demographics, and clinician BP management were extracted by medically-trained coders. Descriptive statistics were used to characterize the rate of out-of-office BP testing in 2014 versus 2016.

RESULTS: In 2014, of 150 visits with USPSTF HTN guideline-eligible patients (mean age 63 years, 51% female, 83% with SBP 140 mmHg and 33% with DBP 90 mmHg), 1 patient was prescribed HBPM, none were referred for ABPM, and 1 patient was diagnosed with HTN and started on BP medication. BP was not mentioned in 73% of visit notes, BP was to be rechecked next time in 24% of visit notes, and BP was to be measured through other methods (i.e. pharmacy) in 3% of visit notes. In 2016, of 80 guideline-eligible patients (mean age 62 years, 58% female, 82% with SBP 140 mmHg and 36% with DBP 90 mmHg), 1 patient was prescribed HBPM, none were referred for ABPM, and none were diagnosed with HTN. BP was not mentioned in 85% of visit notes, and BP was to be rechecked in 14% of visit notes.

CONCLUSIONS: The rates of ordering ABPM or HBPM for guideline-eligible patients remained low pre and post USPSTF guideline updates. This calls for the development of implementation strategies to increase the uptake of this important guideline. Additional interventions may be needed to reduce the predominant wait-and-see approach to elevated office BP.

WHAT ASPECTS OF DIABETIC SELF-CARE ACTIVITIES IS MOST IMPACTED BY PATIENT ACTIVATION AND MHEALTH INTERVENTIONS? THE OFFICE-GUIDELINES APPLIED TO PRACTICE (OFFICE-GAP) PROGRAM.

Sherif Elkinany; Zane Alroshood; Ngoc Nguyen; Karen Kelly-Blake; William Hart-Davidson; Ling Wang; Maya Al-Saghir; Khader Herzallah; Brandon Batarse; Ade B. Olomu. Michigan State University, East Lansing, MI. (Control ID #3183056)

BACKGROUND: Office-Guidelines Applied to Practice (Office-GAP) is a patient activation intervention providing patient and physician training in shared decision-making (SDM) to improve communication and patient-physician relationships. Our objective was to determine aspects of diabetic self-care significantly impacted by the Office-GAP + mHealth intervention compared to mHealth alone.

METHODS: Office-GAP intervention included: 1) group visit 2) SDM physician training and 3) decision support checklist used in real time in the office. Mhealth intervention includes teaching patients to send and receive text messages; patients received daily messages appropriate to their diagnosis and medications for 14 weeks, along with appointment reminders and patients could respond to prompts and contact their providers via text. Seventy-four patients who completed the Summary of Diabetes Self Care Activities (SDSCA) at baseline were assigned to either Office-GAP + mHealth (39 patients) or mHealth only (35 patients). The SDSCA assesses six aspects of diabetic self-care: general diet, specific diet, exercise, blood-glucose testing, foot care, and smoking. Patients in both groups completed SDSCA at baseline, first (2months), and second (4months) follow-up visits. Generalized Estimating Equation for Poisson distribution is employed for statistical analysis.

RESULTS: There were significant improvements in general diet and foot care. For Office-GAP + mHealth, the average number of days/week following general diet was 2.69 at baseline, 3.77 at first follow-up and 3.77 at second follow-up. For mHealth only, the average was 3.23, 2.96 and 3.89 at baseline, first and second follow-ups respectively. Regression analysis showed that after controlling for age, gender, race, health insurance and BMI, from baseline to second follow-up, the incident rate ratios (IRR) for general diet in Office-GAP + mHealth group was 1.19 ($P = 0.005$) while in mHealth only, from baseline to second follow-up, IRR for general diet was 1.10 ($P=0.22$). Compared with mHealth only group, IRR for general diet in Office-GAP + mHealth group was 1.08 ($P=0.43$).

For Office-GAP+ mHealth, the average number of days/week following foot care was 3.05, 4.80 and 4.95 at baseline, first and second follow-ups respectively. For mHealth only, the average following foot care was 3.23, 3.71 and 5.21 at baseline, first and second follow-up respectively. Controlling for age, gender, race, health insurance and BMI, the number of days/week following foot care in both groups increased significantly, with IRR of 1.30 in Office-GAP+ mHealth ($P < 0.01$) and 1.19 in mHealth only ($P < 0.01$). Compared with mHealth only, IRR for foot care in Office-GAP+mHealth was 1.09 ($P=0.32$).

CONCLUSIONS: Combined Office-GAP + mHealth showed significant improvement in patient general diet compared to mHealth alone. Both interventions showed significant improvement in number of days patients engaged in foot care with no significant differences between groups.

WHAT DO PATIENT-CENTERED MEDICAL HOME (PCMH) TEAMS NEED TO BETTER MANAGE CARE FOR THEIR PATIENTS AT HIGH-RISK FOR HOSPITALIZATION OR MORTALITY?

Susan E. Stockdale^{1, 2}; Marian L. Katz¹; Alicia Bergman¹; Donna M. Zulman³; Angela Denietolis⁴; Evelyn T. Chang⁵. ¹VA HSR&D, Los Angeles, CA; ²University of California, Los Angeles, CA; ³Stanford University and VA Palo Alto, Stanford, CA; ⁴Veterans Health Administration, Washington, DC; ⁵VA- Greater Los Angeles, Los Angeles, CA. (Control ID #3179213)

BACKGROUND: Some research shows that intensive primary care (IPC) programs for high-risk patients may not generate cost savings. A recent 5-site IPC demonstration within the Veterans Health Administration (VHA) found that IPC programs resulted in greater use of outpatient services, but costs of the program and increased outpatient services were offset by decreased inpatient and emergency department utilization. Using existing PCMH teams to better manage the most complex patients in primary care through enhanced resources and training may be a less costly alternative to IPC programs. Our objective was to identify which IPC components could be incorporated into PCMH teams' workflow, and what additional resources, trainings, and staff PCMH teams would need to better manage their complex patients.

METHODS: As part of a qualitative evaluation of VHA's 5-site IPC demonstration, we conducted semi-structured interviews with PCMH teams (primary care providers, nurses, social workers; n=24), primary care (n=14) and IPC program leaders (n=6). We asked interviewees which components of IPC the PCMH teams could feasibly perform and what resources, trainings, or staffing PCMH teams would need. We conducted analysis of a priori themes using a rapid qualitative analysis approach.

RESULTS: Perspectives on which IPC components would be feasible for PCMH teams to perform varied by interviewee role. Most thought that PCMH teams could do clinic-based aspects of IPC, including more frequent calls/visits with patients, patient/caregiver education and psychosocial support, referrals to community services, and managing care transitions. Home visits and co-attending appointments requiring PCMH team members' physical absence from clinic were perceived as key IPC components but less feasible for PCMH teams. Use of existing home visit services buttressed with better collaboration between PCMH teams and these services may be more feasible than PCMH teams conducting home visits. Interviewees said that PCMH teams would need full staffing (including behavioral health, pharmacy, and other ancillary services) and more dedicated time for chart reviews and assessments, interdisciplinary team meetings, and patient follow-up. Some thought that additional staffing, especially RN care managers and social workers, or smaller panels would be needed. Most thought PCMH teams could use existing care management tools and resources, but would need more training in identifying and using them, and more training in social determinants of health and patient engagement/goal setting.

CONCLUSIONS: PCMH teams may be able to adopt certain IPC practices for high-risk patients, such as more frequent contact, psychosocial support, and intensive management of care transitions, but are less suited for services such as home visits and co-attending appointments. PCMH teams need full staffing, enhanced collaboration with existing home care services, and training in use of existing tools and resources to optimally manage high-risk patients.

WHAT DO PROVIDERS WANT TO KNOW ABOUT MEDICAL LEGAL PARTNERSHIP?

Claire Popplewell¹; Johanna Martinez²; Anthony C. Serrano³; Omolara T. Uwemedimo⁶; Joseph Conigliaro⁴; Eun Ji Kim⁵. ¹Northwell Health, Manhasset, NY; ²Northwell Health, Lake Success, NY; ³Maurice A. Deane School of Law at Hofstra University, Forest Hills, NY; ⁴North Shore LIJ Health System, New Hyde Park, NY; ⁵Northwell Hofstra School of Medicine, Lake Success, NY; ⁶Northwell Health, New Hyde Park, NY. (Control ID #3170065)

BACKGROUND: Medical legal partnerships aim to address social determinants of health that require legal interventions to manage. Our healthcare system and an affiliated law school have recently partnered to create a Medical Legal Partnership (MLP) to assist our diverse patient population with various legal needs, including immigration, housing, and public benefit procurement. The MLP program was implemented in 2018 at ambulatory clinics where more than half of patients are racial/ethnic minorities with Medicaid/Medicare or who are uninsured. We conducted a qualitative study using an open-ended survey to identify providers' experience with and need for MLPs.

METHODS: We created a short survey to assess medical providers' attitudes about and previous exposure to MLPs. Participants were asked to complete this short survey during a departmental Grand Rounds session. We collected information about their role in the health system (attending physician, nurse practitioner, etc.) and years they had been in practice. The survey included items about previous exposure to medical-legal partnerships, what providers would like to learn about the Medical Legal Partnership, and how the Medical Legal Partnership could help their clinical practice. A qualitative analysis was performed to identify themes that arose from participants' responses.

RESULTS: 34 participants completed the survey. The majority of participants were attending physicians (n=19, 56%); other participants included residents/fellows (n=10, 29%), nurse practitioners (n=2, 6%), a student, and a pharmacist. Only one participant had previous experience with medical legal partnerships. Topics of interest about the MLP to participants included: (1) which patients were appropriate to refer, (2) what was the process to refer patients to the MLP program, and (3) what specific services were offered by the MLP. Three main themes emerged when participants were asked how the MLP would help their clinical practice: (1) assistance with immigration issues, (2) addressing social determinants of health through increased access to services, and (3) improving patient wellness.

CONCLUSIONS: Most clinical providers in our health system had no exposure to medical legal partnerships in the past but they were interested about learning more about them and what the logistics were of our newly-developing MLP program. Providers were hopeful that the MLP would be able to address social determinants of health that impact many of our patients as well as provide support to patients dealing with immigration concerns or other legal issues.

WHAT DO WOMEN IN THE UNITED STATES THINK OF ANNUAL VERSUS BIENNIAL SCREENING MAMMOGRAPHY?

RESULTS OF A NATIONAL SURVEY.

Mia Djulbegovic^{2, 3}; Jessica R. Hoag^{1, 7}; Jenerius Aminawung^{1, 7}; Susan Busch^{4, 1}; Xiao Xu^{1, 7}; Kelly A. Kyanko⁵; Cary Gross⁶. ¹Yale University School of Medicine, New Haven, CT; ²National Clinician Scholars Program, Yale University School of Medicine, New Haven, CT; ³Veterans

Affairs Connecticut Healthcare System, West Haven, CT; ⁴Yale University School of Public Health, New Haven, CT; ⁵NYU School of Medicine, New York, NY; ⁶Yale School of Medicine, New Haven, CT; ⁷Yale Cancer Outcomes, Public Policy, and Effectiveness Research (COPPER) Center, New Haven, CT. (Control ID #3183852)

BACKGROUND: In the United States, clinical practice guidelines (CPG) provide conflicting recommendations on whether screening mammography (SM) should be annual versus biennial. We assessed whether women who receive annual SM are aware that some CPG recommend biennial SM and whether they would be willing to change from annual to biennial SM.

METHODS: This is a cross-sectional study of women aged 40-59 years with no history of breast cancer and 1 SM. Women recruited by GfK KnowledgePanel®(a survey research firm that uses probability-based sampling) participated in an online survey in 2018. Survey items assessed whether women who reported annual SM use were aware that some CPG also recommend biennial SM and if they would be willing to change to biennial SM if their doctor recommended it. Women who were unwilling to switch to biennial screening were asked why. We used multivariable logistic regression to estimate sociodemographic factors associated with 1) awareness that some CPG recommend biennial screening, and 2) willingness to change from annual to biennial SM. The model adjusted for age, race, education, income, health insurance, history of dense breasts and geographic region. We conducted all analyses in Stata using poststratification weights to generate nationally representative estimates.

RESULTS: Of the women invited to participate, 68.2% completed the survey, of whom 60.7% reported receiving SM annually. Of these women, 50.9% were aware that some CPG also recommend biennial SM, and 42.8% were unwilling to switch to biennial SM. In adjusted analysis, women who were younger (age 40-49 versus 50-59 years, OR 0.66 [95% CI 0.49, 0.88]) and those with lower levels of education versus those with graduate degrees (did not graduate high school, OR 0.36 [95% CI 0.14, 0.93]; graduated high school, OR 0.31 [95% CI 0.19, 0.50]; completed some college, OR 0.41 [95%CI 0.26, 0.66]) were significantly less likely to be aware that some CPG recommended biennial SM. However, we found no significant association between any sociodemographic factors with willingness to change from annual to biennial SM, including awareness that some CPG recommend biennial SM. The most common reasons cited by women who were unwilling to transition to biennial SM were that annual SM: is superior at detecting breast cancer (46.1%), eases their mind (22.9%), or is part of a regular health routine that they wouldn't want to change (17.8%).

CONCLUSIONS: In this nationally representative survey, the majority of women received SM annually, approximately half of whom were unaware that some CPG recommended biennial SM, and half were unwilling to adopt biennial SM even if it was recommended by their physician. Future attempts to modify the frequency of SM use may depend on an improved understanding of the beliefs that hinder willingness to change from the existing annual approach to screening.

WHAT FACTORS IMPACT PATIENT PERCEPTIONS OF PRIMARY CARE ACCESS?: QUALITATIVE ANALYSIS OF VETERAN PATIENT INTERVIEWS

Susan E. Stockdale^{1, 3}; Alicia Bergman¹; Danielle Rose¹; Michael McGowan¹; Lisa Edwards¹; A. Laurie Graaff⁴; Timothy Dresselhaus².

¹VA GLA Healthcare System, Sepulveda, CA; ²VA San Diego Healthcare System, San Diego, CA; ³University of California, Los Angeles, CA; ⁴Veterans Health Administration, Gilbert, AZ. (Control ID #3179169)

BACKGROUND: The 2014 "access crisis" within the Veterans Health Administration (VHA) revealed that some administrative access measures (e.g., appointment wait time in days) may be susceptible to "gaming", and emphasis has since shifted to performance measures based on patient perception surveys. Although some research shows patient survey-based

measures are correlated with administrative measures, improvement efforts such as "open access" that target administrative measures may not result in improved patient perceptions. To inform improvement efforts, our objective was to understand what factors impact patients' perceptions of primary care access.

METHODS: We used a two-stage sampling approach, randomly sampling within 1 VHA region from among clinics with better than the regional average administrative access and worse than average patient survey ratings of access, stratified by clinic panel size (2 small, 1 medium, 2 large). We used quota sampling targeting 10 patients per clinic within 6 gender-by-age strata. We conducted 15-minute semi-structured telephone interviews (June-Sept. 2018) with 47 patients who had sought access to primary care for an urgent medical concern within the past 6-12 months. We analyzed qualitative data using a rapid qualitative analysis approach.

RESULTS: The response rate was 64%. Overall, Veterans were satisfied with care received and most did not describe access as problematic. To obtain access, most reported first attempting to contact the primary care clinic by telephone. A few described strategies that involved multiple modes of contact (e.g., call first, then walk in if clinic doesn't call back). Of those who reported calling, a few reached the clinic directly, but most called an administrative call center. About half reported being seen in primary care or specialty within 1 week, but a few were unable to get needed care and sought care outside VHA. The most important aspect of access for most was getting a response back to messages or a timely appointment (urgent and routine). Several mentioned communication quality or ability to contact the clinic directly as important aspects of access, and several expressed concerns about provider/staff turnover.

CONCLUSIONS: Besides appointment availability, Veterans' perceptions may be shaped by many factors, including difficulty scheduling appointments (e.g., a multi-stage triage process involving the call center, care team, and/or nurse advice line), lack of timely response to requests/questions, and staffing turnover. While most Veterans had positive experiences using VHA, our results suggest that the cumulative "hassle factor" and the steps involved in getting care may affect Veterans' responses to survey questions about access. Improving Veterans' perceptions may require a multi-faceted, multi-level intervention, including improving response/resolution time, Veteran education about the multiple modes of accessing care, and provider and staff training in patient-centered communication.

WHAT IF IT'S NOT SCREENING? HEPATITIS C ANTIBODY PERFORMANCE AND ABNORMAL LIVER TESTS

Andrew Schreiner¹; Jingwen Zhang²; Patrick D. Mauldin¹; William P. Moran¹. ¹Medical University of South Carolina, Charleston, SC; ²MUSC, Charleston, SC. (Control ID #3186057)

BACKGROUND: Hepatitis C virus (HCV) antibody (Ab) serologies are the tests of choice for HCV birth cohort screening given their high sensitivity and relatively low cost. However, how these tests perform in diagnosing HCV in patients with clinical signals of possible liver abnormality is less well known. We studied the performance characteristics of HCV Ab testing in patients with abnormal liver chemistries.

METHODS: This retrospective study of administrative data investigates diagnostic testing for HCV in primary care patients with abnormal liver tests between 2007 and 2016 in an academic patient-centered medical home (PCMH). Patients seen in the PCMH at least once and possessing at least one abnormal liver test result in the electronic health record were included in the study. Abnormal liver tests included any elevation in bilirubin, aminotransferases, or alkaline phosphatase. Patients were evaluated for the first appearing HCV serologic testing results, including both Ab (ARCHITECT) and RNA tests, during the study period. The institution's laboratory incorporated reflex HCV RNA testing in response to positive Ab tests in 2015. The sensitivity and specificity of HCV Ab testing was analyzed in comparison to the gold standard of RNA testing results, when available. We conducted this analysis on patients with at

least one abnormal liver test, and again on patients with at least 2 consecutive liver test abnormalities.

RESULTS: In total, 9,545 unique patients were studied, (Table 1). The 2,812 patients tested for HCV Ab yielded 335 (11.9%) positive results. Unfortunately, 80 (23.9%) of the HCV Ab positive patients did not have HCV RNA testing documented. Of those with RNA follow-up, 205 of 255 (80.4%) were positive. Only 54 patients with negative HCV Ab tests had RNA testing, yielding 0 (0.0%) positive RNA results. From the 309 patients with HCV Ab and RNA test results, the HCV Ab tests had a sensitivity of 100% and specificity of 51.9%. We also looked at HCV Ab performance in the 5,364 patients with consecutive liver test abnormalities. Of these patients, 2,125 had HCV Ab testing and 301 (14.2%) had positive results. From the 278 patients with consecutive liver test abnormalities and HCV Ab and RNA results, the sensitivity of HCV Ab testing was 100% and the specificity was 53.3%.

CONCLUSIONS: HCV Ab testing is highly sensitive but poorly specific in primary care patients with abnormal liver tests. While such performance suits birth cohort screening, HCV Ab testing (vs. RNA) in response to potential signals of liver abnormality may contribute to diagnostic error (i.e. false positives with patient worry and missing follow-up) and added costs. Future investigation with a cost-effectiveness analysis in similar patient populations is warranted.

WHAT IS MISUSE? CLINICIAN CONSENSUS ON SECURE MESSAGING WITH PATIENTS

Joy L. Lee^{1, 3}; Marianne S. Matthias^{2, 3}; Michael Weiner^{4, 3}. ¹Indiana University School of Medicine, Indianapolis, IN; ²Roudebush VAMC, Indianapolis, IN; ³Regenstrief Institute, Indianapolis, IN; ⁴Indiana University, Indianapolis, IN. (Control ID #3185246)

BACKGROUND: Secure messaging provides patients access to clinicians, care, and health information. Yet misuse of secure messaging by both patients and clinicians can lead to miscommunications and errors. We sought to uncover variations in provider approaches and responses to messaging, particularly their perceptions of appropriateness, and preferences for when to use secure messaging, to understand the potential to improve care via this mode of communication.

METHODS: This qualitative study targeted primary care clinicians from a Midwestern Veterans Affairs medical center and a tax-supported safety-net medical center. Participants were presented with five clinical vignettes and corresponding secure messages from hypothetical patients, asked to compose responses, and then interviewed about the messaging process, their preferences for how to respond, as well as their understanding of appropriateness. Recruitment is still ongoing and will continue until the findings reach saturation.

RESULTS: We uncovered key differences in clinicians' (13 physicians, 2 nurse practitioners, and 4 registered nurses) experiences with, and perceptions of, secure messaging. Clinicians disagreed about the circumstances for which responding to a secure message from patients by secure messaging was preferred over telephone calls with patients. Their rationales revealed differences in understandings of appropriate uses of secure messaging. There was most, but not complete, agreement that secure messaging should not be used to respond to a message from a patient with an urgent health issue (95% preferred to call) or symptoms of depression (89%). Clinicians disagreed regarding their use of secure messaging to discuss medication adjustments and laboratory results, and to respond to a dissatisfied patient. Although the 19 clinicians represented diversity in their approaches and secure messaging workload—half received 10 or fewer messages a week, and half received more—all indicated that the workload was manageable.

CONCLUSIONS: Among physicians, nurse practitioners, and nurses, this study revealed variations in approaches to secure messaging, particularly a lack of consensus about preferences and perceptions of appropriateness of secure messaging. Clinicians' perspectives about secure messaging can influence their patients' adoption and use of the technology.

Further guidance on the appropriateness and effectiveness of the delivery of various facets of care through secure messaging may aid both clinicians and patients. Future work will explore patient understandings of appropriateness and misuse.

WHAT MAKES A MEDICAL STUDENT LEADER? AN EXPLORATORY STUDY OF STUDENTS' PERSPECTIVES ON LEADERSHIP

Alison M. Holliday¹; Galina Gheihman¹; Erin E. Sullivan¹; Amy M. Sullivan¹; Rebecca Karp Leaf^{2, 1}. ¹Harvard Medical School, Boston, MA; ²Massachusetts General Hospital, Boston, MA. (Control ID #3184898)

BACKGROUND: Physicians hold leadership roles within healthcare and within spheres of education, business, and government. Yet few medical students receive formal leadership training. While medical schools are beginning to recognize the need for a leadership curriculum, there is a gap in understanding of how students view themselves as leaders. We conducted an exploratory study to characterize medical students' perception of leadership and identify areas of improvement in leadership training at a top medical school.

METHODS: Two open-ended questions related to leadership were included as part of a larger cross-sectional survey between June and August 2018 at Harvard Medical School. We invited 753 students by email to complete a web-based survey with five follow-up reminders. We asked students to describe via free text responses: 1) characteristics and behaviors of successful medical students, and 2) what being a leader as a medical student means. We analyzed results in aggregate but separate from primary survey responses and used qualitative content analysis to identify major themes.

RESULTS: The primary survey response rate was 64% (n=485); 467 (96%) of those participants completed the free-text responses. The scope and frequency of successful medical student characteristics and behaviors identified by respondents is shown in a word cloud. Qualitative content analysis to analyze what being a leader means to students revealed three major themes: 1) domains in which students could demonstrate leadership: classroom, clinical domain, and wider society; 2) leadership qualities: adaptable, emotionally intelligent, diligent; and 3) leadership practices: supporting others, taking initiative, staying true to one's values, demonstrating resilience and vulnerability, maintaining a healthy lifestyle, and showing humility, among others.

CONCLUSIONS: Medical students see an important role for student leaders in the classroom, the clinical setting, and within society at large. Curricula should be developed to build leadership skills and practices aligned with themes identified by students—fostering courage, resilience, vulnerability, self-care, integrity, and commitment to serving others. Practicing these qualities and behaviors may help individuals demonstrate student leadership, becoming effective team members, providing excellent clinical care, and maintaining their own sense of wellbeing.

Figure 1. Student responses to the open-ended query, "In your opinion, a successful medical student has the following characteristics and behaviors:"

WHAT STUMPS PRIMARY CARE CLINICIANS? FIRST PHASE ANALYSIS OF DIAGNOSTIC UNCERTAINTY CASES

Lucia S. Sommers¹; Viralkumar Vaghani^{2, 3}; Traber Giardina^{2, 3}; Hardeep Singh⁴. ¹University of California, San Francisco, San Francisco, CA; ²Baylor College of Medicine, Houston, TX; ³Center for Innovations in Quality..., Houston, TX; ⁴Michael E. DeBakey Veterans Affairs Medical Center and Baylor College of Medicine, Houston, TX. (Control ID #3148418)

BACKGROUND: Diagnostic difficulty is frequent in primary care, yet we know little about situations that present uncertainty to primary care practitioners (PCPs). We explored how PCPs discuss diagnostic conundrums with colleagues, frame dilemmas, and seek/receive support. These findings could advance understanding of knowledge/cognitive problems contributing to diagnostic error.

METHODS: We analyzed data from 459 uncertainty cases compiled by the first author while PCPs presented cases to peers in "Practice Inquiry Colleague Groups" conducted at 17 San Francisco-Bay Area PCP practices from 10/2002 to 9/2015. Clinicians discussed patients where they encountered uncertainty of any type (e.g., diagnostic, ethical) for ideas and support. Meeting notes on each case included: 1)PCP presenter's uncertainty statement; 2) patient's medical history; and 3) Colleague Group's discussion summary. We assessed meeting notes for diagnostic uncertainty building on criteria developed in prior work on measuring uncertainty from EMR review. Specific data collected for analysis: presenters' uncertainty statement, abnormal physical exam, abnormal test/imaging findings; diagnoses/conditions under consideration by presenter; and patients' prior diagnoses/known conditions. Two authors analyzed data using a consensus approach to reconcile differences.

RESULTS: Of 459 cases discussed, 258(56%) involved diagnostic uncertainty. Most cases involved women (61%); median age decade 50-59 years. Most(93%) had one/or more physical complaints and/or abnormal findings. (See Table.) Colleagues speculated about specific diagnoses/conditions contributing to uncertainty in 129 cases (50%); of these, 27% were mental/behavioral/neurodevelopmental conditions. They discussed patients' prior diseases/ known conditions related to the uncertainty in 183 (71%) cases; of these, 17% were mental/behavior/ neurodevelopmental conditions. Adverse events were reported in 14% of cases including 6 deaths.

CONCLUSIONS: Practice inquiry-based techniques illustrate unique diagnostic uncertainties faced by PCPs. Certain situations, such as patients with mental, behavioral or neurodevelopmental conditions, might pose particular diagnostic challenges. This small-group process also facilitated discussions of diagnostic error and patient harm. We now plan to analyze colleagues' responses to these cases

First Phase Findings: What Stumps PCPs?

| PCP Presenters' Data Category | #/% Cases |
|---|-----------|
| 1. Types of Diagnostic Uncertainties (N = 258 cases) | |
| • ≥1 non-pain, physical symptom | 182 (71%) |
| • ≥1 abnormal lab/imaging finding | 87 (34%) |
| • ≥1 pain symptom | 72 (28%) |
| 2. Possible Diseases/Conditions (ICD-11) (N = 171 diseases/conditions) | |
| • Mental, behavioral or neurodevelopmental disorders | 46 (27%) |
| • Diseases of the nervous system | 14 (8%) |
| • Diseases of the circulatory system | 14 (8%) |
| 3. Past, Known Diseases/Conditions (ICD-11) (N= 402 diseases/conditions) | |
| • Mental, behavioral or neurodevelopmental disorders | 70 (17%) |
| • Endocrine, nutritional or metabolic diseases | 50 (12%) |
| • Diseases of the circulatory system | 42 (10%) |

WHEN LESS IS MORE: EVALUATION OF POST-PARACENTESIS ALBUMIN DOSAGE AND ADVERSE EVENTS IN HOSPITALIZED PATIENTS.

James E. Anstey³; Claire Bainbridge²; Wendi Zhao¹; Yumiko Abe-Jones³; Marissa Hom²; Anthony Wong²; Priya A. Prasad²; Margaret Fang⁴; Andrew Lai³. ¹University of California San Francisco, San Francisco, CA; ²UCSF, San Francisco, CA; ³University of California at San Francisco, San Francisco, CA; ⁴University of California, San Francisco, San Francisco, CA. (Control ID #3185261)

BACKGROUND: Large volume paracentesis is commonly performed in patients with refractory ascites but can induce hypotension and kidney injury. There is evidence that administering albumin at 6-8 grams per liter (g/L) of ascites removed during paracentesis can reduce these adverse events. Guidelines recommend this practice when >2 liters are removed in high-risk patients or >5 liters in any patient. Despite these guidelines, clinical practice varies widely potentially resulting in albumin overuse. We retrospectively analyzed the association of albumin dose and adverse events following large volume paracentesis in hospitalized patients at a single academic teaching hospital.

METHODS: Patient data were obtained from a registry of all procedures performed by a hospitalist procedure service at an academic teaching hospital from June 2013 to July 2018. We identified all patients who received large volume paracentesis (>2 L) and obtained electronic health record data on vital signs, laboratory tests, patient demographics, severity of illness, and albumin administration. We excluded patients with severe chronic kidney disease (serum creatinine [Cr] >3), for whom albumin was not indicated, or who received >25 g/L of albumin (considered treatment for hepatorenal syndrome). Albumin administration was categorized as 6-8 g/L vs >8 g/L. We used multivariable logistic regression to test the association between albumin dose and acute kidney injury (AKI), defined as >30% increase in serum creatinine over 72 hours post-procedure. We also examined mean change in systolic blood pressure (SBP) 24 hours post-procedure.

RESULTS: A total of 452 patients underwent >2L paracentesis (182 with >5L removed) and were eligible for analysis. One hundred fifty-four (34%) were on the medicine service, 226 (50%) on the liver transplant service, and 72 (16%) on all other services. In all, 85 (19%) patients received 6-8 g/L, and 367 (81%) received >8 g/L of peri-procedural albumin. Patients who received >8 g/L of albumin were more likely to have a higher baseline Cr (1.18 vs 1.41; mean difference 0.23 [95%CI: 0.08-0.37] p=0.003), higher MELD score (18.5 vs 21.3, mean difference 2.8 [95% CI: 0.48-5.06] p=0.018) and be on the liver transplant service (p <0.001). Multivariate analysis showed albumin dosage was not associated with post-procedure AKI (10.4% in 6-8 g/L vs 16.9% in >8 g/L, adjusted OR 1.24 [95% CI: 0.52-2.99], p=0.625). Post-paracentesis mean change in SBP also did not differ by albumin dose (mean SBP drop of 2.95 in 6-8 g/L vs 4.36 in >8 g/L, Coefficient = 0.71 [95% CI -1.92 - 3.34], p=0.594).

CONCLUSIONS: Patients undergoing large volume paracentesis at our institution received widely varying doses of albumin, with the majority of patients receiving >8 g/L. Albumin doses above current guidelines were not associated with a lower incidence of AKI or mean drop in SBP following paracentesis. Given the high cost of albumin and potential for volume overload, guideline-recommended dosing should be more consistently adopted.

WHEN THE TEAM WINS, YOU WIN: RESIDENT PERSPECTIVES ON IDENTITY FORMATION IN INTERPROFESSIONAL TEAMS AND LESSONS FOR GENERAL MEDICAL EDUCATION

Katarzyna Mastalerz^{1, 2}; Sarah Jordan²; Nikki Townsley². ¹Rocky Mountain VAMC, Aurora, CO; ²University of Colorado, Aurora, CO. (Control ID #3171551)

BACKGROUND: Forming team-oriented professional identities is essential to becoming effective team members in healthcare settings. However, little is known about how medical residents form professional identities in the context of interprofessional teams. In order to inform lessons for graduate medical education, we sought to understand residents' perspectives on and experiences with forming professional identities while working with interdisciplinary teams.

METHODS: We conducted a qualitative study using in-depth, semi-structured interviews with medical residents working on Accountable Care Units (ACU, a geographic team-based unit) at one community teaching hospital between July 2017 and March 2018. Interviews explored perceptions of teamwork and professional roles and identities. All residents that rotated on the ACU were eligible for inclusion. Interviews were audio-recorded, transcribed, and entered into qualitative software for organization (Atlas.ti.v8). During regular group meetings, we systematically analyzed interview transcripts and identified emerging themes using inductive thematic analysis. Saturation was reached.

RESULTS: Twenty-five interns and 16 senior residents were interviewed (n=41). Resident participants were predominantly male (65%) and Caucasian (65%). Three key themes emerged: 1) negotiating new roles in team structures, 2) learning to self-advocate and integrate personal expertise into hierarchical team settings, and 3) bolstering professional identities by incorporating interprofessional expertise. Senior residents described new tensions in their identities as both learners and experts; interns described feeling '*responsible but powerless*.' Interns and residents both practiced strategies to integrate their own growing expertise into interprofessional teams and to '*find their voice*.' Senior residents recognized their dependence on interprofessional team members and sought out ways to defy existing hierarchies that constrained interdisciplinary teamwork. Interns struggled with balancing their lack of experience with the tenure of others, and with responding to the implicit expectation for physician leadership. Residents felt that their constant movement between rotations impaired authentic teaming. These perspectives inform several strategies for medical education that could support the creation of team-oriented professional identities for residents: longitudinal integrated programs, purposeful interprofessional shadowing experiences, and explicit leadership curricula.

CONCLUSIONS: Understanding resident professional identity formation provides insight into how residents integrate into interprofessional teams. Based on our study, residency is a time of a growing awareness of interprofessional work and its challenges. We suggest several education strategies that may improve resident interprofessional teaming skills and the formation of team-oriented professional identities.

WHERE IS ALL THE MIXING HAPPENING? A VENUE-BASED ANALYSIS OF SEX NETWORKS IN BALTIMORE, MD

Benjamin Meza²; Ian McCulloh²; Marc A. Johnson¹; Ravikiran Muvva³; Carla Tilchin²; Jacky M. Jennings^{2, 2}. ¹Johns Hopkins University, Laurel, MD; ²Johns Hopkins University, Baltimore, MD; ³Baltimore City Health Department, Baltimore, MD. (Control ID #3185626)

BACKGROUND: Baltimore has some of the highest numbers of new HIV and syphilis cases in the country. Nationally, STI prevention strategies often target specific priority populations (i.e., men who have sex with men [MSM], individuals who inject drugs [IDU], commercial sex workers [CSW], youth under 25 years old), yet studies show that transmission frequently occurs between different priority populations. Our objective was to use social network analysis to map the extent to which different physical and online spaces serve as sites of mixing and identify venues to focus limited prevention resources.

METHODS: We employed data from the Baltimore City Health Department on all new cases of HIV and syphilis reported in Baltimore City from 2009 to 2015. Data included the type of STI, demographic characteristics, priority population classification, self-reported high-risk behaviors, and sex partner meeting venues visited in the last 12 months. We created a

social network in which venues were linked to one another via the individuals who reported those venues. We then applied a novel method to reduce the network's complexity, improving interpretability. Our method applies a Jaccard similarity algorithm followed by an irreducible backbone to derive a simplified version of the network that maintains important structural features. Using this network of sex partner meeting venues, we drew network diagrams to describe where mixing between priority populations was occurring.

RESULTS: The analytic set consisted of 932 new cases of HIV (31.9%), syphilis (64.8%), and HIV-syphilis coinfection (3.3%). The median age at diagnosis was 27 years, 72.7% were Black, 72.5% were classified as MSM, 12.0% as CSW, and 4.5% as IDU. From a total of 1511 nominations, we identified 425 unique venues, including bars/clubs (13.2%), internet/apps (12.7%), and street addresses (53.6%). The simplified network consisted of 259 venues and 356 links, with a single large interconnected group of 143 venues at its core. Unexpectedly, Facebook received the greatest number of nominations (17.6% of all nominations) but was completely disconnected from this core group. Similarly, other large internet venues were highly nominated but were absent from central positions that would make them important mediators of transmission across the network. As expected, highly nominated venues were associated with greater mixing of priority populations, but exceptions to this pattern highlight unique qualities of certain venues, e.g., Craigslist was associated with a small, unconnected cluster of venues with multiple priority populations.

CONCLUSIONS: This study provides preliminary evidence that certain venues are important spaces for mixing between priority populations. We demonstrate a method for capturing difficult to measure local sex networks and reducing their complexity to identify discrete spaces where interventions may have the greatest impact on interrupting STI transmission.

WHO HAS PRIMARY CARE IN THE UNITED STATES, 2002 TO 2015

David M. Levine¹; Jeffrey A. Linder²; Bruce E. Landon³. ¹Brigham and Women's Hospital, Boston, MA; ²Northwestern University Feinberg School of Medicine, Chicago, IL; ³Harvard Medical School, Boston, MA. (Control ID #3185704)

BACKGROUND: Primary care - first contact, comprehensive care that is coordinated and continuous - is considered an essential component of well-functioning health care systems. The clinical and demographic characteristics of Americans with primary care, and changes over time, are unknown.

METHODS: We analyzed 2002-2015 data from the Medical Expenditure Panel Survey, a nationally-representative annual survey of the non-institutionalized US civilian population. We used a patient-centered definition of primary care to replicate the 4 "C's" of primary care, requiring that an individual had an identified physician for "new health problems" (first contact); "preventive health care, such as general checkups, examinations, and immunizations" (comprehensive); "ongoing health problems" (continuous); and "referrals to other health professionals when needed" (coordinated). To identify how the odds of having primary care changed between 2002 and 2015, we performed multivariable logistic regression controlling for over 20 sociodemographic characteristics, including clinical and health status. We also examined beliefs about health insurance over time.

RESULTS: In 2002, 77% (95% CI, 76 to 78) of Americans had primary care vs 75% (95% CI, 74 to 76) in 2015 ($p=0.01$), representing 4.2 million fewer Americans without primary care in 2015. Receipt of primary care increased with age, but younger Americans were less likely to have primary care in 2015 than 2002. For example, in 2015, 64% of 30-year-olds had primary care compared to 71% in 2002 ($p<0.01$). Americans less likely to have primary care included those who were male (aOR vs females, 0.61 [95% CI, 0.57 to 0.65]), Latino (aOR vs Whites, 0.72 [0.64-0.8]), resided in the South (aOR vs the West, 0.83 [0.74-0.94]),

and poor (aOR vs high income, 0.60 [0.51-0.70]). Americans more likely to have primary care included those who resided in the Northeast (aOR vs the West, 1.49 [1.26-1.76]), were married (aOR vs not married, 1.23 [1.11-1.37]), privately insured (aOR vs uninsured, 3.08 [2.75-3.44]), and unemployed (aOR vs employed, 1.15 [1.05-1.26]). After adjustment, Americans overall were significantly less likely to have primary care in 2015 than in 2002 (aOR, 0.77 [0.69-0.84]). Other[BL1] predictors of having primary care were generally stable over time, except for race/ethnicity and census region. Between 2002 and 2015, Latinos increased their receipt of primary care by 15% ($p=0.04$) and northerners decreased by 12% ($p=0.03$). In 2015, 46% (44-47) of those with primary care vs 27% (26-29) of those without primary care believed health insurance was worth the cost, and 68[BL2] % (67-69) vs 40% (38-42), respectively, believed they needed health insurance.

CONCLUSIONS: Significantly fewer Americans had primary care in 2015 than in 2002, particularly among younger Americans. To our knowledge, this is the first nationally-representative description of receipt of primary care and demonstrates an alarming trend toward a reduction in primary care health care relationships.

WHO, WHAT, AND WHERE? MULTIPLE CHRONIC CONDITIONS IN A LOW-INCOME, VALUE-BASED URBAN COHORT: CLUSTERING FOR INTERVENTION

Usnish Majumdar¹; Christophe Hunt²; Patrick Doupe¹; Aaron Baum¹; David J. Heller¹; Rashi Kumar³; Robert Futterman³; Cother Hajat⁴; Erica Levine¹; Sandeep Kishore¹. ¹Icahn School of Medicine at Mount Sinai, New York, NY; ²Mount Sinai Health Partners, New York, NY; ³Healthfirst, New York, NY; ⁴United Arab Emirates University, Al Ain, United Arab Emirates. (Control ID #3185543)

BACKGROUND: In the US, patients with multiple chronic conditions (2, MCC) account for more than 70% of all healthcare spending. Health systems have responded to this challenge with both clinical and financial innovations. Importantly, efforts to select sub-populations for intervention have been limited methodologically, and it remains difficult to compare and contrast the clinical and financial reforms enacted in different patient populations. Furthermore, literature on MCC patterns and trends among lower socioeconomic status and vulnerable populations is scarce, despite their carrying a disproportionately large share of chronic disease burden. In this study, we aim to (1) examine the burden of MCC in the low-income population served by an urban health system, and (2) propose a methodology to identify sub-populations of interest for both clinical and financial interventions.

METHODS: We used retrospective data from capitated Medicaid contracts in an urban health system. Combined data from 2012-2014 from 192,085 plan members were analyzed. Adults were categorized as having any number of chronic diseases from a list of 69 chronic conditions provided by the Agency for Healthcare Research & Quality (AHRQ). After summarizing the demographics, geography, and prevalence of MCC within this population, we then explored groups of patients (clusters) using a novel methodology: We iteratively defined all (26,495) potential clusters of patients as defined by a pair of chronic conditions, a sex, and an age group, and then ranked them by frequency, cost and ratios of observed to expected frequencies of co-occurring chronic conditions. We further explored the presence of certain clusters within bounded geographic "hot-spots" to suggest opportunities for co-localized specialty clinics.

RESULTS: 52.7% of the study population suffers from MCC, as compared to 42% nationally. The most frequent pair was hypertension and hyperlipidemia (18% age-adjusted) and the most frequent trio was diabetes, hypertension and hyperlipidemia (9% age-adjusted). Women aged 50-65 with hypertension and hyperlipidemia were the leading cost segment in the study population. Medicaid patients are concentrated geographically and MCC burden differs by locale. Of note, we find that anemia, pulmonary heart disease, congestive heart failure, and conduction disorders occur together more frequently than expected in geographically distinct locales.

CONCLUSIONS: In this low-income, urban population, multiple chronic conditions are more prevalent than nationally. Furthermore, our identification of costly and co-occurring conditions in a capitated cohort of patients demonstrates potential for our novel methodology to inform decision-making in healthcare administration, especially under new value-based financing schemes. We argue this methodology has utility for health systems, financiers, and researchers working to address MCC, and provide a common approach to targeting populations for financial and clinical intervention.

WITHIN AFRICAN-AMERICAN HETEROSEXUAL HIV-SERODISCORDANT COUPLES, AWARENESS OF PRE-EXPOSURE PROPHYLAXIS (PREP) AMONG HIV-POSITIVE PARTNERS PREDICTS PREP AWARENESS AMONG HIV-NEGATIVE PARTNERS

Alicia Morehead-Gee¹; Tamra B. Loeb²; Muyu Zhang²; Gail Wyatt².

¹National Clinician Scholars Program at UCLA, Los Angeles, CA;

²UCLA, Los Angeles, CA. (Control ID #3185748)

BACKGROUND: Although approximately 500,000 African-Americans qualify for pre-exposure prophylaxis (PrEP, a daily pill to prevent HIV infection) in the US, only 1% of African-Americans eligible for PrEP have received a prescription (CDC 2018), raising the issue of a possible lack of PrEP awareness among this population. This study examines whether sociodemographic factors, HIV-transmission-related behaviors, health systems experiences, and/or partner factors were associated with PrEP awareness among HIV-negative African-Americans in heterosexual HIV sero-discordant couples in South Los Angeles (LA).

METHODS: Cross-sectional baseline survey data was collected from 2013 to 2016 through "Eban II: Intervention for HIV Sero-Discordant Couples," an implementation study of a risk-reduction intervention for African-American heterosexual HIV sero-discordant couples. The primary outcome measure was PrEP awareness. Predictor variables included sociodemographic factors, HIV-transmission-related factors (including direct [condom use, multiple sex partners] and indirect [mental health disorders, history of trauma] factors), health systems experiences (including satisfaction with doctor and experiences of discrimination), and HIV-positive partner's PrEP awareness. Multiple logistic regression was used to create adjusted odds ratios (aOR) of PrEP awareness according to predictor variables.

RESULTS: Ninety-one (91) participants were enrolled in the study, including 46 (50.5%) HIV-negative participants. Among HIV-negative participants, 32 (69.6%) were male, average age was 51.9 years, 6 (13.3%) were employed, and 43 (93.5%) had health insurance. Eleven (24.4%) HIV-negative participants were aware of PrEP. In examining sero-discordant couples as a unit, 6 (14.0%) of 43 couples had shared PrEP awareness. In bivariate analyses, HIV-negative participants were more likely to be aware of PrEP if they felt that their doctor "understood their background and values" ($p = 0.02$) or if their HIV-positive partner was aware of PrEP ($p = 0.0008$). Factors related to sociodemographics, HIV transmission risk, and other health systems experiences had no significant association with PrEP awareness. Controlling for age, gender and presence of a regular doctor, HIV-negative participants had higher odds of PrEP awareness if their HIV-positive partner was aware of PrEP (aOR 48.8, 95% confidence interval [CI] 4.2 to 562.9).

CONCLUSIONS: Few HIV-negative African-Americans were aware of PrEP despite meeting criteria (HIV-serodiscordant relationship) to take PrEP. We found that HIV-positive partners' PrEP awareness significantly predicted HIV-negative participants' PrEP awareness, demonstrating the importance of PrEP education for people living with HIV in sero-discordant relationships. There was no association between PrEP awareness and factors related to sociodemographics or HIV transmission risk, which implicates a need to increase efforts to screen African-American patients for HIV risk and provide PrEP information to those at risk.

WORK REQUIREMENTS IN MEDICAID: RESULTS FROM THE FIRST YEAR OF ARKANSAS'S PROGRAM

Benjamin D. Sommers^{1, 2}; Anna Goldman^{1, 4}; Robert Blendon¹; E. John Orav^{2, 1}; Arnold M. Epstein^{3, 2}. ¹Harvard School of Public Health, Brookline, MA; ²Brigham & Women's Hospital, Boston, MA; ³Harvard School of Public Health, Boston, MA; ⁴Cambridge Health Alliance, Cambridge, MA. (Control ID #3185359)

BACKGROUND: Six states have received approval to implement work requirements in Medicaid, and nine others have proposed similar requirements. Arkansas became the first state to implement this policy in June 2018, requiring beneficiaries ages 30-49 to report at least 80 hours a month of employment or other "community engagement" activities to maintain their coverage. The state began disenrolling people not meeting the reporting requirement in October 2018. We conducted a novel telephone survey in late 2018 to assess the policy's early effects.

METHODS: We conducted a random-digit dialing telephone survey of low-income adults in four states - Arkansas, Kentucky (which also plans to implement work requirements, but implementation has been blocked by a federal judge), Louisiana, and Texas - from November 8 to December 30, 2018. We assessed employment, other qualifying community engagement activities (e.g., job training, community service, and childcare), health insurance, and several measures of health care access in all four states. We also explored knowledge of and experiences with the work requirements among Arkansans; for this reason, we oversampled respondents in this state ($n=1501$), particularly 30-49 year-olds subject to the requirements. We compared their responses to those from the other three states ($n=1504$), as well as historical data from a similar survey conducted in 2016 in these states ($n=2951$), to estimate changes in outcomes before and after work requirements, using a difference-in-differences design.

RESULTS: 59% of 30-49 year-olds in Arkansas were aware of the new policy, with awareness lowest among those without a high school degree. Among those who were told by the state that they needed to report their employment status to maintain Medicaid, only 49% were doing so regularly. Medicaid coverage in Arkansas for 30-49 year-olds decreased (-15.1%, $p=0.004$) and uninsured rates increased (+6.7%, $p=0.04$) since 2016, compared to those not subject to the new requirements. There were no significant changes in access to primary care or affordability of care associated with the policy thus far. Meanwhile, the policy to date has not lead to any significant change in employment, hours worked, or other community engagement activities. Notably, more than 95% of respondents were already spending at least 80 hours a month on required activities or appear to qualify for an exemption such as a disability.

CONCLUSIONS: The first six months of Arkansas's Medicaid work requirements led to significant coverage losses for low-income adults, without any detectable impact on employment or other community engagement behavior. Many adults subject to the requirements were not aware of them, and less than half were regularly reporting their activities to the state (putting them at risk for disenrollment), even though most respondents already met the policy's requirements. Future studies will be needed to explore this policy's longer-term impact.

WORRY ABOUT MEDICAL EXPENSES AND ITS ASSOCIATIONS WITH PATIENTS' QUALITY OF LIFE IN END-OF-LIFE CANCER CARE

Lauren Kelly¹; Holly G. Prigerson²; Paul K. Maciejewski². ¹New York Presbyterian - Weill Cornell Medical Center, New York, NY; ²Weill Cornell Medical College, New York City, NY. (Control ID #3185602)

BACKGROUND: Burdensome medical costs disproportionately affect cancer patients compared to patients with other chronic illnesses. Cancer patients who are uninsured, a high proportion of whom are Black and Latino, face an even greater degree of financial hardship related to their

medical care. A growing body of literature suggests that financial burden, or financial toxicity, has harmful effects on well-being and health-related quality of life (QoL). This study investigates patients' worry about paying medical expenses (WAPME) and its association with their QoL in end-of-life (EoL) cancer care.

METHODS: The sample includes patients (N=343) who participated in Coping with Cancer-II (CwC-II), a multi-site observational cohort study between 2010-2015 to examine racial and ethnic disparities in EoL cancer care. Measures included assessments of patients' sociodemographic characteristics (age, sex, race, ethnicity, education and health insurance status), degree of WAPME, and QoL (using the multi-domain McGill QoL Questionnaire). Unadjusted and adjusted odds ratios between patient WAPME and patient sociodemographic characteristics were estimated using ordinary and multiple ordinal logistic regression, respectively. Odds ratios between dichotomized patient QoL outcomes and patient worry about paying medical expenses, adjusted for patient sociodemographic characteristics (and, for some models, patient psychological well-being), were estimated using multiple logistic regression.

RESULTS: Patients who were less than 65 years of age (OR=2.67, p<0.001), female (OR=1.60, p=0.037), Black (OR=1.69, p=0.039), Latino (OR=2.52, p=0.003) and uninsured (OR=3.40, p<0.001) were more likely to have WAPME. Adjusting for other sociodemographic characteristics, only patients' sex (female vs. male; AOR=1.65, p=0.038) and insurance status (uninsured vs. insured; AOR=2.46, p=0.012) remained significantly associated with patients' WAPME. Adjusting for sociodemographic characteristics, patients' WAPME was associated with worse psychological (AOR=0.66, p<0.001) and existential (AOR=0.75, p<0.002) well-being, as well as worse physical symptoms (AOR=0.77, p<0.025) and worse overall QoL (AOR=0.70, p<0.001). Patients' psychological well-being mediated the effects of WAPME on their existential well-being, physical symptoms QoL and overall QoL.

CONCLUSIONS: Health insurance disparities may explain racial and ethnic disparities in worry about paying medical expenses in EoL cancer care. Advanced cancer patients' WAPME has a direct, adverse association with their psychological well-being, and has indirect, adverse associations with their existential well-being, physical symptoms QoL and overall QoL. This investigation extends findings on financial toxicity in that it highlights the importance of patients' psychological well-being as a key (modifiable) mediator of the effects of financial distress on patients' physical and spiritual well-being.

WORTH THE WEIGHT? RESIDENT ATTITUDES TOWARD DIET AND EXERCISE COUNSELING

Adam Prince; Yashvi Patel; Rebecca Mazurkiewicz. Lenox Hill Hospital, New York, NY. (Control ID #3185201)

BACKGROUND: Recent studies suggest nearly 80% of chronic diseases can be prevented through regular exercise, maintaining a healthy weight, healthy diet, and not smoking. We aimed to assess the attitudes, knowledge, and confidence of medicine residents toward lifestyle risk factor modification counseling in the outpatient setting.

METHODS: We sent an electronic, anonymous survey to categorical internal medicine residents of PGY1, PGY2, and PGY3 levels at Lenox Hill Hospital, a community hospital in New York, NY. This ten question survey was sent in February 2018, and assessed importance placed on lifestyle risk factor counseling, frequency of discussions in appropriate patients, comfort with counseling, familiarity with evidence-based behavioral change techniques, and confidence that patients would make changes based on counseling interventions.

RESULTS: Our survey received 41 out of 77 resident responses, including 10 PGY1, 16 PGY2, and 15 PGY3 residents; 23 respondents were male and 18 were female. Lifestyle counseling was rated

as very or extremely important to 95% of respondents. Similarly, 78% stated that they usually or always discuss lifestyle risk factors in the outpatient clinic. With regard to comfort in providing counseling, 69% responded that they were very or extremely comfortable, but 32% rated their comfort as somewhat or slightly comfortable. For duration of counseling, 71% indicated that they spent 3-10 minutes providing counseling per intervention. When asked about techniques for counseling, only 12% stated that they were familiar with evidence-based methods for behavior change. Lastly, only 7% of residents rated themselves as very or extremely confident that patients would make changes based on counseling, while 78% were slightly or somewhat confident, and 15% were not at all confident.

CONCLUSIONS: Residents at our institution place high importance on lifestyle risk factor counseling interactions and most feel comfortable having these conversations with applicable patients in the outpatient setting. However, residents do not appear to have a ready repertoire of evidence-based behavior change techniques, and do not feel that their counseling will be effective in leading to actual behavior change. This highlights the importance of teaching internal medicine residents evidence-based behavior change techniques. We are in the process of developing an educational intervention to provide our residents with tools for lifestyle risk factor modification counseling.

YOU ARE WHAT YOUR SOCIAL NETWORK EATS: PUBLIC HOUSING SOCIAL NETWORKS AND FAST FOOD CONSUMPTION

Benjamin Meza¹; Craig E. Pollack²; Kimberly Gudzune³. ¹Johns Hopkins, Baltimore, MD; ²Johns Hopkins University School of Medicine, Baltimore, MD; ³Johns Hopkins University, Baltimore, MD. (Control ID #3162713)

BACKGROUND: High sodium diets, such as those that include fast food, are associated with cardiovascular disease (CVD), illnesses which occur at twice the rate among public housing residents as the general population. Perceived dietary patterns of one's social network members are theorized to set dietary norms and model practices that influence one's own dietary behaviors. As a basis for using social network principles as part of dietary interventions among public housing residents, our objective was to determine the association of high fast food intake among one's social network members and an individuals' own fast food consumption.

METHODS: We conducted a cross-sectional survey of randomly selected households in public housing complexes in Baltimore, MD from August 2014 to August 2015. Adult survey respondents answered an in-person survey of questions regarding their own diet, perceived dietary habits among their social network members, and the frequency of interaction with and among their social network members. Our dependent variable was self-reported frequency of fast food intake, dichotomized to eating fast food at least once daily or less than once daily. Our independent variable was the proportion of the respondent's social network who were perceived to consume fast food at least once daily. We used multivariable logistic regression to examine the association between the respondent's fast food consumption and consumption among their social network members, adjusted for individual demographic and health covariates as well as social network factors.

RESULTS: The sample included 266 respondents (response rate 48%). Mean age was 44.5 years, 86.1 % were women, 95.5% were Black, and 58.3% had a history of CVD (hypertension, myocardial infarction, cerebrovascular accident, or congestive heart failure). On average, 7.1% of respondents ate fast food daily themselves and the perceived proportion of network members who ate fast food daily was 10.5%. After adjustment, there was a significant positive relationship between respondents eating fast food daily and a greater proportion of their social network members eating fast food daily (OR 1.18, 95%CI [1.00, 1.38], p=0.034).

CONCLUSIONS: We found a strong positive association between one's own consumption of fast food and fast food consumption in their social network. Our results highlight the importance of considering one's social network when designing dietary interventions, particularly among low income urban populations such as public housing residents at high risk of CVD.

YOU CAN'T SCALE UNICORNS: EXPLORING COMMUNITY BASED ORGANIZATIONS' PERSPECTIVES ON HEALTH CARE'S SOCIAL DETERMINANTS OF HEALTH PROGRAMMING

Elena Byhoff¹; Lauren A. Taylor². ¹Tufts Medical Center, Boston, MA; ²Harvard Business School, Boston, MA. (Control ID #3183013)

BACKGROUND: Policymakers are interested in the appropriate role for health care organizations in addressing social determinants of health (SDOH). Recent changes in Massachusetts Medicaid policy encouraged health care organizations to screen for and address SDOH deficits through Medicaid ACO models. Little is known about how community-based organizations (CBOs) view this new policy, nor how it may impact the social service delivery landscape.

METHODS: We conducted semi-structured interviews lasting 1 hour with representatives of health care systems participating in the Massachusetts Medicaid Accountable Care Organization (ACO) program and representatives from Massachusetts CBOs. We recruited representatives from the health care sector based on publicly available information on participation in the Medicaid ACO program. CBO recruitment focused on SDOH domains identified by health care interviewees as priorities. We used a snowball sampling strategy for recruitment until achieving thematic saturation. Interviews were transcribed and inductively coded to identify themes. We empaneled an advisory board of CBO representatives, academics, and health care representatives to provide feedback and ensure findings accorded with participant experiences.

RESULTS: Participants included health care executives (n=8) at Massachusetts Medicaid ACOs and leadership (n=46) from CBOs across Massachusetts. Health care interviewees were consistent in prioritization of SDOH domains (housing, food, transportation), concerns about scale and accountability among potential CBO partners, and ambivalence towards "owning" responsibility for SDOH. On the contrary, CBOs were highly varied in their perspectives of health care's entry into SDOH programming. This variation presented both within and between SDOH domains. The CBOs expressed variation along key dimensions: (1) awareness of policy incentives to promote health care entering the SDOH space, (2) duration of experience in partnering with health care to provide social services in the community (3) enthusiasm for partnership with health care and (4) estimation of CBO's value to health care. CBOs with more experience partnering with health care were more skeptical of the potential for successful partnership, expressing specific concerns about conflicts of interest and misalignment of targeting priorities (covered lives vs whole community).

CONCLUSIONS: CBOs varied in identifying benefits of partnership with the health care sector to provide social services. Several cited concerns of medicalizing social services. CBO's limited partnership experience with the health care sector suggests that financial incentives may be necessary but insufficient to bridge the gap between the sectors. Expectations of what could be achieved through partnership diverged considerably. Our findings urge policymakers to carefully consider both stakeholder positions if and when they (a) devise policies for and (b) provide incentives to health care organizations to move into SDOH programming.

CLINICAL VIGNETTE

"WHEN CLAP GETS YOUR HAND"

Sarabjeet S. Suri; Justine Phifer; Andrea Porrovecchio. Montefiore Medical Center, Bronx, NY. (Control ID #3184768)

LEARNING OBJECTIVE #1: Recognize disseminated gonococcal infection (DGI) as a cause of polyarticular septic arthritis and more rarely, osteomyelitis.

LEARNING OBJECTIVE #2: Assess all sexual risk factors, including oral sex as a source of gonococcal infection.

CASE: A 37-year-old man with well controlled HIV (undetectable viral load) presented with pain in his right wrist and left shoulder for 4 weeks. He never had fever, chills, rash, dysuria, or penile discharge. He endorsed having sex with men, but denied any sexual activity in the past year. On presentation, pertinent exam findings included swelling and tenderness of right wrist with limited active and passive range of motion. Left shoulder had tenderness with decreased range of motion. X ray of right wrist revealed erosion of the palmar aspect of the distal radius. Labs were significant for sedimentation rate of 110, c reactive protein of 5.9, and a negative immunologic work up. Right wrist aspiration revealed a white count of 43 K with intra-op cultures revealing growth of *Neisseria gonorrhoeae*. Antibiotics were initiated and left shoulder fluid aspiration revealed a white count of 850K. On repeat questioning, patient revealed he performed oral sex approximately 7 weeks prior to onset of his wrist pain. MRI right wrist revealed osteomyelitis of the distal radius and ulna. An echocardiogram revealed no vegetation, blood cultures had no growth, and urine NAAT was negative for gonorrhea. He was treated with IV ceftriaxone & clinically improved.

IMPACT/DISCUSSION: The most common etiologies of infectious arthritis in HIV patients include *S. aureus* and Streptococcal species. DGI is a far less common etiology of septic arthritis. It is usually seen in male patients under age of 40 with an estimated incidence of 0.5-3% in people infected with *N. gonorrhoeae*. The incubation period is around 1-2 weeks with hematogenous spread occurring within 2-3 weeks post primary insult. Internists should be aware of risk factors for DGI, including complement deficiency, HIV, postpartum state, lupus, or any immunocompromised state and should take a thorough sexual history. DGI presents as arthritis dermatitis syndrome (tenosynovitis, dermatitis and polyarthralgia) or as purulent arthritis and results from intermittent bacteremic spread of gonorrhea (blood cultures may be negative). Synovial fluid analysis and anogenital/oral swabs should be obtained. Imaging of involved joints should also be performed to determine the extent of disease, as osteomyelitis is an uncommon but important sequela of DGI. Treatment in DGI involves joint drainage and 1-2 weeks of parenteral therapy with a third generation cephalosporins and a dose of azithromycin, with some requiring longer duration of parenteral therapy.

CONCLUSION: DGI is on the differential diagnosis for polyarticular septic arthritis even in a patient with well controlled HIV. It is important to obtain complete sexual history and recognize that DGI may rarely lead to osteomyelitis.

"WHEN A TICK GETS THE TICKER"

Sarabjeet S. Suri¹; Kristin A. Swedish². ¹Montefiore Medical center, Bronx, NY; ²Montefiore Medical Center, Bronx, NY. (Control ID #3183953)

LEARNING OBJECTIVE #1: Recognize that Lyme carditis can manifest from weeks to months after exposure

LEARNING OBJECTIVE #2: Discuss how conduction abnormalities due to Lyme are variable and can include AV block, QT prolongation, bundle branch blocks and Ventricular tachycardia

CASE: A 34-year old man presented with dyspnea and palpitations for one week. He had no significant past medical history. He reported trouble walking up one flight of stairs, which was atypical, as he was otherwise an avid gym goer and outdoorsman. He had no significant family history, did not smoke or use drugs. He was bradycardic but otherwise hemodynamically stable. Physical exam was significant for irregular rhythm, bradycardia, and fading circular rash on left thigh. EKG revealed complete heart

block. Basic labs were unremarkable, Lyme serology was positive. He reported hiking about four weeks prior to presentation. Echocardiogram (TTE) revealed decreased Ejection fraction (EF) at 40%. He was treated with ceftriaxone. Within three days, his complete heart block converted to 1st degree AV block. On follow up six weeks later, EKG revealed sinus bradycardia, TTE revealed normal EF.

IMPACT/DISCUSSION: There are only a few reversible causes of complete heart block: medication overdose with beta blockers, Lyme carditis and viral myocarditis. Lyme disease is a multisystem disease caused by infection with *Borrelia burgdorferi*. Cardiac involvement usually occurs within a few weeks or months of exposure. Lyme carditis is estimated to occur in approximately 1% of patients infected with Lyme. The pathophysiology of the disease is incompletely understood in humans, but animal studies have shown transmural inflammation in the connective tissue at the base of the heart, the basal interventricular septum, and perivascular regions including the aortic adventitia. The symptoms usually start within 4-6 weeks and may include palpitations, lightheadedness, syncope and chest pain. AV block is the most common manifestation of Lyme carditis ranging from 1st degree AV block to complete heart block. Other manifestations include myopericarditis, LV dysfunction, and heart failure. Diagnosis is made via serologic testing with ELISA/western blot. The management involves hospitalization with telemetry monitoring in symptomatic patients (high grade block or first degree AV block with PR > 300 msec). Lyme carditis is treated with intravenous antibiotics. Third generation cephalosporins are preferable; if patient is penicillin/cephalosporin's allergic, desensitization should be performed. Patients should remain hospitalized until resolution of symptoms/blocks. The usual resolution occurs within one week of antibiotic therapy. Patient who are asymptomatic should be treated with oral antibiotics.

CONCLUSION: Detailed travel history and skin examination are important and can help pinpoint the diagnosis. Recognizing the reversible etiology of Lyme carditis helped prevent unnecessary intervention.

A CASE OF THE B'S: B1, BLURRY VISION, AND BARIATRIC BERIBERI

Tina P. Kapadia; Samir Bhalla. UCLA, Santa Monica, CA. (Control ID #3186743)

LEARNING OBJECTIVE #1: Recognize and diagnosis significant vitamin deficiencies in bariatric patients.

CASE: A 28 year old morbidly obese female status post gastric sleeve surgery two months prior presented to the hospital with falls and double vision for two days. Her surgery had resulted in a fifty pound weight loss. Her post operative period was complicated by intermittent bouts of nausea and vomiting and she was found to have pyloric stenosis requiring balloon dilation and botox injections. She developed a recurrent episode of nausea, vomiting and insufficient oral intake requiring around the clock Zofran. Approximately 1 week later she developed unsteadiness while walking with a sensation of falling associated with double vision and inability to focus eyesite. Physical examination demonstrated nystagmus with horizontal eye movements bilaterally, dysmetria with finger-to-nose testing, as well as an ataxic gait. Her strength, sensory and reflex examinations were otherwise normal, and labs noted a microcytic anemia. She was evaluated both neurology and ophthalmology and underwent CT and MRI imaging of the head and neck which were negative for acute findings. The patient was given IV fluids, multivitamin and high dose IV thiamine. Her symptoms rapidly improved with resolution of her diplopia and ataxia by hospital day 2. Labs later resulted in low levels of vitamin A, B1, iron, and serum ferritin. She was continued on bariatric vitamin supplementation and was discharged to home.

IMPACT/DISCUSSION: Micronutrient derangements are common following bariatric surgery. Thiamine (B1) deficiency is more commonly associated with malabsorptive procedures that decrease the surface area for nutrition utilization, metabolism, and absorption. B1 is typically absorbed in the duodenum, thus the mechanism for B1

deficiency in gastric sleeve surgeries has not been fully elucidated, although it is postulated that the stomach plays some key role in absorption. Some data shows that B1 can be depleted after only 20 days of inadequate supply. There have been numerous reports of acute thiamine deficiency in early post operative period in bariatric surgery patients leading to the term "bariatric beriberi." The term beriberi means "weakness" and refers to a spectrum of deficiencies in B1 including its effect on peripheral and central nervous systems. Only 16% of patients demonstrate the classic Wernicke's triad of encephalopathy, ophthalmoplegia and ataxia. Encephalopathy typically occurs more commonly than the other two features of the triad, interestingly this patient presented primarily with ataxia and ophthalmoplegia. Diagnosis mainly relies on clinical suspicion as there may be a delay in laboratory results, and brain imaging may not reveal any abnormal findings. Rapid recognition and treatment is important to prevent long term morbidity, or even mortality.

CONCLUSION: Thiamine deficiency can occur after gastric sleeve surgery and requires rapid treatment to prevent morbidity as in this case.

FEVER IN A TRAVELER: DIAGNOSIS WITH THE PERIPHERAL SMEAR

PRIYANKA BHUGRA¹; Abhishek Maiti²; Richard Wu¹; Alia N. Nazarullah¹. ¹University of Texas Health Science Center at San Antonio, San Antonio, TX; ²University of Texas MD Anderson Cancer Center, Houston, TX. (Control ID #3181679)

LEARNING OBJECTIVE #1: Parasitic infections should be high on the list of differential diagnoses of fever in a returning traveler, with relapses seen weeks to years after *P. vivax* and *P. ovale* infection.

LEARNING OBJECTIVE #2: Peripheral blood smears are key to diagnosis and following the response to treatment after anti-malarial therapy.

CASE: A 50-year-old previously healthy woman presented with a 3 day history of fevers, chills and severe frontal headache in the evenings. She traveled from Rwanda to the United States 8 months ago. Physical examination was unremarkable. Laboratory studies were significant for thrombocytopenia (platelet count of $87 \times 10^9/L$). A peripheral blood smear showed schizonts containing merozoites and intracellular ring forms, consistent with *Plasmodium ovale* infection. The patient was treated with artemether/lumefantrine for 3 days. Her fevers, headache and thrombocytopenia resolved by third day of treatment. She was subsequently treated with primaquine for 14 days. At 3-month follow-up, the patient remained asymptomatic.

IMPACT/DISCUSSION: Malaria poses an important diagnostic challenge to the physicians in United States due to unfamiliarity with the disease and lack of specific clinical features in the early phase. Majority of the cases of malaria in US are associated with history of travel to the endemic areas including Africa, South-East Asia and South America. Relapse after initial infection can occur with *P. vivax* and *P. ovale* species of *Plasmodium*. This is due to the presence of the hepatic dormant hypnozoite stage that can last for weeks to several months or even years. Thus, a single infection can be responsible for series of waves of parasitemia or relapses by reactivation of hypnozoite stage. Early recognition of the disease is important to reduce mortality and prevent its spread in the community. Delay in diagnosis can lead to progression to severe disease with multi-organ failure and death. Examination of peripheral blood smear helps in prompt diagnosis of malaria, identification of the *Plasmodium* species and quantification of parasitemia. The treatment of non-falciparum malaria includes use of chloroquine or artemisinin-based combination therapy. The clearance of parasitemia is confirmed by serial blood smear examination after initiation of treatment. Patients with *P. vivax* and *P. ovale* need further treatment with 2-week course of primaquine to eradicate the liver hypnozoites and prevent future relapses. Tafenoquine is a newly approved anti-relapse drug which can be used as a single dose regimen in nonpregnant individuals. Testing for glucose-6-phosphate-dehydrogenase deficiency is mandatory prior to starting the anti-relapse therapy.

CONCLUSION: Malaria is an important differential diagnosis in patients travelling from endemic areas. Late relapses of malaria can occur with *P. vivax* and *P. ovale* species. Early identification with peripheral smear examination is important for timely diagnosis and treatment.

INCIDENTAL DIAGNOSIS OF POLYMYOSITIS IN PRIMARY CARE CLINIC

Emily Fessler, Hospital of the University of Pennsylvania, Philadelphia, PA. (Control ID #3177385)

LEARNING OBJECTIVE #1: Develop an approach to asymptomatic abnormal liver function tests (LFTs) in the primary care setting

LEARNING OBJECTIVE #2: Recognize the potential for depression to delay care-seeking and diagnosis

CASE: A 68 year old woman with hypertension and depression presents for a routine primary care visit. Her only complaint is discomfort with swallowing which she attributes to "chronic tonsillitis". Her exam is unremarkable and plan made for non-urgent ENT referral. In addition, her 10-year ASCVD risk is 10.6%, thus she is prescribed a high-intensity statin and ordered for baseline LFTs. Unexpectedly, her transaminases return markedly elevated with AST 322 and ALT 131 from normal 1 year prior. On further questioning, she denies alcohol use, strenuous activity, or herbal supplements. She returns for additional testing including hepatitis serologies, TSH, creatine kinase (CK), and right upper quadrant ultrasound. CK is elevated to 6196. With direct questioning she endorses several months of generalized weakness with difficulty climbing the stairs and raising her arms. Autoimmune labs reveal ANA >1:20480. She undergoes thigh MRI with signal enhancement in the musculature, followed by muscle biopsy consistent with polymyositis. Anti-Ku antibodies are positive. She is seen by rheumatology and started on 60mg prednisone daily. CK remains elevated despite 4 weeks of prednisone, thus started on methotrexate and monthly IVIG. Barium swallow shows evidence of esophageal dysmotility. Screening for occult malignancy is negative. CK normalizes after 5 months of treatment and steroids tapered over 1 year.

IMPACT/DISCUSSION: Asymptomatic LFT elevation is often encountered in primary care. The first step in diagnosis is careful history including review of medications/supplements, alcohol use, and viral hepatitis risk factors. In patients with hepatocellular injury pattern it is important to consider non-hepatic sources including hyperthyroid, strenuous exercise and muscle injury; this is associated with a disproportionate elevation of AST>ALT. Further testing should be done in a stepwise manner (Schreiner 2018). Much of this process can be completed by a general internist prior to specialist referral. In addition, while it is acknowledged that depression can manifest as somatic complaints (Tylee 2005), the opposite is also true: depression can lead to underreporting of symptoms. For example, depression is associated with delayed care-seeking in both acute myocardial infarction and decompensated heart failure (Johansson 2011, Bundle 2006). Despite months of symptomatic weakness, had this patient not warranted LFTs for preventative care her polymyositis would likely have gone unrecognized until later in the disease process.

CONCLUSION: 1. Workup of abnormal LFTs should be done in a stepwise fashion based on history and injury pattern; differential should include both hepatic and non-hepatic sources. 2. Patients with depression require close attention to history and follow-up as they may delay care-seeking despite new symptoms.

KHAT GOT YOUR LIVER? A CASE OF KHAT-INDUCED LIVER INJURY

Amanda Pechman; Jennifer P. Weintraub. Icahn School of Medicine at Mount Sinai, New York, NY. (Control ID #3163629)

LEARNING OBJECTIVE #1: Identify khat use as a risk factor for liver disease

LEARNING OBJECTIVE #2: Apply khat-use screening questions to patients from countries where khat use is prevalent

CASE: A 31-year-old male with a history of cirrhosis presented to the emergency room with the chief complaint of altered mental status. He arrived with a note from his PCP stating a history of cirrhosis and concern for hepatic encephalopathy. On arrival to the emergency room the patient was reportedly confused and drowsy, without asterixis. His initial labs were normal except for a transaminitis, elevated ammonia, and negative urine toxicology. Initial imaging showed a normal head CT. This patient's only past medical history was cirrhosis of unknown etiology; as per his PCP he had a CT and MRI showing cirrhosis and an endoscopy showing small esophageal varices, and he had an upcoming appointment with hepatology for further workup. His social history was significant for tobacco use and frequent chewing of khat leaves, a stimulant native to East Africa and the Arabian Peninsula that is a common social practice in his home country of Yemen. He was given one dose of lactulose with improvement in his mental status and by the time he was admitted to the medicine service he was at his baseline. He was found to have negative hepatitis serologies, a negative alcohol level, as well as normal ceruloplasmin and iron studies. He was discharged to home with outpatient liver follow up. The patient saw a hepatologist as an outpatient the following month and underwent a transjugular liver biopsy that demonstrated chronic hepatitis, cirrhosis, and mild steatosis. The cause of his liver disease was deemed likely secondary to his khat use, and he was recommended to stop chewing khat to prevent further liver injury.

IMPACT/DISCUSSION: Khat-induced liver disease is a rare but important side effect of this substance. Though the mechanism of hepatotoxicity is unknown, there have been case reports of khat-induced liver damage. Khat use is a common social practice with an estimated 5-10 million users worldwide, particularly in the so-called khat belt countries of Ethiopia, Somalia, and Yemen. Given that there are over 300,000 immigrants from these nations in the U.S., it is likely that providers will encounter patients who use this substance and should thus screen for its use and recognize associated health risks. Risks of chewing khat include not only liver disease but also hypertension, tachycardia, stroke, decreased sperm count, and psychiatric disease. This case underscores the importance of taking a detailed social history that is both comprehensive and culturally sensitive to identify practices that can be harmful, and shows the importance of providing culturally competent care.

CONCLUSION: Chewing khat, a common social practice in Africa and the Middle East, can cause liver damage. It is important to screen for khat use in patients from countries where this practice is common

TB OR NOT TB: A CASE OF PLEURAL TB

Nikita Fernandes; Lakshmi Priyanka Mahali; Kristin A. Swedish. Montefiore Medical Center, Bronx, NY. (Control ID #3185875)

LEARNING OBJECTIVE #1: Diagnose pleural tuberculosis (TB).

LEARNING OBJECTIVE #2: Recognize the importance of considering TB in the differential, even when pleural fluid may not reveal a typical presentation.

CASE: A 31 year-old woman from Honduras presented with moderate right sided pleuritic chest pain, aggravated by deep breathing for two weeks. She did not have cough, sputum production, or dyspnea. Patient reported recent travel to Honduras. Six months prior, she had a positive PPD. Chest X-Ray (CXR) at that time was normal; she did not receive any treatment. On examination, she had diminished breath sounds and dullness to percussion of the right lung field. CXR revealed moderate right pleural effusion and some sub-centimeter pulmonary nodules. A thoracocentesis revealed exudative effusion, lymphocyte predominant, and elevated Adenosine Deaminase (ADA) enzyme level; fluid cultures and cytology were negative. Patient underwent robotic video-assisted thoracic surgery (RVATS) with evacuation of the effusion and pleural biopsy. The pleural biopsy revealed multiple non-necrotizing granulomas. The acid fast bacilli stain was negative. The tissue cultures grew Mycobacterium TB. She was treated with

Isoniazid, Rifampin, Pyrazinamide, and Ethambutol. Patient improved clinically and follows with pulmonology on outpatient basis.

IMPACT/DISCUSSION: Pleural TB is the most common extra pulmonary form of TB in adults, particularly in countries where the prevalence of the disease is high or moderate. However, pleural TB is under-reported, as negative pleural fluid mycobacterial cultures contribute to an underestimated incidence of disease. Although pulmonary TB can be a manifestation of primary infection, it is most commonly associated with reactivation of pre-existing foci. Tuberculous pleuritis develops from direct infection of pleura and lymph nodes as a result of a ruptured subpleural caseous focus in the lung. It is generally accepted that pleural TB results from a late hypersensitivity reaction to *Mycobacterium Tuberculosis* antigens. In patients with disseminated TB, the yield of pleural biopsy (77%) is higher than the yield of AFB staining (43%), PCR (70%) or culture (72%). In an instance of negative culture, such as in our case, biopsy can help increase the yield and decrease the time of diagnosis. Pleural biopsy can aid in diagnosis and treatment of TB.

CONCLUSION: This case illustrates the diagnostic difficulty of disseminated TB with atypical organ involvement. Culture is the gold standard for diagnosing TB, but is a long process and as 23% of TB in the United States is culture negative, the diagnosis sometimes relies on ruling-out other etiologies in the differential diagnosis and histologic examination.

THE FORGOTTEN CONSEQUENCES OF THE OPIOID EPIDEMIC: ADRENAL INSUFFICIENCY PRESENTING WITH HYPERCALCEMIA

Christina Ryu, CPMC, San Francisco, CA. (Control ID #3178626)

LEARNING OBJECTIVE #1: Chronic opioid use is often overlooked as a cause of secondary adrenal insufficiency, but physicians should be aware of this increasingly common cause, especially with the current opioid epidemic.

CASE: A 54-year-old woman with history of opioid abuse presented with generalized weakness, anorexia and depressed mood. Labs showed a corrected calcium of 13.7 mg/dL. Work-up revealed non-parathyroid hormone (PTH) mediated hypercalcemia with PTH 17 pg/ml in setting of non-elevated PTH related peptide (PTHrp), low 25-hydroxyvitamin D, low 1,25 dihydroxyvitamin D, normal free light chain ratio, low vitamin A and normal thyroid function. Calcium normalized and symptoms improved with IV fluids, calcitonin, furosemide and zoledronic acid. Etiology of hypercalcemia remained unclear at discharge. She represented to the ED 1 day later with hypoglycemia (glucose 13 mg/dL) and hypotension. Work-up revealed undetectable morning cortisol and ACTH levels, suggestive of secondary adrenal insufficiency. Unfortunately, cosyntropin stimulation test was not performed to confirm diagnosis prior to starting glucocorticoids. Pituitary MRI revealed a microadenoma measuring 5x3x3 mm, but all other pituitary hormones were intact. Based on history and work-up, it was determined chronic opioid abuse was the most likely cause of her secondary adrenal insufficiency. The patient was started on steroids with immediate improvement.

IMPACT/DISCUSSION: Studies have shown that chronic opioid use affects cortisol secretion likely due to interactions in the hypothalamus-pituitary-adrenal (HPA) axis. Opioids affect the HPA axis at multiple levels, but the primary site of action is thought to be the hypothalamus as seen in a study of morphine's effect on rat hypothalamic fragments leading to the suppression of CRF-41 release. In studies of healthy volunteers, naloxone, an opioid antagonist, led to an increase in cortisol and CRH levels, suggesting that opioids exert tonic inhibition on the HPA axis. One study showed that acute administration of oral morphine led to suppression of serum basal cortisol and plasma ACTH. Further, though rare, adrenal insufficiency can cause hypercalcemia. The pathophysiology is unclear but appears to be related to increased bone resorption, volume contraction from adrenal insufficiency and increased proximal tubular calcium reabsorption in the setting of decreased kidney function.

CONCLUSION: This case highlights two points: adrenal insufficiency should be considered as a cause of unexplained non-PTH mediated hypercalcemia and the significant impact of chronic opioid use on the HPA axis. Given the current opioid epidemic, physicians need to recognize this commonly overlooked clinical entity.

VITAMIN B12 DEFICIENCY PRESENTING AS HEMOLYTIC ANEMIA

Suheil Albert Atallah-Yunes; Fatima Ali; Philip Brandt. UMASS-Baystate, Springfield, MA. (Control ID #3185780)

LEARNING OBJECTIVE #1: Recognize hemolysis as a rare complication of Vitamin B12 deficiency

CASE: A 34-year-old male with no significant past medical history presented to the hospital with one month of progressive weakness and fatigue. He reported 11 kg weight loss in the previous 4 weeks. Physical exam did not find any palpable lymphadenopathy, jaundice or organomegaly. Blood work demonstrated a white cell count of 5.5 k/uL, hemoglobin of 8.8 gm/dL, platelet count of 190 k/uL with an MCV of 93 fL. CBC differential was significant for 2% myeloblasts. Hemolysis panel revealed an LDH of 4896 U/L, haptoglobin level less than 10, total bilirubin of 2.5 mg/dL and indirect bilirubin of 2.1 mg/dL. A Coomb's test was negative. Peripheral blood smear raised the concern for a bone marrow problem after dysplastic red blood cells with macroovalocytes, teardrop shaped cells and red blood cell precursors were observed. CT of the abdomen and pelvis did not demonstrate any splenomegaly or any evidence of a neoplastic process. Bone marrow biopsy findings were significant for megaloblastic changes and erythroid dysplasia. Cytogenetic analysis failed to highlight any abnormalities and hence the suspicion for a malignant process decreased. The negative Coomb's test and the low suspicion for microangiopathic hemolytic anemia in addition to the severely dysplastic myeloid cells raised the concern for nutritional deficiencies causing intramedullary hemolysis and bone marrow dysplasia. Evaluation then found a significantly low Vitamin B12 and high methylmalonic acid levels; <150 pg/ml and 26 nmol/ml respectively. Anti-Parietal antibodies were elevated at 40. Atrophic gastritis was encountered on an EGD and gastric biopsy results demonstrated evidence of chronic gastritis all consistent with pernicious anemia, which eventually lead to the patient's intramedullary hemolysis.

IMPACT/DISCUSSION: Hemolysis is a very rare complication of Vitamin B12 Deficiency. Most of the cases of hemolysis due Vitamin B12 deficiency occur in patients with pernicious anemia. The pathophysiology is still unclear. The most commonly proposed mechanism for intramedullary and intravascular hemolysis caused by Vitamin B12 deficiency is ineffective erythropoiesis. Other proposed theories include elevated homocysteine levels in patients having vitamin B12 deficiency which could cause endotoxic injury and eventually microangiopathic hemolysis. Low Vitamin B12 levels indicate vitamin B12 deficiency however methylmalonic acid and homocysteine levels should be checked if suspicion is still high in the setting of normal Vitamin B12 level. Vitamin B12 replacement is the treatment for hemolysis related to Vitamin B12 deficiency.

CONCLUSION: Hemolysis is a very rare complication of Vitamin B12 Deficiency and should be suspected in patients presenting with a Coomb's negative hemolytic anemia and signs of Vitamin B12 deficiency under peripheral blood and bone marrow review. Given its rarity, physicians should have a high clinical suspicion for this rare complication.

12 MM LUNG NODULE DEVELOPED INTO METASTATIC LUNG ADENOCARCINOMA IN 2 YEARS

Mukesh Kumar¹; Aimar Zafar²; Charles Fishman³. ¹Montefiore Medical Center, Bronx, Pakistan; ²Montefiore Medical center, Yonkers, NY; ³Montefiore Medical Center, Bronx, NY. (Control ID #3184227)

LEARNING OBJECTIVE #1: To recognize the malignant potential of lung nodules even in young patients

LEARNING OBJECTIVE #2: To review criteria for early intervention for lung nodules in lower risk populations

CASE: A 30 year old man who presented appendicitis underwent abdominal CT scan and was incidentally found to have 12 mm irregularly bordered lung nodule. No prior chest imaging was available. Patient was discharged after appendectomy and was advised to have follow up imaging, but was thereafter lost to follow up. Two years later patient presented with productive cough and scant hemoptysis. A CT scan of the chest then revealed a 6.7 cm lung mass. Carcinoid tumor was suspected but octreotide scan was negative. A CT guided lung biopsy revealed adenocarcinoma positive for EGFR mutation. Three weeks later patient was admitted with headache and right arm weakness. Magnetic resonance imaging (MRI) of brain revealed left sided metastases in parietal and occipital lobe, confirming stage IV disease.

IMPACT/DISCUSSION: Risk of a lung nodule being malignant depends on size, consistency and patient risk factors. The risk of malignancy in a nodule of 5 mm is < 1 %, 5-9 mm is 2-6%, 8-20 mm is 18% and > 20 mm is 50%. Solid nodules are at greater risk than semi solid and ground glass nodules. Significant risk factors include cigarette smoking, age>35 years, female gender, exposure to radiation or environmental toxins, pulmonary fibrosis, alcohol consumption and positive family history. According to Fleischner society guidelines a lung nodule > 8 mm should be either resected for biopsy in patients with risk factors for lung cancer, or followed up with CT chest in 3 months in low risk patients. In patients under 35 years old with no risk factors, the chance of a lung nodule proving to be malignant is <3%. It has also been noted that patients with nodules between 8-30 mm and concern of poor follow up (due to socioeconomic status, psychological issues, young age) should undergo either non-surgical biopsy or video assisted thoracoscopic surgery with wedge resection. Lung adenocarcinoma commonly presents as a pulmonary nodule. 5 year survival rate of stage IV lung adenocarcinoma is <10 % while for stage I it is 60-80%. The patient in this case presented 2 years after the finding of an incidental nodule with cancer that had progressed to stage IV. We suggest that timely intervention with biopsy of the nodule on first presentation could have altered this course.

CONCLUSION: Guidelines should be used in the proper clinical context as a tool to help in patient management as exceptions always exist. In any patient, including young patients with no risk factors for lung cancer presenting with nodules > 8 mm in size, there should be significant clinical suspicion of malignancy. Follow up and tissue diagnosis are essential.

A 'LOUSY' ANEMIA: SEVERE ANEMIA SECONDARY TO LICE INFESTATION

Adina Wise; Hailey Gupta; Saad Khan; Seema Quraishi; Erica Grabscheid. Mount Sinai Beth Israel, Icahn School of Medicine, New York, NY. (Control ID #3160816)

LEARNING OBJECTIVE #1: Recognize chronic pediculosis corporis infestation as a potential cause of severe anemia.

CASE: A 26 year-old undomiciled man with an unknown past medical or psychiatric history presented with fatigue. Review of systems revealed no chest pain, shortness of breath, hemoptysis, palpitations, loss of consciousness, abdominal pain, melena, hematchezia or hematuria. Vital signs were all within normal limits (T: 98.7 F, HR: 73, RR: 19, BP: 108/72). Physical exam revealed overall poor hygiene, including an extensive infestation of pediculosis corporis (body lice). Patient's lice infestation was severe for at least several months according to documentation from prior ED visits. The patient displayed a disorganized thought process consistent with chronic mental illness. All other physical exam findings were within normal limits, including guaiac negative stool testing. Initial labs revealed hemoglobin of 2.9 g/dL, hematocrit 10.1%, mean corpuscular volume 58 fL, RDW 19%, platelet count 474 K/uL. Further workup for severe anemia revealed a ferritin of 6 ng/mL, iron 6 ug/dL, TIBC 280 ug/dL, transferrin saturation 2.14%, reticulocyte count 2%, LDH 223 U/L, haptoglobin 55 mg/dL, B12 423 pg/mL and folate 10.99 ng/ml. Peripheral blood smear, Coombs test,

bilirubin, parvo b19, EBV, CMV, lead level, hemoglobin electrophoresis and urinalysis were all normal. Anti-transglutaminase antibody was 11 U/mL (nl 0-5). Upper and lower gastrointestinal endoscopy were offered, but the patient declined. Three permethrin treatments and a total body shaving were required to adequately treat the lice infestation. Patient received 5 days of intravenous iron sucrose followed by daily oral ferrous sulfate, with significant and rapid improvement in his Hgb to 10.4 g/dL.

IMPACT/DISCUSSION: Body lice infestations are particularly common among homeless and chronically mentally ill populations, and may go untreated for years while feeding off their host's blood. Thus, heavily infected individuals may suffer from clinically significant blood loss. A limited number of previous case reports have documented a possible causal relationship between severe anemia and chronic lice infestation in animals, as well as in human patients without access to adequate hygiene. This undomiciled patient presented with severe iron deficiency anemia (IDA) and chronic pediculosis corporis. A gastrointestinal bleed was unlikely given the negative fecal occult blood test and clinical presentation. Lab studies ruled out hemolytic, infectious, nutritional and hereditary etiologies (although anti-transglutaminase antibody was weakly positive, patient denied celiac disease symptoms while consuming a gluten-containing diet). This patient's IDA may, therefore, be attributable to the chronic pediculosis corporis infestation.

CONCLUSION: As body lice feed on human blood, long-term and heavy infestations could lead to severe anemia. The differential diagnosis for severe IDA should include blood loss secondary to chronic lice infestation in select patients.

A 16 - YEAR DELAYED PRESENTATION OF ANTHRACYCLINE-INDUCED CARDIOMYOPATHY

Ansh Johri¹; Gloria Hwang¹; Robert Wu¹; Sally Ng¹; Nicholas Duca². ¹Pennsylvania State University, Hershey, PA; ²Penn State Health Milton S. Hershey Medical Center, Hershey, PA. (Control ID #3146788)

LEARNING OBJECTIVE #1: Describe the typical time courses and risk factors for anthracycline-mediated cardiotoxicity.

LEARNING OBJECTIVE #2: Recognize the importance of long-term follow up of patients previously treated with anthracycline.

CASE: A 57-year-old female with breast cancer in remission, status post lumpectomy and 4 rounds of chemotherapy with doxorubicin, cyclophosphamide, paclitaxel, and a 5580 cGy dose adjuvant radiation therapy completed 16 years ago, presented with 1 week of severe exertional dyspnea. Vital signs were unremarkable, and physical exam revealed diffuse bilateral coarse crackles and jugular venous distension. Serum BNP was 7600 pg/mL. Chest X-ray showed bilateral pulmonary interstitial edema, and transthoracic echocardiogram confirmed congestive heart failure (CHF) with ejection fraction of 20-25%, a dilated left atrium and left ventricle, and diffuse hypokinesis. Further ischemic workup was deferred in the absence of CHF risk factors, such as hyperlipidemia, hypertension, smoking history, and family history of cardiovascular disease. After 4 days of diuresis with furosemide 40 mg b.i.d., the patient ambulated without dyspnea and was discharged on furosemide, lisinopril, and metoprolol for chronic CHF management.

IMPACT/DISCUSSION: Doxorubicin, an anthracycline, is commonly used to treat breast cancer, but it can also cause dilated cardiomyopathy. Cardiotoxicity typically occurs within 3 days of anthracycline therapy, but studies have shown cardiotoxicity up to 10 years later. A case report presented a 57-year-old female who developed diffuse cardiovascular dilation and CHF 17 years after doxorubicin therapy. The patient several features with our patient, such as age, gender, ejection fraction, cardiac morphology, and lack of cardiovascular risk factors. A major risk factor for anthracycline cardiotoxicity is a higher cumulative dose: one prospective study of 630 subjects found a greater incidence of CHF in patients when the cumulative dose exceeded 400 mg/m². Concurrent cyclophosphamide chemotherapy, adjuvant radiation therapy, and female gender

also increase this risk. This patient's gender, concurrent cyclophosphamide and radiation therapy, and multiple doxorubicin doses put her at greater risk for cardiotoxicity, resulting in CHF without traditional CHF risk factors. In patients treated with anthracycline, delayed-onset cardiotoxicity must be considered when the etiology of their CHF is not apparent. Patients with the previously mentioned risk factors for cardiotoxicity should therefore undergo routine echocardiographic assessment. There is controversy regarding testing frequency but since cardiotoxicity incidence is typically within 5 years post-treatment, it is reasonable to follow up yearly for 5 years and then every 2 years for the next 10 years. This way, cardiotoxicity can be identified early for these patients, reducing their risk of developing CHF.

CONCLUSION: -Anthracycline-mediated cardiotoxicity can have a delayed presentation. -Long-term follow up for high-risk patients can prevent CHF.

A 65-YEAR-OLD WOMAN WITH NEW PANCYTOPENIA

Tara M. Skorupa; Molly Brett. Beth Israel Deaconess Medical Center, Boston, MA. (Control ID #3183154)

LEARNING OBJECTIVE #1: Distinguish severe B12 deficiency from potential mimickers causing similar hematologic abnormalities, including acute leukemia and hemolytic anemia.

CASE: A 65-year-old otherwise healthy woman presented to her primary care physician with three 3 months of worsening dyspnea on exertion, fatigue, and gait instability, with 1 week of tingling in her fingertips. She endorsed 20-lb weight loss which she attributed to fatigue and anorexia. She denied recent travel or dietary changes and was not vegetarian. She denied smoking or illicit drug use and drank wine rarely. She was not taking any medications or supplements. Exam was unremarkable. Labs showed new pancytopenia with WBC 3.0 (ANC 1700), hemoglobin 7.2 with MCV 118, and platelets 134. All were normal when last checked 5 years ago. She was referred to the emergency room and admitted to the medicine service. Further workup revealed B12 <150 and elevated ferritin. Reticulocyte count showed hypoproliferation. Haptoglobin <10 and elevated LDH and indirect bilirubin suggested hemolytic anemia. Fibrinogen and INR were normal, and Coomb's test was negative. CT abdomen showed mild splenomegaly. Anti-intrinsic factor antibody was positive, consistent with pernicious anemia. She was started on cyanocobalamin injections, and her CBC normalized within one month. Her initial presenting symptoms of dyspnea, fatigue, and gait instability resolved as well.

IMPACT/DISCUSSION: This vignette describes a patient with exertional dyspnea, fatigue, and gait instability who was found to have new pancytopenia. The differential for acquired pancytopenia is broad and can be divided into disorders of production (related to marrow infiltration or failure), consumption, and sequestration¹. Given the life-threatening nature of several items on this differential, a finding of pancytopenia can lead to an invasive workup. In pancytopenic patients found to be B12 deficient, unnecessary diagnostic testing can often be avoided by treating the B12 deficiency. In our patient, macrocytosis with MCV 118 provided a major clue to her diagnosis. Vitamin B12 is a key cofactor in DNA synthesis, so B12 deficiency can lead to ineffective erythropoiesis and large, immature red blood cells, typically >115fL^{1,2}. In severe cases of B12 deficiency, all blood counts in the periphery can be low; paradoxically, the bone marrow is hypercellular². Ineffective erythropoiesis can result in intramedullary hemolysis and early destruction of immature red cells and leads to a low reticulocyte count¹. After initiation of treatment, patients with hematologic abnormalities typically show improvement in blood counts within 1-2 weeks, and complete resolution within 8 weeks¹.

CONCLUSION: Severe B12 deficiency can cause pancytopenia and hemolytic anemia and can mimic acute leukemia and microangiopathic hemolytic anemia. For patients with clear B12 deficiency, macrocytic anemia, and mild leukopenia and thrombocytopenia, a trial of B12 supplementation is warranted before pursuing more invasive diagnostic testing.

A CASE OF A PATIENT WITH EXTREMELY ELEVATED FERRITIN AND SEPTIC SHOCK

Brianna Knoll¹; Pamela Boodram¹; Taiye Odedosu². ¹New York University School of Medicine, New York, NY; ²NYU Medical Center, New York, NY. (Control ID #3179286)

LEARNING OBJECTIVE #1: Recognizing hemophagocytic lymphohistiocytosis (HLH) in septic patients with ferritin levels greater than 20,000

CASE: A 35-year-old woman with a history of recurrent urinary tract infections (UTIs) complicated by nephrolithiasis presented with four days of fever and a sore throat. She was febrile to 103.1, blood pressure 99/62, and heart rate 100. WBC was 12, Hgb 8.6, creatinine 1.8, AST 304, ALT 92, and HIV, streptococcus, mononucleosis and EBV IgM testing were all negative. Urinalysis was consistent with a UTI, she was admitted, and started on antibiotics. A CT scan of the abdomen revealed a right, staghorn calculi with surrounding, ill-defined lesions in the parenchyma. Urology placed a right nephrostomy tube which drained frank pus. Other work-up revealed an LDH of 2,502, triglycerides of 474, ferritin of 31,000. An Interleukin 2 Receptor (CD25) soluble test was sent but bone marrow biopsy was deferred given improvement in clinical symptoms and laboratory data. Twelve days into her admission, the patient clinically deteriorated. Lactate was elevated to 5.7, LFTs and LDH began to rise, and ferritin was 24,000 from a nadir of 8,000. Repeat triglycerides were 1,210. She was transferred to the intensive care unit for septic shock, placed on vasopressors and was subsequently intubated. A bone marrow biopsy revealed histiocytosis in a scattered and cluster pattern and hemophagocytosis and hemophagocytic lymphohistiocytosis (HLH) was diagnosed. Treatment with dexamethasone and etoposide was initiated on day fourteen based on the modified HLH 94 protocol. Her CD25 soluble test later came back elevated. She was weaned of vasopressors, extubated and completed chemotherapy inpatient. She was discharged three months after presentation.

IMPACT/DISCUSSION: HLH is a rare, life-threatening condition characterized by excessive immune activation that is most common in the pediatric population but can occur at any age. There are pre-disposing genetic defects and/or an immunological trigger such as infection, malignancy or rheumatologic disorder that have been linked to the development of HLH. Most commonly infectious HLH is reported in viral infections - commonly EBV - but it is possible the diagnosis is being overlooked in bacterial infections that lead to sepsis. It is easy in sepsis to attribute cytopenia and rising LFTs to end organ damage from the sepsis itself, making it difficult to distinguish from HLH. Infection itself is also commonly associated with high ferritin levels making it even more difficult to distinguish from HLH. Without treatment, patients often only survive a few months and overall mortality is as high as 75%. Appropriate, early treatment have shown remission rates up to 71%.

CONCLUSION: Thus, this case report exemplifies the importance of investigating HLH as a possible contributor to end-organ damage in septic shock when extremely high ferritins are noted. Mortality is high in patients with HLH which makes timely diagnosis of the utmost importance.

A CASE OF A RARE INFECTION WHICH MIMICS MALIGNANCY

Belaal Sheikh. Chicago Medical School, McHenry, IL. (Control ID #3185859)

LEARNING OBJECTIVE #1: How to recognize clues which distinguish malignancy from a rare infection prior to lobectomy.

CASE: A 69 year old female with known emphysema and COPD on home oxygen presented with a 2 week complaint of progressive dyspnea, dry cough, and fever. She was an active smoker with a history of pulmonary nodules which presented intermittently on imaging. The patient also had a right middle and partial right lower lobe lobectomy 5 years

ago after biopsy performed on 1 of 2 nodules present at the time raised a suspicion for possible non-small cell lung carcinoma. Multiple attempts at pathology and histology were nonspecific or negative on the remaining pulmonary nodules to confirm malignancy. Since the lobectomy the patient's condition worsened as she has recurrent pneumonia and worsening chronic respiratory failure. During this admission she was admitted with a diagnosis of acute on chronic hypoxic respiratory failure secondary to low lung volume from lobectomy and COPD exacerbation. Sputum cultures during this admission returned positive for *Achromobacter xylosoxidans*. Diagnosis was confirmed via bronchoscopy and the patient was started on ertapenem. Her condition improved and she was discharged on ertapenem for a total of 6 weeks of intravenous treatment. Follow up outpatient showed improvement in respiratory status and she has not since had pulmonary nodules appear on imaging.

IMPACT/DISCUSSION: *Achromobacter xylosoxidans* is a pulmonary infection which appears on imaging as speculated lung nodules mimicking malignancy. There have been a few reported cases of an unnecessary lobectomy due to misdiagnosis of *Achromobacter xylosoxidans* as non-small cell lung cancer. Though cases such as this are rare, it is important to differentiate *Achromobacter xylosoxidans* from malignancy as both may present with spiculated nodules on imaging. A clue favoring *Achromobacter xylosoxidans* infection is the intermittent nature of the nodules that come and go on imaging without explanation. This case highlights the importance of ruling out an acute or chronic infection presenting as neoplasia prior to any invasive procedures which may affect quality of life.

CONCLUSION: *Achromobacter xylosoxidans* is a rare gram negative catalase positive ubiquitous organism typically found in aqueous marine environments. The pathogen has a slow growing prevalence of 2.3% to 8% within healthcare facilities causing a prolonged, incapacitating pneumonia with a mortality rate of up to 50%. Classically this organism gravitates to patients with cystic fibrosis due to the salty aqueous environment within their pulmonary parenchyma. It causes pneumonia in immunosuppressed individuals and presents as fleeting, spiculated, pulmonary nodules on imaging commonly mimicking pulmonary carcinoma. Successful identification and treatment of *Achromobacter xylosoxidans* can decrease morbidity, mortality, and unnecessary interventions for patients.

A CASE OF ACUTE INTERSTITIAL NEPHRITIS RELATED TO SPIRONOLACTONE AND MENTAL HEALTH SUPPORTS IN A TRANSGENDER WOMAN

Andrew Silapaswan^{1, 2}; Joseph J. Baker^{1, 2}. ¹Beth Israel Deaconess Medical Center, Boston, MA; ²Fenway Health, Boston, MA. (Control ID #3180797)

LEARNING OBJECTIVE #1: Recognize acute interstitial nephritis (AIN) related to spironolactone

LEARNING OBJECTIVE #2: Assess the impact of cross-sex hormone therapy (CSHT) interruptions on mental health in transgender patients

CASE: A 21-year-old transgender woman with history of depression presented with several weeks of nausea, vomiting, and poor oral intake. History was notable for CSHT maintained on estradiol and spironolactone since 2016. Review of systems was otherwise negative and physical exam was unremarkable. Initial labs showed acute kidney injury (AKI) with creatinine of 2.66 from baseline of 0.8-1.0, and peaked at 4.6 mg/dL 10 days later. She was admitted and received several liters of IV fluids, however did not have improvement in renal function. Urine sediment showed significant white cells, mild proteinuria, and white cell casts, although urine culture returned negative. Renal ultrasound was normal. Given the concern for AIN, spironolactone and estradiol were held. She ultimately underwent renal biopsy showing severe AIN, likely related to spironolactone. She completed a 2-month steroid taper with recovery in renal function to baseline. She was then re-started on estradiol and her renal function remained stable. While off spironolactone and estradiol, she experienced worsening gender dysphoria requiring increased mental health supports.

IMPACT/DISCUSSION: AKI is a common inpatient presentation and the differential diagnosis in a patient with nausea and vomiting should include pre-renal AKI. However, intrarenal etiologies should be considered when patients do not respond to IV fluids. Diagnostic tools include urinalysis with microscopy, urine albumin to creatinine ratio, renal ultrasound to rule out obstruction, and renal biopsy if indicated. Multi-system adverse effects can occur with spironolactone including gynecomastia, nausea, and vomiting. Spironolactone can also cause dehydration leading to renal insufficiency and AIN. Treatment of AIN includes discontinuing the offending medication and in this case, the risks of resuming spironolactone were thought to outweigh the benefits. Comprehensive care of transgender patients should also focus on mental health and the provision of adequate behavioral health supports. Our patient had worsening gender dysphoria and suicidal ideation during the interruption in CSHT. She was ultimately re-started on estradiol, however providers must be equipped to provide additional mental health supports and appropriate pharmacotherapy if indicated. Our patient benefited from weekly behavioral health visits and ultimately referral for surgical therapy with orchectomy as part of her gender affirmation.

CONCLUSION: This case illustrates potential adverse effects of spironolactone including renal insufficiency and AIN. Providers should be aware that interruptions in CSHT place transgender patients at higher risk for worsening mental health and should anticipate the need for increased mental health supports.

A CASE OF ACUTE PANCREATITIS SECONDARY TO MILK-ALKALI SYNDROME IN A PATIENT WITH DIGEORGE SYNDROME

Fareeha A. Khan¹; Hunter Mwansa¹; Basel Altaqi². ¹St. Vincent Charity Medical Center, Lakewood, OH; ²St. Vincent Charity Medical Center, Cleveland, OH. (Control ID #3167255)

LEARNING OBJECTIVE #1: Recognize hypercalcemia as a rare, but possible cause of acute pancreatitis.

LEARNING OBJECTIVE #2: Recognize milk alkali syndrome causing hypercalcemia in patients with DiGeorge Syndrome, supplemented with extrinsic calcium

CASE: A 48-year-old female, with a past medical history of DiGeorge Syndrome and mental retardation was admitted to the Intensive Care Unit with a 2 days history of altered mental status. She had non-bloody, non-bilious vomiting, and non-bloody watery diarrhea in addition to poor appetite and anorexia. She had a remote cholecystectomy and no history of alcohol abuse. Home medications included hydrochlorothiazide, losartan, metformin, and supplementation with calcium acetate daily, calcitriol daily, calcium carbonate/vitamin D3 daily, and cholecalciferol daily. Physical exam was significant for Glasgow Coma Scale of 11, tachycardia, tachypnea and hypotension. Abdomen was distended and tender over the right upper quadrant and epigastric areas. Lab work revealed elevated white blood cell count and acute renal failure. Amylase and lipase were found to be elevated, as was serum calcium to 12.1 mg/dL. Serum IgG4 antibodies were found to be within normal limits. Abdominal CT scan revealed an enlarged pancreas at the level of the head and body with ill-defined fluid and fatty stranding surrounding the pancreas. The patient was initially managed as a case of sepsis, however, later the diagnosis was confirmed and revised to acute severe pancreatitis. The etiology was established to be hypercalcemia due to Milk-Alkali Syndrome and HCTZ. The patient subsequently received hemodialysis due to ischemic acute tubular necrosis.

IMPACT/DISCUSSION: MAS has become the third leading cause of hypercalcemia in hospitalized patients, behind hyperparathyroidism and malignancy. [7] Our patient fulfilled four of the five major criteria for diagnosis of MAS except, metabolic alkalosis. [11] Pathophysiology of MAS includes a cyclic pathway where hypercalcemia is the main driving

force of the entire cascade. [8] In this situation, differentiation from other causes of hypercalcemia is imperative. Our patient brings an interesting twist to this discussion due to her comorbid condition of DiGeorge Syndrome, deletion of chromosome 22q11.2, which inherently results in PTH deficiency, thus making patients prone to hypocalcemia. Our patient's intake of calcium is at par with the threshold described by Beall *et al.* of >4g/day. [5] This is the first case report of its kind, presenting pancreatitis due to milk-alkali syndrome in a patient with DiGeorge Syndrome, the picture here however is complicated with metabolic acidosis due to renal failure and lactic acidosis.

CONCLUSION: • Clinicians should consider Milk-Alkali Syndrome as a potential cause of acute pancreatitis and measure should be taken to address it. • Patients with DiGeorge Syndrome are prone to developing hypercalcemia due to continued extrinsic calcium supplementation.

A CASE OF ACUTE PE-RICARDITIS

Christine Chan¹; Natalie Kappus²; Stefanie Reiff³. ¹NYU Langone Health, Brooklyn, NY; ²NYU Langone Brooklyn, Brooklyn, NY; ³NYU Langone Hospital - Brooklyn, Brooklyn, NY. (Control ID #3147048)

LEARNING OBJECTIVE #1: Explain how the hemodynamics of pericarditis can produce the clinical manifestations (signs and symptoms) seen in pericarditis.

LEARNING OBJECTIVE #2: Categorize the progressive electrocardiogram stages consistent with pericarditis.

CASE: A 70 year-old female with hypertension and diabetes presented to the hospital with a one-day history of non-positional, left-sided chest pain associated with shortness of breath and subjective fevers. Physical exam and vitals were unremarkable. Work up included three negative troponins, EKG in normal sinus rhythm (Figure 1), and D-Dimer of 1100 ng/mL. CTA chest revealed a right subsegmental middle lobe filling defect consistent with pulmonary embolism for which patient was initiated on anticoagulation with resolution of chest pain. Approximately 24 hours after initial presentation the patient reported a new chest pain described as sharp, pleuritic, worse with lying flat and improved with sitting forward. Vitals revealed fever to 100. 5 F. Repeat EKG demonstrated diffuse ST elevations (Figure 2). Labs showed a negative troponin and ESR and CRP at 63 mm/hr and >190 mg/L, respectively. Echo showed a trace pericardial effusion, normal ejection fraction, and no evidence of right heart strain. The patient was diagnosed with acute pericarditis and initiated on colchicine and NSAIDs with resolution of symptoms. Common causes for pericarditis including viral URI, TB, connective tissue disorders, and malignancy were ruled out with a negative review of symptoms, subsequent laboratory analysis and additional history from the patient's primary care provider. Given the unlikelihood of other etiologies, her acute pericarditis was felt to be secondary to her pulmonary embolism.

IMPACT/DISCUSSION: Between 80-90% of pericarditis cases are idiopathic or presumed to be of viral etiology. Given the relatively benign course of the majority of causes of pericarditis a definitive work up is often not performed. However, this case highlights an additional "can't miss" cause of pericarditis - pulmonary embolism. Although rare, post-pulmonary embolism pericarditis is a well-documented phenomenon associated with elevated ESR, CRP, and low-grade fevers as in this patient's presentation. Proposed mechanisms include increased friction of an enlarged pulmonary artery and right ventricle against the pericardium and an immunologic response, similar to Dressler syndrome.

CONCLUSION: Despite being a known cause of pericarditis, pulmonary embolism is frequently overlooked or completely excluded from clinicians' differentials. Although the exact cause of pericarditis is often unknown, in patients with idiopathic pericarditis with no infectious signs, pulmonary embolism should always be considered based on history and physical exam findings to avoid missing a "can't miss" diagnosis.

A CASE OF AMIODARONE-INDUCED SWEET SYNDROME.

Aditya Singh; Junior Uduman. Henry Ford Hospital, Detroit, MI. (Control ID #3183653)

LEARNING OBJECTIVE #1: Recognize and differentiate Sweet syndrome (acute febrile neutrophilic dermatosis) from an infectious process.

LEARNING OBJECTIVE #2: Recognize amiodarone as a potential cause of drug-induced Sweet syndrome.

CASE: Our patient was a 41-year-old Caucasian male, with a past medical history of atrial fibrillation (Afib), non-ischemic cardiomyopathy (Ejection Fraction 9 %), and diabetes mellitus presented to the hospital with signs and symptoms of decompensated heart failure and skin lesions. He was febrile and had innumerable tender, pruritic, violaceous, annular plaques with central ulceration which had a contiguous centripetal spread from extremities extending to abdomen and chest over a period of 2 weeks. Careful medication review suggested recent re-initiation of amiodarone for Afib. Additional history revealed similar rashes in the past which were temporally related to amiodarone use. Interestingly each subsequent exposure resulted in increased severity and rapidity of skin lesions. Thought to be infectious in origin the patient had been treated with antibiotics each time, however, the patient identified improvement after stopping the offending drug. Differential diagnosis included amiodarone-induced adverse drug reaction, leukocytoclastic vasculitis, Sweet syndrome, IgA dermatosis, atypical infection or septic thrombi. Autoimmune serology was unyielding and empiric antibiotics failed to improve skin lesions. Confirmatory punch biopsy of the lesions revealed perivascular neutrophilic dermal infiltrate consistent with Sweet syndrome. Due to the severity of the disease and systemic involvement intravenous methylprednisolone was initiated, resulting in rapid clinical remission of symptoms, cutaneous lesions, and leukocytosis.

IMPACT/DISCUSSION: Sweet syndrome is characterized by a constellation of fever, neutrophilia, tender erythematous skin lesions with diffuse perivascular neutrophilic dermal infiltrate. It has been correlated with inflammatory bowel disease, antecedent respiratory/ gastrointestinal infection, active malignancy, autoimmune disease, vaccines, and medications. Pathophysiologically hypersensitivity reaction is thought to play a role, given recurrence of the dermatosis with re-exposure of the offending agent and prompt response to corticosteroid therapy, as demonstrated in our patient. Amiodarone has been associated with various dermatological reactions, including photosensitivity, blue/grey hyperpigmentation and rarely vasculitis. The temporal association with amiodarone in our patient highlights amiodarone as a potential cause of drug-induced Sweet syndrome, which to the best of our knowledge has not been previously described in the literature.

CONCLUSION: Sweet syndrome can resemble an infectious process, usually, patients receive antibiotic treatments before glucocorticoid therapy, delaying definitive treatment. Hence clinicians should maintain a high suspicion of drug-induced Sweet syndrome in such patients, in order to improve patient-related outcomes.

A CASE OF CLANDESTINE CANCER: INCREASING AWARENESS OF NON-HEMATOLOGIC CANCERS IN PATIENTS WITH ATAXIA TELANGIECTASIA

Britney N. Bell¹; Naomi Habib¹; Mital Patel². ¹Creighton University Residency, Phoenix, AZ; ²University of Arizona/Dignity Health Cancer Center, Phoenix, AZ. (Control ID #3186533)

LEARNING OBJECTIVE #1: To discuss ataxia- telangiectasia and oncologic sequelae to better equip providers in the diagnosis of carcinomas in these patients

LEARNING OBJECTIVE #2: To discuss the occurrence the severity of gastric adenocarcinom in patients with ataxia-telangiectasia

CASE: A 25-year-old female with ataxia-telangiectasia (A-T), diagnosed at age 7, who presented with a 2-month history of progressive nausea and mid-

abdominal pain, regurgitation of solids and liquids, and associated weight loss of 40lbs. Evaluation at an outside facility one month prior with an esophagogastroduodenoscopy (EGD) showed grade B esophagitis with hypertrophied gastric folds. Biopsies were negative for cancer. On current evaluation, her vital signs and basic laboratory data were normal, but she had some mild epigastric tenderness. Esophagram showed marked gastric slowing. CT scan of the abdomen revealed a diffuse gastric wall thickening. A repeat EGD showed worsening edematous, friable gastric folds without an obvious mass, concerning for gastric outlet obstruction. Biopsy confirmed this to be a poorly differentiated gastric adenocarcinoma. Staging laparoscopy with biopsies confirmed peritoneal metastatic disease. Her baseline performance was poor due to ataxia. Palliative chemotherapy was cautiously started on single agent 5-fluorouracil without severe side-effects and was escalated by adding a platinum agent, oxaliplatin as part of the modified FOLFOX regimen. She has been on this chemotherapy for the last 9 months (19 cycles) tolerating it well and has maintained stable disease on imaging.

IMPACT/DISCUSSION: A-T is an autosomal recessive chromosomal instability disorder characterized cerebellar ataxia, conjunctival telangiectasias, oculomotor apraxia, choreoathetosis, immunodeficiency, and increased risk of malignancy. The defect in DNA damage repair due to mutations in the ATM (ataxia-telangiectasia mutated) gene leads to early onset of non-Hodgkin lymphoma and acute lymphoid leukemia. As patients with AT are living longer, there is an increasing, though under-recognized incidence of solid tumors including gastric cancer. In one literature review only 7 known cases of gastric cancer in patients with AT have been reported. Our patient had a diffuse gastric cancer which had metastasized to the peritoneum. Her diagnosis was delayed a few months due to her diffuse gastric involvement and she was metastatic at presentation. A heightened awareness of non-hematologic malignancies in patients with chromosomal instabilities can lead to diagnosis at an earlier, curable stage of cancer. Due to their inherent susceptibility to DNA breaks, these patients remain very sensitive to radiation and chemotherapy with toxic side-effects. Our patient has been cautiously escalated to a dual chemotherapy regimen and is tolerating treatment almost 10 months out from diagnosis.

CONCLUSION: A heightened awareness of non-hematologic malignancies in patients with chromosomal instabilities can lead to diagnosis at an earlier, curable stage of cancer

A CASE OF CUSHING'S DISEASE SUSPECTED FROM THE EXACERBATION OF GLUCOSE INTOLERANCE AND DIAGNOSED BY SURGERY.

Toyohiro Miyata¹; AOI YOGO¹; Masaki Maeda²; Keisuke Kadooka²; Masahiro Masuzawa². ¹Kameda Medical Center, Kamogawa, Japan; ²Kameda Medical Center, Chiba, Japan. (Control ID #3186227)

LEARNING OBJECTIVE #1: Suspect Cushing's disease (CD) in patients with diabetes mellitus (DM) if glucose intolerance rapidly exacerbates.

LEARNING OBJECTIVE #2: Recognize cases of CD on the basis of normal magnetic resonance imaging (MRI) findings.

CASE: A 50-year-old female with hypertension, hyperlipidemia, and type 2 DM was referred from a neighborhood clinic because of worsening HbA1c and blood pressure control. Four months before the current admission, she presented with bilateral leg edema, polydipsia, polyuria, and psychiatric symptoms, such as irritability and anxiety. Her HbA1c level increased from 6.5% to 10.4% and average blood pressure from 130/80 to 200/100 mmHg. She had no history of alcohol abuse or depression. Other signs and symptoms were suggestive of hypercortisolism, including moon face, buffalo hump, central obesity, wide purplish striae, bruising, and virilizing features. Laboratory examinations revealed elevated 24-h urine cortisol, and incomplete suppression of serum cortisol levels with low-dose (1mg) dexamethasone suppression test. Additionally, the level of plasma adrenocorticotropic hormone was markedly elevated, suggesting CD. Further endocrine tests such as the high-dose dexamethasone

suppression test, corticotropin-releasing hormone stimulation test, desmopressin test indicated pituitary lesion. On the other hand, 3-Tesla MRI with gadolinium enhancement indicated no evidence of a pituitary tumor. Finally, we performed bilateral inferior petrosal sinus sampling (BIPSS), which indicated pituitary lesion. Based on the result of BIPSS, endoscopic transsphenoidal surgery was performed despite no evidence of a pituitary tumor following 6 months of metyrapone and glucocorticoid replacement therapy. Microadenoma was found across both sides of the lower portion of the pituitary. Finally, symptoms such as glucose intolerance and bilateral leg edema were improved.

IMPACT/DISCUSSION: General practitioners may miss CD among patients with DM if they do not recognize the signs of hypercortisolism. Moreover, there is no single best approach for diagnosing CD, and MRI with gadolinium contrast enhancement identifies pituitary tumors in less than half of all patients with CD. For patients with suspected CD but no detectable pituitary lesions on MRI, BIPSS is recommended for confirmation. Surgical excision is required for definitive diagnosis as well as first-line treatment.

CONCLUSION: CD should be suspected in patients with sudden exacerbation of glucose intolerance, even if MRI findings are unremarkable.

A CASE OF ERYTHEMA NODOSUM - HOW THE RESIST THE MILLION-DOLLAR WORKUP

Max Ruge; Jordan Scharping; Michelle Sweet. Rush University Medical Center, Chicago, IL. (Control ID #3184922)

LEARNING OBJECTIVE #1: Discuss the various etiologies of erythema nodosum.

LEARNING OBJECTIVE #2: Describe a high value workup for erythema nodosum.

CASE: A 53-year-old female with a history of mild pancytopenia presented to the ED with fatigue, chills, decreased appetite, myalgias, non-productive cough, and a frontal headache that began 3 days prior. Shortly after symptom onset, she noticed multiple 2-5 cm, erythematous, tender and raised nodules on her lower extremities and one on her left upper arm. In the ED, she was febrile (101.9), and her labs were significant for a CRP/ESR of 130/75, white blood count of 10.7, hemoglobin of 9.4, and platelets of 87. Lumbar puncture demonstrated 13 WBCs (predominantly lymphocytes) with 82 RBCs. On the general medical floor, biopsy confirmed the nodules to be erythema nodosum. Chest CT, ANCA levels, autoimmune panel, complement levels, TSH, respiratory pathogen panel, serum protein electrophoresis, and urine protein electrophoresis had no significant abnormalities. Outpatient workup for pancytopenia had been unrevealing, so bone marrow biopsy was done that showed hypercellular marrow without evidence of malignancy. While her systemic symptoms improved, the nodules remained present and tender. She was discharged 5 days after admission with the diagnosis of idiopathic erythema nodosum.

IMPACT/DISCUSSION: Erythema nodosum (EN) typically appears as raised tender nodules in the pretibial area. Most commonly, these lesions are idiopathic (55%). However, EN can also be secondary to other diseases such as streptococcal pharyngitis (28-48%), sarcoidosis (11-25%), and drugs such as antibiotics or oral contraceptives (3-10%). Other rarer causes include pregnancy, enteropathies, malignancy, and other infections. Obtaining a complete history is critical and should include recent illnesses, associated symptoms (particularly systemic symptoms, sore throat, or cough), and medication use. A thorough physical exam to evaluate for tonsillopharyngitis, abnormal breath sounds, or ocular abnormalities can help identify the underlying condition and direct testing. Excisional biopsy can confirm the diagnosis. Initial labs and imaging should include a CBC with differential, ESR, CRP, ASO antibodies, throat culture, and chest x-ray. Further labs should be obtained only if the patient's history significantly increases suspicion for a rarer cause. For example, while malignancy is a rare cause of EN, this patient's history of cytopenia warranted a bone marrow biopsy.

CONCLUSION: The massive differential associated with EN can tempt providers into the over-ordering of tests. However, to ensure high value care, a thorough history and physical exam combined with diagnostic discipline is critical as these nodules are idiopathic in ~55% of cases. We recommend obtaining a CBC with differential, ESR, CRP, ASO antibodies, throat culture, and chest x-ray in patients with idiopathic EN, and further tests should be obtained only if the patient's history and physical exam significantly increase suspicion for an underlying condition.

A CASE OF HEPATITIS LEADING TO INITIAL DIAGNOSIS OF SYSTEMIC LUPUS ERYTHEMATOUS

Ryan Burkholder¹; Patrick B. Harriss³; Daniella Lopes⁴; Hrishikesh Samant². ¹LSU Health Sciences Center, Shreveport, LA; ²Louisiana State University, Shreveport, LA; ³LSU Health Sciences Center - Shreveport, LA, Shreveport, LA; ⁴Willis-Knighton Hospital, Shreveport, LA. (Control ID #3184816)

LEARNING OBJECTIVE #1: Distinguish features of lupus hepatitis after appropriate workup has excluded other common causes of transaminitis.

CASE: We present a 56 yr old female with past medical history of Raynauds, MVP, and GERD who presents with a two week history of fatigue, malaise, anorexia, fever and jaundice. Physical exam was unremarkable except for generalized jaundice. Laboratory analysis revealed AST 1286, ALT 1191, total bilirubin 12.7, INR 1.2, albumin 3.7 and WBC 5.8k. Platelets decreased to 125k and WBC decreased to 3.6k during hospital course. Further ultrasound and CT of the abdomen showed no obstructive process. Due to suspicious for a mononucleosis type picture, CMV serologies and an EBV viral panel were obtained which showed CMV both positive IgM and IgG, however CMV DNA PCR was negative. EBV serologies were positive for IgG and negative for IgM. Acute hepatitis panel, HIV, and anti liver-kidney microsomal screen, and anti Smith/RNP, anti-smooth muscle antibody were negative; However both ANA and dsDNA were positive with positive cytoplasmic reticular pattern observed which may be associated with antimitochondrial antibodies. Complements were mildly decreased. Since both AST and ALT remained elevated with no clear etiology, a liver biopsy was performed which showed predominantly lymphocytic inflammatory infiltrate with parenchymal areas demonstrating confluent hepatocellular necrosis consistent with lupus hepatitis. An immunohistochemical stain for cytomegalovirus was negative. Patient was treated as lupus and subsequently discharged home on an oral steroid regimen with rheumatology follow-up. Liver enzymes several weeks later were as follows: AST 26, ALT 16 and total bilirubin 0.8.

IMPACT/DISCUSSION: Systemic lupus erythematosus (SLE) is an autoimmune disorder infecting multiple organs. Severe hepatic involvement is rare in patients with SLE, although 25-50% of patients will experience some form of transaminitis. In many cases, elevated transaminases are due to inciting factors such as hepatotoxic drugs, viral hepatitis or fatty liver disease. Viral infections can be triggering events in autoimmune disorders and CMV may have been an inciting factor that prompted acute liver injury in our patient.

CONCLUSION: Due to frequent multifaceted manifestations of liver diseases in SLE, an assessment of immunological, serological and virological markers should be performed. Autoimmune hepatitis (AIH) should always be considered in a patient with multiple positive autoantibody markers since it has a much more severe disease progression. Testing for AMA, ASMA, anti-liver kidney antibodies, and soluble liver antigen may be helpful in differentiating AIH. Finally, histopathology is the key method of diagnosis, and histopathological findings led to diagnosis of SLE in our patient.

A CASE OF HPV RELATED OROPHARYNGEAL SCC IN THE ABSENCE OF TRADITIONAL RISK FACTORS: A RISING CLINICAL ENTITY

Ahmed S. Ahmed; Sami G. Tahhan. EVMS, Norfolk, VA. (Control ID #3185178)

LEARNING OBJECTIVE #1: HPV-related oropharyngeal squamous cell carcinoma (OPSCC) represents a growing etiologically distinct subset of head and neck cancers with unique epidemiological, clinical, and prognostic characteristics. We report an interesting case of HPV related OPSCC in the absence of other identifiable risk factors.

CASE: A 49-year-old Caucasian male with no prior history of smoking or alcohol abuse presented in 2011 with complaints of asymptomatic left-sided neck swelling. Neck CT revealed a malignant appearing complex mass in the left neck, posterior to the submandibular gland. FNA biopsies revealed proteinaceous debris and were negative for malignancy. The patient was scheduled for surgical excision but was lost to follow up. In 2017, the patient presented again, now with complaints of a persistent left-sided neck mass. Examination revealed a firm lesion measuring approximately 3 x 4 cm at the anterior border of his left SCM. Reimaging demonstrated a left palatine tonsillar mass with multiple multifocal ipsilateral cervical malignant appearing adenopathy concerning for metastatic malignancy from a palatine tonsil mucosal primary tumor. FNA biopsy was positive on immunohistochemistry for p16 HPV mediated OPSCC. The patient was treated with chemoradiation with a good clinical response.

IMPACT/DISCUSSION: Despite the decrease in tobacco use, the incidence of oropharyngeal cancer initially remained constant and then began to rise. Public health sources describe it as an upcoming epidemic. HPV related OPSCC seems to account for this incidence trend with one study suggesting that the annual number of HPV-associated oropharyngeal cancers in the United States will overtake the incidence of invasive cervical cancer cases by 2020. As in cervical cancer, oral HPV infection appears to be a sexually-acquired disease likely through oral sex thus reflecting societal changes in sexual behavior that have occurred over time in the developed world.

CONCLUSION: HPV infection, and in particular type 16 (HPV-16), is now recognized as a significant player in the onset of OPSCC. Diagnosis is made through Immunohistochemistry for p16 which is overexpressed and highly sensitive for HPV associated OPSCC. The p16 protein functions as a tumor suppressor preventing phosphorylation of the Retinoblastoma protein (Rb) and affecting cell growth. Compared to non-HPV OPSCC, HPV associated tumors predominantly arise in the tonsillar region or the base of the tongue, it's more likely to present with an early-stage and usually have a better prognosis. The age of presentation tends to be younger peaking around 30 and 55 years with less exposure to the traditional risk factors of tobacco and alcohol. HPV positivity is less frequent in African Americans than in Caucasians with a threefold higher incidence in males than females. Treatment of HPV OPSCC includes a multimodality approach with chemotherapy, radiation therapy, and/or surgery with significantly better prognosis and five-year overall survival compared to HPV free OPSCC.

A CASE OF KRATOM INDUCED CHOLESTASIS

Randeep Kaur; Charles Siedlecki; Syed-Mohammed Jafri. Henry Ford Hospital, Detroit, MI. (Control ID #3185390)

LEARNING OBJECTIVE #1: Recognize that there are many uncommon and likely unrecognized drugs including prescription, over the counter and herbal remedies that can cause cholestasis

CASE: The patient is a 42 year old female with a history of polio, with no residual deficits, who presented with generalized symptoms of subjective fever, fatigue, nausea and poor appetite. She was being worked up in an outpatient setting however when her urine turned dark orange, she decided to present to the hospital. When she initially presented, she had elevated

transaminases; alanine aminotransferase (ALT) 371, aspartate aminotransferase (AST) 171. Her ALT increased to 606 on recheck. Other labs included total bilirubin 3.3, alkaline phosphatase 298 and INR 0.97. Ultrasound of the abdomen showed a thickened gallbladder wall without Murphy's sign and a normal evaluation of the liver. On initial questioning, she denied a previous history of liver disease, alcohol use, or tylenol use. Autoimmune liver panel, hepatitis and HIV screen was negative. Epstein-Barr virus and cytomegalovirus was negative. Alpha-1-antitrypsin, iron, ceruloplasmin were within normal limits. Upon further questioning of home medications, she reported kratom use for treatment of her chronic pain secondary to her past history of polio. Her duration of use of kratom was 4 months with her last use 4 weeks prior to presentation. She was diagnosed with herbal induced cholestasis by kratom. Her jaundice improved, liver enzymes trended down and she was discharged. Her one month outpatient follow up revealed normal liver enzymes with no further reported kratom use.

IMPACT/DISCUSSION: The herbal remedy kratom has been long used in traditional medicine most commonly for depression, anxiety and pain since the nineteenth century, however its impact on the liver is not well known. The mechanism by which kratom induced liver injury in this patient is unknown. The pattern of liver injury was mixed between hepatocellular and cholestatic suggesting that there might be multiple mechanisms of injury. Injury can present with generalized symptoms which can often times be mistaken for other pathologies which is why a thorough history is required to further understand and discontinue offending agents such as kratom. Although kratom was helping to alleviate pain in this patient, discontinuation was necessary to allow complete resolution of liver injury.

CONCLUSION: This case represented short term use of kratom which induced liver injury with subsequent resolution upon discontinuation. There are many oral agents that are still not fully understood or well known which cause liver injury. With this lack of knowledge, it remains important for internists to obtain thorough histories of everything that is ingested prior to presentation. With this information, better understanding and insight can be obtained to which agents should be avoided in the general population.

A CASE OF LEVOFLOXACIN INDUCED PSYCHOSIS IN A YOUNG HEALTHY PATIENT

Michael Muradian; Kaitlin Annunzio; Zachary Kaczmarek; Shaheena Khan; Kavita Naik; Pinky Jha. Medical College of Wisconsin, Milwaukee, WI. (Control ID #3185210)

LEARNING OBJECTIVE #1: To recognize levofloxacin as a cause of acute psychosis.

LEARNING OBJECTIVE #2: Discuss the course and treatment of antibiotic induced psychosis.

CASE: A 23 year old African American female with a history recurrent submandibular abscesses treated with antibiotics presented to the hospital emergency department with anxiety, paranoia, visual hallucinations, and psychosis. She had been recently discharged from the hospital 4 days prior following incision and drainage with prescriptions for levofloxacin and metronidazole. Two days following discharge she developed paranoia and insomnia which progressively became more severe and the following day she developed visual hallucinations. On admission drug and toxicology screens were negative and a head CT showed no signs of intracranial pathologies. Labs showed no evidence of metabolic causes for altered mental status such as electrolyte abnormalities, hypoglycemia, or encephalopathies. The patient had no psychiatric history and her symptoms were not consistent with a primary psychiatric disorder. Given the lack of evidence for other causes of psychosis this raised concern it may be due to her antibiotics. The levofloxacin and metronidazole were promptly discontinued and she was then prescribed ceftriaxone. Over the following days additional testing including EEG were negative and no other causes of psychosis could be identified. She gradually improved and 3 days after discontinuing the antibiotics she had returned to baseline mental status.

IMPACT/DISCUSSION: Levofloxacin is in the fluoroquinolone class antibiotics and has activity against a wide range of organisms making it a commonly prescribed antibiotic. This medication is generally well tolerated; gastrointestinal distress is the most common adverse effect reported but the medication has an otherwise favorable side effect profile. Neuro-psychiatric side effects are very rare and poorly described in the literature with psychosis only being reported in a few cases. It is believed that this effect may be related to possible inhibition of GABA receptors and some have reported that renal disease may increase the risk for these effects. The time of symptom onset in relation to the initiation of antibiotic treatment is highly variable which makes identifying the cause more challenging. These effects can be severe, but they are reversible within a few days of discontinuation of the drug. We present a case that highlights how otherwise healthy individuals with no significant risk factors or psychiatric history are susceptible. Medical providers should consider these poorly understood effects in any patient receiving levofloxacin who develops altered mental status or psychiatric symptoms.

CONCLUSION: Antibiotics should be considered as a cause of psychosis in patients with new symptoms. Patients with no significant risk factors can develop drug induced psychosis.

A CASE OF LOSARTAN-ASSOCIATED GENERALIZED ERYTHRODERMA WITH FEVER

Ruth Jobarteh²; Emily Peng²; Allan C. Gelber¹; Paul O'Rourke¹. ¹Johns Hopkins University, Baltimore, MD; ²Johns Hopkins Bayview Medical Center, Baltimore, MD. (Control ID #3185819)

LEARNING OBJECTIVE #1: Recognize clinical features of a delayed-type drug reaction, including erythroderma, fever, transaminitis and eosinophilia (including DRESS syndrome)

LEARNING OBJECTIVE #2: Manage a new diagnosis of DRESS syndrome

CASE: A 74-year-old disabled woman with multiple sclerosis and prior pulmonary embolism presented with a prominent truncal erythematous rash of 5 days duration. The rash spread to her arms, palms, buttocks and legs, became pruritic and desquamating, sparing only her face. On the day of admission to the Medicine Service, she developed a fever of 102.5°F/39.2°C and was hospitalized. Home medications were warfarin, simvastatin, fluoxetine, methenamine, baclofen, tizanidine, furosemide and losartan, the latter begun the prior month. Examination was notable for BP 129/67 mmHg, HR 88 beats/min, Temp 36.7 °C, RR 22 breaths/min and S02 of 96% on 2L of O2. There was marked diffuse blanchable erythroderma over the back, chest, scalp, breasts, abdomen, arms and legs. There was no mucositis, conjunctivitis, axillary or supraclavicular lymphadenopathy. Laboratory findings were significant for WBC 22.64 (peak eosinophil level 5%), alkaline phosphatase 289, AST 299, ALT 230, bilirubin 0.4 and ESR 79. Urine and blood cultures were negative. Viral hepatitis serologies were negative. Upon admission, losartan was discontinued. Skin biopsy revealed focal neutrophilic infiltrate, dyskeratotic keratinocytes, diffuse spongiosis and subtle vacuolar alteration, without eosinophils. Oral prednisone 30 mg thrice daily was commenced. Liver function tests trended down. By the third day of steroid therapy, the rash had substantially improved. She was discharged on a steroid taper with instruction to never resume losartan.

IMPACT/DISCUSSION: Delayed-type drug hypersensitivity reactions range in severity from skin eruptions alone, to the DRESS syndrome, to toxic epidermal necrolysis and can be life-threatening. Symptoms typically manifest 1-3 weeks after exposure to an inciting drug. Rash, fever, leukocytosis, eosinophilia and abnormal liver enzymes are hallmark findings. Skin manifestations in DRESS syndrome include diffuse erythroderma but can have various morphologies. It is critical to consider prescribed medication in the differential diagnosis of fever, skin rash and transaminitis. The next step is to terminate use of the putative culprit drug, consider steroid administration and furnish supportive skin care. Losartan has been linked to

anaphylaxis, angioedema and to skin rashes. Yet, we identified no reports of losartan inducing overt DRESS. In our patient, once losartan was stopped and systemic corticosteroids were begun, clinical improvement ensued.

CONCLUSION: • Drug reaction, including DRESS syndrome, may result in diffuse erythroderma, fever, eosinophilia and transaminitis. • Cessation of the inciting medication and initiation of corticosteroids are the mainstays of therapy in DRESS.

A CASE OF MEDICATION-INDUCED HYPOGLYCEMIA IN AN ELDERLY PATIENT WITH POORLY CONTROLLED TYPE 2 DIABETES

Katharine Lawrence; Saif Laljee; Diana Randlett. NYU School of Medicine, New York, NY. (Control ID #3184686)

LEARNING OBJECTIVE #1: Recognize risks of hypoglycemia associated with sulfonylureas and thiazolidinediones

LEARNING OBJECTIVE #2: Apply evidence-based guidelines for appropriate management of diabetes in elderly patients

CASE: A 72 year-old Spanish-speaking man with poorly controlled type 2 diabetes, hypertension, and newly diagnosed prostate cancer was brought by ambulance with confusion and weakness. He was found to have a fingerstick glucose of 30 mg/dl. Additional workup was unremarkable and symptoms resolved with 50% dextrose. He was admitted for symptomatic hypoglycemia. The patient reported taking multiple oral hypoglycemic agents, including glipizide twice daily, pioglitazone, metformin, and sitagliptan. Four months prior, pioglitazone was tripled due to A1c 10.4%. He also revealed unintentional weight loss (possibly due to his cancer), and multiple home fingersticks in the 60s. Repeat A1c was 6.7%. The sulfonylurea and pioglitazone were discontinued. The patient was educated on his medications, glucose targets, and symptoms of hypoglycemia. He was discharged with advice to follow with his primary physician.

IMPACT/DISCUSSION: Nearly 25% of patients over age 65 have diabetes. Elderly diabetics are uniquely vulnerable, with higher risks of symptomatic hypoglycemia, increased hospitalizations, and higher overall associated morbidity and mortality. Polypharmacy, low health literacy, and language barriers contribute to their complex medical management. Recent studies have shown that tighter A1c control (<7.0%) is associated with additional harms in geriatric patients, including a higher mortality rate. As a result, medical organizations have revised their glycemic control guidelines towards more personalized, patient-centered management. These guidelines include differential A1c goals (from 7.0-9.0%) based on overall health, comorbidities, and life expectancy. Guidelines for geriatric diabetes care were updated in 2018 to include recommendations that overtreatment of diabetes should be avoided, medication classes at low risk of hypoglycemia are preferred, and complex medication regimens should be simplified to reduce hypoglycemia. Our patient illustrates the importance of each of these guidelines. With his age and comorbidities, including newly diagnosed cancer, he had indications for looser A1c goals. He was also at high-risk for medication-related adverse events, given his polypharmacy and limited health literacy. Metformin and sitagliptin would have been favored agents. Education on symptoms of hypoglycemia, as well as interpreting fingersticks, was crucial to prevent rehospitalization and improve health literacy.

CONCLUSION: Geriatric patients with diabetes represent a unique and vulnerable population. Guidelines for diabetes management in these patients are evolving, with increased emphasis on personalized, patient-centered management, including looser A1c goals for those with comorbidities or shorter life expectancy. Providers are encouraged to simplify medications and avoid polypharmacy to improve outcomes and save lives.

A CASE OF METASTATIC ACRAL LENTIGINOUS MELANOMA MASQUERADING AS HEMORRHAGIC CVA

Farukh Ikram; Leslie Cler; Haseeb Ikram; Syeda A. Raza. Methodist Dallas Medical Center, Plano, TX. (Control ID #3185439)

LEARNING OBJECTIVE #1: Recognize malignancy as a potential cause of intra-parenchymal hemorrhage

CASE: A 75 yo man with a history of hypertension presented with generalized weakness along with a severe, unremitting headache. The patient also reported a growth on his foot of unknown chronicity as well as back pain and urinary retention. The physical exam was significant for left-sided neglect and a large fungating mass on the plantar aspect of his left foot measuring approximately 5x5cm. The mass had patchy areas of necrosis and was visibly bleeding. A stat CT head demonstrated a 4.6cm x 4.4cm x 3cm frontoparietal hematoma. He was taken to the operating room by neurosurgery for evacuation of the hematoma and was found to have a mixed density intracerebral hemorrhage. Pathology of the solid component of the hemorrhage, along with biopsies of the foot mass, was sent for laboratory analysis. Histopathology was consistent with acral lentiginous melanoma. Tumor markers were positive for BRAF mutation. An intrathecal melanoma at T11-T12 of his spinal cord was identified via MRI for which he underwent laminectomy. Unfortunately, the patient's health continued to decline and he eventually elected for hospice.

IMPACT/DISCUSSION: This is a case of acral lentiginous melanoma (ALM) presenting as hemorrhagic CVA. ALM very rarely metastasizes to the brain making this a unique form of presentation for the disease. Furthermore, the sheer size of the mass - nearly golf-ball sized - is remarkable. Most lesions are much smaller, especially in respect to thickness. If the melanoma were not as prominent and the hematoma had been medically managed, the diagnosis could have been missed as there was no radiographic evidence for malignancy. This underscores the importance of including malignancy on the differential when a patient presents with intra-parenchymal hemorrhage. Patients should always be asked whether they have received age-appropriate cancer screening or have noticed any concerning skin growths or changes.

CONCLUSION: There are four subtypes of invasive cutaneous melanoma: 1) superficial spreading 2) lentigo maligna 3) nodular and 4) acral lentiginous. Superficial spreading melanoma accounts for approximately 70% of melanomas. Acral lentiginous melanoma (ALM) is the rarest subtype and accounts for 5% of melanomas. Although rare, it is the most common form of melanoma in darker skinned individuals and is typically found on the palm, soles, and feet. Definitive diagnosis is through histopathology. Testing should always be performed for V600 BRAF mutation. If results are positive, then the patient is eligible for immunotherapy and/or targeted therapy. Unfortunately, patients have an overall poor prognosis when presenting with advanced melanoma and CNS melanoma worsens prognosis even further. Stage IV melanoma has a median survival of 6 to 9 months and 5-year survival is estimated to be 10-20%.

A CASE OF MYCOSIS FUNGOIDES BULLOSA MIMICKING STEVENS-JOHNSON SYNDROME

Sophia Zhang¹; Hilary C. Strollo¹; Sarah B. Merriam². ¹University of Pittsburgh, Pittsburgh, PA; ²University of Pittsburgh Medical Center, Pittsburgh, PA. (Control ID #3185699)

LEARNING OBJECTIVE #1: Recognize Symptoms of Mycosis Fungoidea Bullousa

LEARNING OBJECTIVE #2: Differentiating MFB from other acute vesiculobullous eruptions

CASE: A 74-year old veteran with a past medical history of gout was admitted for culture-negative septic arthritis and treated with IV vancomycin. On hospital day 3, he developed acute, diffuse blistering and desquamation of the trunk in the setting of recent allopurinol use. Review of symptoms was significant for a one-month history of bilateral palmar desquamation with pruritis and fatigue. He denied other new medications (i.e. NSAIDs, anti-convulsants, antibiotics aside from vancomycin), drug allergies, and a history

of immunobullous disease or recent insect bites. The patient was afebrile with stable vital signs. Small flaccid, non-tender bullae with positive Nikolsky sign were present on the trunk, thighs, and intergluteal folds, covering less than 10% of the skin, sparing mucosa and eyes. CBC showed persistent lymphocytosis to $36 \times 10^9/L$. Histopathology revealed intraepidermal deposits of atypical CD4+ lymphocytes forming Pautrier microabscesses. Direct immunofluorescence (IF) studies were negative. Peripheral blood flow cytometry revealed clonal T-cell receptor gamma gene rearrangement with corresponding bone marrow involvement on biopsy. CT abdomen/pelvis demonstrated widespread lymphadenopathy. The patient was diagnosed with Stage IVA2 cutaneous T-cell lymphoma (CTCL) and started on low dose oral methotrexate and topical hydrocortisone cream for symptomatic relief.

IMPACT/DISCUSSION: Mycosis fungoides bullosa (MFB) is a rare but aggressive variant of CTCL with a poor prognosis. It presents as a rapidly progressive desquamating vesiculobullous eruption, which can be mistaken for Stevens-Johnson Syndrome (SJS) especially in the setting of common pharmacologic culprits such as allopurinol. This case adds to the sparse literature on MFB and the differential diagnosis of acute vesiculobullous eruptions. Four criteria are recommended for diagnosis of MFB: 1) vesiculobullous lesions with or without typical MF lesions, 2) typical histologic features of MF (atypical lymphoid cells, epidermotropism, Pautrier's microabscesses) with intraepidermal blisters, 3) negative IF to rule out concomitant autoimmune bullous diseases, and 4) negative workup for other etiologies of vesiculobullous lesions (e.g., medications, infections). In our case, all diagnostic criteria were met with corresponding clinical and histologic findings. In cases of acute vesiculobullous eruption, SJS is an important, rapidly fatal diagnosis to rule out. Our patient did not have ocular or mucosal involvement (present in >90% of SJS patients), nor systemic symptoms associated with SJS. Histopathologic findings specific to MFB such as CD4+-predominant lymphocytes forming Pautrier's microabscesses can facilitate diagnosis.

CONCLUSION: MFB is a rare variant of CTCL with a poor prognosis and should be on the differential workup for vesiculobullous eruptions to ensure prompt diagnosis and treatment.

A CASE OF NONBACTERIAL THROMBOTIC ENDOCARDITIS IN A YOUNG PATIENT WITH ACUTE MYELOGENOUS LEUKEMIA

Rami Atallah²; Nicholas Ojile²; Kamal Chamoun³; Mohinder Vindhyal¹.

¹KU - Wichita, Wichita, KS; ²University of Kansas Wichita, Wichita, KS;

³Case Western Reserve University, Cleveland, OH. (Control ID #3185270)

LEARNING OBJECTIVE #1: Recognize the causes and clinical features of nonbacterial thrombotic endocarditis.

LEARNING OBJECTIVE #2: Recognize that nonbacterial thrombotic endocarditis is potentially underdiagnosed.

CASE: A 29 year-old female with a history of recurrent pancreatitis presented to her primary care physician complaining of severe dyspnea on exertion and fatigue. Outpatient laboratory work revealed severe anemia and the patient was sent to the emergency department for further evaluation. She denied any symptoms of bleeding at the time. Family history was remarkable for maternal grandfather with history of leukemia. Her physical examination was significant for skin pallor and tachycardia. Complete Blood Count (CBC) on presentation showed hemoglobin of 4 g/dL, platelets of $56 \times 10^9/L$, and white blood cells (WBC) of $14 \times 10^9/L$ with 40% peripheral blasts. A bone marrow biopsy confirmed the diagnosis of AML with complex karyotype, and negative NPM1 and CEBPA mutations. An initial echocardiogram revealed an ejection fraction of 55% with no valvular abnormalities. Blood cultures were obtained and she was started on broad spectrum antibiotics. The DIC panel was negative. Induction chemotherapy was then started using cytarabine and daunorubicin. After initiating chemotherapy, she developed bilateral infiltrates on chest X-ray and her respiratory status rapidly deteriorated requiring

mechanical ventilation. Bronchoscopy was consistent with diffuse alveolar hemorrhage (DAH). Multiple sets of blood cultures in the setting of persistent neutropenic fever were repeatedly negative. Patient was on vancomycin, meropenem, acyclovir, and voriconazole. Suddenly, a week later, she developed neurological deterioration including absent brainstem reflexes, renal failure and left leg ischemia caused by an arterial clot in the deep femoral artery. Family discussion led to comfort care. Autopsy revealed fibrin vegetation on the aortic valve and tricuspid valve with massive ischemic infarct involving the left frontal, parietal and occipital lobes of the brain in addition to bilateral kidney and spleen infarcts. Bilateral pulmonary hemorrhage was also noted.

IMPACT/DISCUSSION: Nonbacterial thrombotic endocarditis (NBTE), formerly known as marantic endocarditis, is a rare condition characterized by deposition of sterile thrombi on heart valves with the absence of bacterial growth on blood cultures. NBTE increases the risk of systemic embolic events including stroke. Microscopically, NBTE results from agglutinated platelets mixed with strands of fibrin. NBTE is most commonly associated with advanced malignancy and systemic lupus erythematosus. In this case, NBTE has led to significant multi-organ failure including kidney failure, massive stroke and leg ischemia.

CONCLUSION: NBTE is uncommon but associated with poor outcomes. It is uncommonly reported in patients with AML and is often a postmortem diagnosis. NBTE is potentially underdiagnosed and should be considered in any cancer patient with an episode of arterial thromboembolism.

A CASE OF OXALOSIS FOLLOWING ROUX-EN-Y BYPASS SURGERY

John Paul Mikhaiel; Ryan M. Commins; Margot Wheeler. Georgetown University, Washington, DC. (Control ID #3168633)

LEARNING OBJECTIVE #1: Recognize the clinical presentation and risk factors for hyperoxalemia

CASE: A 61-year-old male with history of acute renal failure on hemodialysis and obesity, four years status post Roux-en-Y bypass, presented with episodic skin changes and paresthesia in his fingers and toes as well as hemoptysis. Six months prior to presentation, he was admitted for acute renal failure with renal biopsy revealing ethylene glycol crystals. In the preceding months, he also complained of sporadic day-long episodes of burning and paresthesia in his fingers and toes and three episodes of small volume hemoptysis. His skin exam revealed distal fingertips with necrotic ulcerations and slight purpura, and distal toes with necrotic ulcerations extending into the fat pads. Lung exam was clear to auscultation with diminished sounds at bases. While initial labs revealed an elevated CRP, follow-up infectious and immunologic studies were unremarkable. CT scan of the chest demonstrated diffuse ground-glass airspace opacities and confluent consolidation in the right upper lobe. Punch biopsy, taken during a stage of healing, of the skin ulcers was suggestive of thrombogenic vasculopathy. Finally, his plasma oxalate level was found to be 28.5 umol/L, greater than 15x the normal limit, indicating hyperoxalemia. He was treated with dietary modification and initiation of cholestyramine.

IMPACT/DISCUSSION: An estimated 100 million American adults are obese, and over 200,000 bariatric surgery procedures were performed in 2017 alone. While Roux-en-Y bypass has been supplanted by the gastric sleeve as the most common bariatric surgery performed, Roux-en-Y was still performed over 40,000 times in 2017. This case highlights the post-operative complication of hyperoxaluria in malabsorptive gastric bypass procedures. Hyperoxaluria following Roux-en-Y gastric bypass is estimated at 20%. While not completely understood, it has been suggested that the enteric hyperoxalemia that follows bariatric surgery is secondary to free fatty acid malabsorption. The excess free fatty acids and bile salts in the intestinal lumen bind to and saponify calcium, inhibiting the formation of calcium oxalate, and increasing absorption of soluble free oxalate. Hyperoxalemia may lead to nephrocalcinosis, often manifesting as nephrolithiasis or progressive renal insufficiency. Hyperoxalemia can also

mimic systemic vasculitis, presenting with Raynaud's, acrocyanosis, livedo reticularis, diminished peripheral pulses, gangrene, and rarely, diffuse alveolar hemorrhage. In this patient, hyperoxalemia due to malabsorptive gastric bypass surgery is a unifying diagnosis for this patient's renal failure, peripheral gangrene, and diffuse alveolar hemorrhage.

CONCLUSION: While hyperoxaluria leading to calcium oxalate nephrolithiasis following malabsorptive gastric bypass is not uncommon, it is important to be aware of other systemic manifestations of hyperoxalemia, which can provide a unifying diagnosis in a challenging clinical presentation.

A CASE OF POTENTIALLY FATAL EPISTAXIS

PRIYANKA BHUGRA¹; Abhishek Maiti². ¹University of Texas Health Science Center at San Antonio, San Antonio, TX; ²University of Texas Health Science Center at Houston, Houston, TX. (Control ID #3187054)

LEARNING OBJECTIVE #1: Pseudoaneurysms of the internal carotid artery are uncommon but potentially life-threatening cause of epistaxis.

LEARNING OBJECTIVE #2: History of prior trauma, surgery or radiation are important clues to diagnosis. Early recognition and endovascular intervention can help improve morbidity and mortality.

CASE: A 42-year-old previously healthy man presented to the emergency room after having epistaxis and syncope. Patient reported having recurrent episodes of right epistaxis over past 2 weeks. Earlier in the day, he had 4-6 cupfuls of bleeding from his nose leading to lightheadedness and eventually passing out. He had a remote history of trauma with facial fractures after a motor vehicle accident 8 years ago for which he underwent surgery. On arrival, patient was hypotensive with blood pressure of 80/ 50 mm Hg and tachycardic with a heart rate of 110 beats/ minute. Examination showed crusted blood in anterior nasal cavity. Laboratory studies showed hemoglobin of 6.4 g/dL. There was minimal improvement in blood pressure and hemoglobin with intravenous fluid resuscitation and blood transfusion. Furthermore, flexible nasopharyngoscopy revealed bleeding originating from the right sphenoid traveling down the posterior nasal cavity to choana and posterior oropharynx. Shortly after the scope was withdrawn, patient sneezed and started bleeding profusely from the right nare. At this point, anterior and posterior nasal tamponade were applied and patient was intubated for airway protection. An emergent angiogram identified a right cavernous internal carotid artery (ICA) pseudoaneurysm as the source of bleeding. Endovascular coil embolization of pseudoaneurysm was performed followed by placement of pipeline embolization device. Subsequently, patient became hemodynamically stable and was successfully extubated. The patient remained asymptomatic at 3-month follow up.

IMPACT/DISCUSSION: Majority cases of epistaxis are self-resolving. However, red flag signs like recurrent or intractable bleeding, heavy blood loss, hemodynamic instability, vision loss or accompanying neurologic deficits should raise concern for more sinister etiology. Pseudoaneurysms of ICA are uncommon but potentially life-threatening cause of epistaxis. These can occur as a result of blunt trauma, surgery or after radiation therapy to the head and neck region. Epistaxis due to post-traumatic pseudoaneurysms usually occurs within weeks of injury, but it may be delayed by years. This poses a significant diagnostic challenge to clinicians. Prompt control of bleeding and airway protection are crucial as rupture of ICA pseudoaneurysms can lead to catastrophic bleeding. Early recognition of this life-threatening condition is important as majority of cases are amenable to endovascular intervention.

CONCLUSION: Pseudoaneurysms of ICA can cause serious epistaxis with significant morbidity and mortality. Timely recognition and endovascular intervention can be life-saving.

A CASE OF PROSTHETIC VALVE DYSFUNCTION PRESENTING WITH DYSPHAGIA AND ACUTE TUBULAR NECROSIS

Yael Tarshish; Vidya Gopinath. Brown Medicine, Pawtucket, RI. (Control ID #3185670)

LEARNING OBJECTIVE #1: Recognize dysphagia as a side effect of mitral valve dysfunction and identify possible mechanisms

LEARNING OBJECTIVE #2: Diagnose acute tubular necrosis (ATN) in the setting of hemolysis with minimal serum creatinine (Cr) elevation

CASE: A 76 year old female with history of five mitral valve replacements (last surgery: 12 years ago for hemolysis) presented with dark urine and intermittent difficulty swallowing for one month. She had been hospitalized two weeks prior for the same symptoms, but had negative esophagogastroduodenoscopy (EGD) and normal swallow evaluation and no valve abnormality on transthoracic echocardiogram. She was discharged home, yet continued to endorse worsening swallowing function and "coca cola" colored urine. Vitals: unremarkable. Pertinent exam findings: scleral icterus; crisp mitral sound. Significant labs: UA positive for 3 RBCs, Hgb 8.5, Cr 0.88, TBili 2, LDH 1961. Cardiology, hematology, nephrology and gastroenterology were consulted. Transesophageal echocardiogram demonstrated a small paravalvular leak with severe mitral regurgitation and left atrium (LA) dilatation. Barium swallow demonstrated severe esophageal dysmotility without barium passage to the lower esophageal sphincter. Hematology found no underlying erythrocyte abnormality. Spun urine revealed muddy brown casts and evidence of ATN despite normal Cr. ATN was attributed to hemoglobinuria from hemolysis and was treated with fluids. Hgb dropped to 6.6, requiring transfusions. She underwent a perivalvular leak repair with valvular plugs. Hemolysis resolved and dysphagia gradually improved.

IMPACT/DISCUSSION: Mitral valve dysfunction causes dysphagia through various potential mechanisms. LA enlargement can cause hoarseness through compression of the recurrent laryngeal nerve, and can impact esophageal functioning through compression of the vagus nerve. A study demonstrated association between LA size and esophageal transit with barium swallows demonstrating cardiac indentation of esophagus. Research in paroxysmal nocturnal hemoglobinuria (PNH) proposes a mechanism by which hemolysis causes dysphagia: increased free hgb binds free nitrous oxide (NO), a modulator of smooth muscle function. Decrease in NO effects esophageal tone. Two case studies describe dysphagia associated with hemolysis caused by left ventricular assist device, providing possible explanations for the mechanism behind our patient's dysphagia. Hemolysis can cause an increase in free hgb resulting in urine dipstick positive for blood and sediment negative for RBCs. Free hgb degradation in the urinary space with release of heme pigment damages the kidneys, leading to ATN. ATN can cause minimal increase in serum Cr with evidence of kidney injury on urine microscopy. Management involves aggressive hydration.

CONCLUSION: Mitral valve dysfunction can manifest pathologically in disparate organ systems. Knowledge of uncommon sequelae can prompt more rapid diagnosis.

A CASE OF PSEUDOHYPONATREMIA FROM SEVERE SECONDARY HYPERCHOLESTEROLEMIA

Leah Bettner¹; Carleigh L. Benton^{2, 1}; Amy Yu¹. ¹University of Colorado Denver, Denver, CO; ²University of Colorado, Denver, CO. (Control ID #3176728)

LEARNING OBJECTIVE #1: Identify severe hypercholesterolemia from cholestasis as a cause of pseudohyponatremia.

LEARNING OBJECTIVE #2: Diagnose pseudohyponatremia by measuring osmolar gap and whole serum sodium levels.

CASE: A 59 year-old man with diabetes and chronic pancreatitis was admitted with weight loss, poor oral intake, abdominal pain, and jaundice. Imaging detected a pancreatic mass and biliary ductal dilation concerning for malignancy. Labs were notable for a total bilirubin

of 22 mg/dL, direct bilirubin 14.1 mg/dL, alkaline phosphatase 1,928 U/L, and serum sodium 119 mmol/L. Initial hyponatremia was attributed to hypovolemia however sodium did not improve with intravenous fluids. Urine studies were consistent with the syndrome of inappropriate antidiuretic hormone secretion but sodium did not improve with fluid restriction. The calculated serum osmolar gap was noted to be high (23 mOsm/kg) and a subsequent lipid panel showed a total cholesterol of 1,289 mg/dL, LDL 1,059 mg/dL, HDL 184 mg/dL, and triglycerides 228 mg/dL. Lipid studies three months prior were normal. The diagnosis of pseudohyponatremia was confirmed with a normal whole blood sodium level of 135 mmol/L. Ultimately, the patient underwent biliary stent placement and biopsy confirmed pancreatic adenocarcinoma. With biliary obstruction relief, the cholestatic labs improved but the hyperlipidemia (HLD) persisted. A statin was prescribed at the time of discharge and was later discontinued.

IMPACT/DISCUSSION: Hyponatremia is common in hospitalized patients and this case highlights the importance of broadening the differential diagnosis to include an otherwise relatively rare laboratory artifact of pseudohyponatremia in a patient presenting with obstructive cholestasis and secondary HLD. Furthermore, understanding that secondary HLD from cholestasis does not confer an atherosclerotic risk prevents unnecessary statin therapy. Our case highlights the importance of considering pseudohyponatremia from severe HLD in patients with hyponatremia and cholestasis. Patients with cholestatic disease may have poor oral intake leading to the assumption of hypovolemic hyponatremia. Calculating an osmolar gap can be a helpful first step, and if elevated, checking a lipid panel and whole blood sodium can help confirm the diagnosis of pseudohyponatremia. Cholestasis can be an important cause of secondary HLD. Case studies have identified an abnormal lipoprotein X (Lp-X) as the primary cholesterol carrier in patients with hepatobiliary and pancreatic cholestasis as opposed to LDL particles found in many patients with primary HLD. Lp-X is thought to have a negligible atherosclerotic effect, and thus statin therapy is not needed.

CONCLUSION: In patients with cholestasis and hyponatremia, early calculation of the osmolar gap and/or obtaining a whole blood sodium level can lead to an earlier diagnosis of pseudohyponatremia. Statin therapy is not necessary to prevent atherosclerosis in patients with secondary HLD from cholestasis.

A CASE OF RAPID NECROTIC SKIN ULCERATIONS IN AN ESRD PATIENT WITH REPORTED ANTIPHOSPHOLIPID SYNDROME ON WARFARIN

Christopher Chen¹; Henry C. Zheng¹; Mikel Etchegaray². ¹Baylor College of Medicine, Houston, TX; ²MD Anderson Cancer Center, Houston, TX. (Control ID #3186404)

LEARNING OBJECTIVE #1: Review differential diagnosis of necrotic skin lesions

LEARNING OBJECTIVE #2: Review pathophysiology, treatments, and recent developments in calciphylaxis

CASE: A 42 year-old woman with HTN, morbid obesity, ESRD on peritoneal dialysis due to recurrent AV fistula thromboses, tertiary hyperparathyroidism, reported anti-phospholipid syndrome on warfarin, three prior strokes presents with 2 months of worsening dyspnea, fatigue, bilateral leg swelling, 1-month painful non-healing ulcer of left ankle. Vitals and exam remarkable for fever, tachycardia, mild hypoxemia, bilateral rales and lower extremity edema with left anteromedial ulcer above the malleolus with clean base and serosanguinous drainage exquisitely tender to palpation. Initial labs showed leukocytosis, azotemia, and calcium-phosphorus product of 81. Left tibial x-ray negative for osteomyelitis. Despite dialysis initiation, her ulcer rapidly worsened into widespread necrotic eschar tracking up bilateral thighs and lateral abdomen. Her ANA was >1:640 speckled pattern but extensive autoimmune and infectious work-up all negative. Punch biopsy showed extensive dermal

purpura, small intravascular fibrin thrombi. Unfortunately, patient refused deep tissue biopsy for further analysis. Given clinical picture, a diagnosis of calciphylaxis was reached. She was started on pulse dose steroids, empiric antibiotics, heparin drip, continued dialysis, aggressive wound care, pain control, and sodium thiosulfate infusions. She underwent 3.5 parathyroidectomy, steroids were tapered, and was transitioned to low dose apixaban. She was discharged to long term care facility for continued wound care, IV antibiotics, and continued dialysis without significant improvement to skin ulcerations.

IMPACT/DISCUSSION: The differential for necrotic skin lesions is broad and often overlapping many body systems. Calciphylaxis, characterized by microvascular calcification, inflammation, and thrombosis in the adipose tissue layer, is even amongst dialysis patients a rare event (4%). With a 1-year mortality of 45-80%, patients are often bedbound with debilitating, uncontrollable pain. Diagnosis is mostly clinical based on risk factors, characteristic skin ulcers and eschar, and calcium phosphorus product >70. Biopsy is controversial given the need for deeper tissue sampling, pathergy risk, and high mortality rate with infection. No guidelines yet delineate standard work-up or treatments. Treatment is multifocal including aggressive wound care, pain control, electrolyte homeostasis, and sodium thiosulfate infusions. Underlying thrombophilia have been found in up to 80% of patients and highlights challenges in anticoagulation especially with co-morbid ESRD and risk of worsening with warfarin. Small studies suggest warfarin may have similar survival profiles to other anticoagulants.

CONCLUSION: Calciphylaxis is a rare but debilitating disease that is a challenge to effectively treat and in need of further trials based on recent evidence of common underlying associated thrombophilias.

A CASE OF RECURRENT SINUSITIS

Rebecca Angoff¹; Vimal Jhaveri²; Marisa Jupiter². ¹Beth Israel Deaconess Medical Center, Brookline, MA; ²Beth Israel Deaconess Medical Center, Boston, MA. (Control ID #3183857)

LEARNING OBJECTIVE #1: Recognize the features and epidemiology of extranodal NK/T-cell lymphoma.

LEARNING OBJECTIVE #2: Reassess the differential diagnosis when a patient's presentation no longer fits the illness script.

CASE: Mr. T is a 43-year-old male from Vietnam with a history of treated latent tuberculosis who presented with fevers, weight loss, and left facial swelling. In the weeks prior to admission, he had two Emergency Department (ED) visits due to fevers, headache, rhinorrhea, congestion, and left maxillary tenderness and was prescribed amoxicillin then subsequently amoxicillin-clavulanate without improvement of his symptoms. On his third ED visit, he also endorsed night sweats and a 6-pound weight loss. He had a CT that showed sinusitis of the left maxillary and anterior ethmoid sinuses and chest imaging that showed a 3cm cavitary lung lesion in the right upper lobe. He was admitted and underwent a tuberculosis rule out. He had three negative sputums for acid fast bacilli and a negative nucleic acid amplification test. Otolaryngology performed an endoscopy which showed nasal polypsis. A nasal sinus aspirate grew pan sensitive Klebsiella pneumoniae on culture, and the patient was initiated on ceftazidime. He continued to have fevers so was transitioned to meropenem. His fevers persisted, and he underwent a biopsy of his nasal polyp, which seven days later, resulted in extranodal NK/T-cell lymphoma, nasal type. Therefore, he was transferred to the oncology service for treatment.

IMPACT/DISCUSSION: In retrospect, his night sweats, refractory symptoms to antibiotics and lack of history of prior sinusitis made this an atypical presentation of simple bacterial sinusitis and there were clues that could have possibly put his rare diagnosis on the differential. Extranodal NK/T-cell lymphoma is an aggressive lymphoma with tropism for the nasopharyngeal and aerodigestive tracts. Rarely, it can metastasize to the lung and cavitate as it did in this case. The disease is associated with EBV and is more common in patients from Asia. The SMILE regimen,

which consists of dexamethasone, methotrexate, ifosfamide, L-asparaginase, and etoposide, while aggressive, has shown favorable outcomes. Mr. T is from Vietnam and presented with night sweats, sinusitis, and weight loss. When he was first admitted, there was appropriately high concern for mycobacterium tuberculosis. He then failed to improve on broad spectrum antibiotics, despite a sensitive isolate, and the team had to revisit the initial framing of the case by obtaining a tissue sample. This case highlights the importance of avoiding diagnostic anchoring by reassessing the differential diagnosis when a patient no longer fits the illness script for a disease.

CONCLUSION: In patients from Asia with persistent sinusitis and polyposis, extranodal NK/T-cell lymphoma should be on the differential. NK/T-cell lymphoma is associated with EBV, and it is treated with the SMILE regimen. When patients are not improving as expected, revisit the initial diagnosis.

A CASE OF SIMULTANEOUS OCCURRENCE OF GRAVES' DISEASE(GD) AND SEROSITIS CAUSED BY SYSTEMIC LUPUS ERYTHEMATOSUS (SLE) WITH ANTI-DSDNA ANTIBODY NEGATIVE

KENJI TSUKAMOTO. Okazaki city hospital, Okazaki, Japan. (Control ID #3183771)

LEARNING OBJECTIVE #1: It needs to pay attention to clinical condition of SLE when examining a patient with GD.

CASE: The case was for female at the age of 48 with no past medical history and no family medical history for thyroid disease and collagenosis. She visited a clinic in May 2018 due to edema and weight gain. She was given furosemide and levocetirizine. However, the symptom tended to be worsened with respiratory discomfort and she was hospitalized in October 2018. She had blood pressure 108/60 mmHg, pulse 86 beats/minute, respiration rate 15 times/minute, and body temperature 36.9 degrees Celsius. We recognized systemic pitting edema and lower bilateral respiratory sound without any other specific abnormal findings. There was no particular examination findings for SLE, but the patient had loose stool. The laboratory tests indicated C3 69 mg/dL/C4 9 mg/dL for hypocomplementemia, 80x for antinuclear antibody, 1.60 for Lupus Anticoagulant (diluted Russell's viper venom time), less than 0.01 µIU/mL for thyroid-stimulating hormone(TSH), free T3 5.70 pg/mL, free T4 2.52 ng/dL, 2.1 IU/L for TSH receptor antibody, and negative for anti-dsDNA antibody/anti-histone antibody, but no finding for other collagen diseases and infective diseases. There was no particular finding in the urinary test and also no test result to cause pleural effusion. Bilateral pleural effusion and a small amount of pericardial fluid were found in chest X-ray and echocardiogram respectively, but other sites indicated normal. Because we diagnosed simultaneous occurrence of GD and serositis caused by SLE, celecoxib and azosemide were initiated. For GD, potassium iodide 50 mg/day was used in consideration of SLE-like symptom caused by antithyroid drugs. Although we could manage hyperthyroidism after 2 months, anti-dsDNA antibody turned out positive and serositis control was worsened. When prednisolone 30 mg/day was initiated, serositis was improved after 1 month with weight loss.

IMPACT/DISCUSSION: In this case, serositis could simultaneously develop for a patient with SLE's anti-dsDNA antibody Negative and GD. It is reported that there can be a relation between SLE disease activity and dsDNA for a SLE patient, and serositis is also often found as a clinical finding in SLE's dsDNA antibody Negative. In the recent report, SLE could have development of complication with autoimmune thyroid disease(AITD) including GD and serositis might become a risk in case of SLE associated with AITD. On the basis of the findings in the present case, serositis could be considered as a clinical feature in the development of complication with SLE and GD. However, it still remains unknown regarding the clinical feature of AITD and SLE's dsDNA antibody Negative.

CONCLUSION: We experienced a case of simultaneous occurrence of GD and serositis caused by SLE with anti-dsDNA antibody Negative. Clinicians need to conduct medical examination with the consideration of possible SLE complication when examining a patient with GD.

A CASE OF SKIN RASH AND SEPTIC ARTHRITIS

Hasan Ahmad Hasan Albitar. Mayo Clinic, Rochester, MN, Rochester, MN. (Control ID #3184470)

LEARNING OBJECTIVE #1: Identify the clinical features of rat bite fever syndrome

LEARNING OBJECTIVE #2: Recognize septic arthritis as a rare complication of rat bite fever

CASE: A 27-year-old lady presented to the emergency department with fever, chills and fatigue of 3 days duration. Physical examination revealed temperature of 39.6. Workup revealed neutrophil-predominant leukocytosis with a white blood cell count of $14 \times 10^9/L$ ($3.4 - 9.6 \times 10^9/L$) in addition to elevated CRP of 277.8 mg/L (<8 mg/L). On hospital day 3, the patient developed asymmetric polyarthritis involving the left 3rd MCP, left wrist, right shoulder and right ankle joints. In addition to this, the patient was noted to have a pustular skin rash involving the palms and soles. Screening tests for Neisseria gonorrhoeae, Chlamydia trachomatis, and HIV were negative. In addition to this, syphilis IgG antibody and Parvovirus B19 serology testing were negative. On further questioning, the patient reported that she has 3 pet rats and that she had a rat bite 2 days prior to onset of symptoms. Rat bite fever was suspected and the patient was started empirically on 2 g of IV ceftriaxone daily. Arthrocentesis of the left 3rd MCP joint yielded purulent synovial fluid. Synovial fluid culture was not performed because of the small volume of synovial fluid obtained following during the procedure. Synovial fluid gram stain was negative but numerous white blood cells were noted. Blood cultures were obtained and they showed growth of Streptobacillus moniliformis in 4/6 bottles confirming our initial suspicion of rat bite fever. Repeat blood cultures were negative. The patient had near complete resolution of her symptoms and was discharged on 2 g of IV ceftriaxone for a total of 2 weeks.

IMPACT/DISCUSSION: Rat bite fever (RBF) is a rare disorder most commonly caused by Streptobacillus moniliformis in the USA. The syndrome typically presents with fever and fatigue followed by migratory polyarthralgias and skin rash that involves the palms and soles. Septic arthritis is a rare complication of RBF with only 14 cases in adults reported in the literature. The reported mortality rate approaches 10%. Penicillin is the drug of choice for treatment of RBF and ceftriaxone is a reasonable alternative. For patients with penicillin allergy, tetracyclines can be used

CONCLUSION: RBF is a disease caused Streptobacillus moniliformis. Septic arthritis is a rare complication of RBF. Given the potential for severe and fatal disease in patients with RBF, a therapeutic trial is indicated once the disease is suspected.

A CASE OF STAPHYLOCOCCAL BACTEREMIA WITH IGA DOMINANT CUTANEOUS LEUKOCYTOCLASTIC VASCULITIS AND GLOMERULONEPHRITIS

Joshua Allgaier^{1, 2}; **Osama Kandalaf**^{1, 2}; **Sehar Zulfiqar**^{1, 2}. ¹Baystate Medical Center, Springfield, MA; ²University of Massachusetts, Worcester, MA. (Control ID #3184018)

LEARNING OBJECTIVE #1: To raise awareness of the rare presentation and clinical course of IgA mediated cutaneous vasculitis and acute glomerulonephritis associated with staphylococcal bacteremia

CASE: A 59 year old female with peripheral vascular disease and chronic right heel eschar was admitted for right ankle cellulitis. Blood cultures grew *methicillin sensitive staphylococcus aureus* (MSSA) and MRI identified extensive right ankle osteomyelitis. Cefazolin was started in place of ampicillin-sulbactam and vancomycin. On day 8 of her hospitalization,

she developed a palpable, pruritic rash at her right knee that rapidly spread across her bilateral lower extremities, buttocks and abdomen. Renal function also declined abruptly, coinciding with the onset of the rash. Leukocytoclastic vasculitis (LCV) was suspected and the patient was started on high dose steroids. Cefazolin was the suspected trigger and was changed to oxacillin. Due to worsening renal function with anuria, hemodialysis (HD) was started. Serum IgA was elevated at 1255mg/dl with normal C3 and C4. Renal biopsy revealed acute proliferative glomerulonephritis (GN) with IgA immune complex deposition. Other labs were negative for ANA, c-ANCA, and p-ANCA. Ultimately, her infected foot was amputated, while oxacillin and steroids were continued. The rash disappeared gradually over one week and HD was discontinued after 2 months with some recovery of her renal function.

IMPACT/DISCUSSION: Staphylococcus-associated GN is an uncommon cause of renal failure that can manifest as LCV, most commonly with *methicillin resistant staphylococcus aureus*.¹ While most of these patients have C3, IgG, or IgM glomerular immune complex deposition, there is a less common IgA dominant or co-dominant form that has been increasingly recognized in the literature.³ Optimal evidence based treatment is unclear, but some data suggests that up to 70% of patients have a favorable response.² Satoskar *et al* reported IgA dominant post-infectious GN should not be treated with steroids, but by removing offending infectious agents,⁴ whereas other limited evidence supports short steroid courses if renal failure persists.⁵

CONCLUSION: Our patient suffered with an atypical presentation of acute proliferative IgA-mediated GN and LCV related to MSSA infection ultimately leading to HD. This clinical constellation was identified near the end of her treatment course, progressing despite appropriate antibiotic coverage, source control with amputation and a course of high-dose steroids. We raise awareness to the limited recognition of this clinical entity, as earlier identification of this ambiguous syndrome may have led to improved recovery of her renal function by initiating earlier source control and steroids. Further awareness and recognition of this clinical entity may lead to stronger evidence-based guidelines on its management.

A CASE OF SWELLING IN A FORGOTTEN JOINT

Shane Murray; Ana B Arevalo; Gustavo Contreras Anez; Geeta Varghese. Mount Sinai St Luke's - West, New York, NY. (Control ID #3183582)

LEARNING OBJECTIVE #1: Recognize the clinical features of native joint *Cutibacterium* septic arthritis

CASE: 67-year-old Hispanic Male with a history of treated Hepatitis C presented to clinic with 6 months of chronic dull left shoulder pain. Pain was located over the medial shoulder, radiated to the neck and was associated with enlarging tender lump over the left clavicle. Social history revealed he was born and raised in Puerto Rico, and a history of heroin, cocaine and tobacco use. No prior surgery or history of trauma to the left shoulder. He denied symptoms consistent with an infectious or inflammatory process. Examination revealed a 2cm tender, non-erythematous hard mass over medial third of the left clavicle. Ultrasound confirmed a nonspecific hypoechoic mass in the clavicle. MRI showed marked enlargement of the left sternoclavicular joint (SCJ) with effusion, synovitis, subchondral erosions and marrow edema consistent with an inflammatory arthropathy. Laboratory tests revealed an elevated ESR and CRP with otherwise normal CBC, QuantiFERON gold, CCP antibody, ANA, HIV 1/2 4th, Lyme antibody titers and Uric acid. The patient was subsequently referred to Rheumatology and Infectious Disease for further evaluation. Bone biopsy of the clavicular head was performed. AFB smear, culture and fungal culture tests were negative. Tissue cultures grew *Cutibacterium Acnes*. The patient was treated with Ceftriaxone two grams daily for a total of six weeks.

IMPACT/DISCUSSION: *Cutibacterium* species are a documented cause of joint infection following surgery but its role in native joint infections has only recently become established. Recent literature suggests that the species is underdiagnosed as a cause of septic arthritis due to its indolent

course, frequent dismissal as a contaminant and specific culture requirements. One study looking at a group of patients with synovitis, acne, pustulosis, hyperostosis, osteitis syndrome (SAPHO), which frequently involved the SCJ, found *Cutibacterium acnes* on bone cultures in two thirds of patients. While further research is needed to determine a role for the species in diseases specific to the SCJ, this case adds to the increasing body of literature that suggests that *Cutibacterium* infections are more prevalent than once thought. Cases usually lack signs of acute infection and have a prolonged course often leading to misdiagnosis. Infection should be suspected in patients presenting with atypical osteoarthritis symptoms or features of monoarticular chronic inflammatory arthritis. Arthrocentesis/biopsy and culture may prevent unnecessary invasive procedures in these patients.

CONCLUSION: *Cutibacterium acnes* septic arthropathy is an underdiagnosed entity that typically lacks symptoms of acute infection. One should consider the diagnosis in a patient with atypical osteoarthritis or chronic monoarticular inflammatory symptoms.

A CASE OF THE FEEBLE LEG.

Yulia Khodneva¹; Meghan K. Black². ¹University of Alabama Birmingham, Birmingham, AL; ²University of North Carolina, Durham, NC. (Control ID #3185085)

LEARNING OBJECTIVE #1: Identify vitamin B12 deficiency presenting with unilateral pain and weakness.

CASE: A 61 year-old previously healthy African American man presented with a 5-week history of sharp, shooting pain in his right thigh, exacerbated with weight bearing, and not relieved with symptomatic treatment. Additionally, 2 weeks prior to presentation, he began experiencing difficulty holding onto things with his right hand. He also described multiple falls upon standing and inability to ambulate. He reported current cocaine and alcohol use. Vital signs were within appropriate limits. Cardiopulmonary and abdominal exam were unremarkable. He had limited range of motion in his right hip with tenderness to palpation. Sensation to light touch was diminished up to T2/T3 level bilaterally, with hyperreflexia and negative Babinski reflex. Strength was decreased in his right upper extremity in biceps, triceps, and wrist to 2/5 and in the right lower extremity to 2/5 throughout. Left extremities had intact strength. Muscle atrophy in both hands was noted. Hemoglobin and hematocrit were 13.1g/dL and 39.2% respectively with mean corpuscular volume (MCV) of 87.9 fL. White blood count and electrolytes were normal. Multiple imaging modalities were negative for stroke, but showed areas of nerve root compression with radiculopathy, without cord compression.. There were degenerative changes in hip and spine. Further testing revealed vitamin B₁₂ level was 268 mmol/mL and methylmalonic acid (MMA) was 396 mmol/mL. Folic acid was normal and antibody to intrinsic factor was negative. The patient was started on intramuscular cyanocobalamin and after 7 days had marked improvement in his pain and weakness and was able to walk with assistance.

IMPACT/DISCUSSION: Vitamin B₁₂ deficiency is commonly encountered by the internist, but seldom does it become severe enough to present with extensive neurologic manifestations. It is especially difficult to recognize when it presents with asymmetrical extremity pain and weakness without megaloblastic anemia. While the differential for extremity pain and weakness is broad, the key components of this case leading to a diagnosis of B₁₂ deficiency were the subacute onset, progressive weakness, sensory ataxia and bilateral hand muscle atrophy. Due to demyelination of the dorsal and lateral column of the spinal cord, vitamin B12 deficiency typically manifests with symmetrical combined motor and sensory deficits. However, like our case there have been reports of unilateral findings. The diagnosis of vitamin B₁₂ deficiency is most often made by low serum levels, megaloblastic anemia and an elevated MMA. However, 5-10% patients have normal or low normal B12 levels and 15% have a normal MCV.

CONCLUSION: Patients with polysubstance abuse and poor nutrition are at risk of unrecognized vitamin B12 deficiency. Unilateral presentation of neuropathy and a normal vitamin B12 and MCV level make the diagnosis challenging.

A CASE OF UNEXPLAINED COAGULOPATHY

Amitabh Singh; Neil Evans; Jennifer Schmidt. Saint Louis University, Saint Louis, MO. (Control ID #3185755)

LEARNING OBJECTIVE #1: Recognize the public health emergency of Brodifacoum laced marijuana

LEARNING OBJECTIVE #2: Understand the mechanism of toxicity of brodifacoum and be able to manage toxicity

CASE: A 25-year-old male presented with bilateral lower quadrant abdominal pain radiating to his back starting one day prior to presentation. He also reported hematuria, decreased appetite. He denied new foods, medications, supplements or illicit substances and travel. On presentation, vital signs were normal. Abdomen was distended and tender. Computer tomography showed bilateral acute perinephric hemorrhage extending into the retroperitoneum and pelvis. Lab work showed Hgb:10.1, platelets 178, PTT >212, PT >106, INR >10. Urine drug screen was negative. The patient was admitted to the ICU and given fresh frozen plasma (FFP) and IV vitamin K. Workup showed factors II, IX, and X below 3 (normal range 65-175) and normal levels of factors V and VIII. Warfarin toxicity panel was positive for brodifacoum. PTT and INR trended down and normalized. Patient was discharged with oral vitamin K. On further discussion, the patient admitted to smoking synthetic marijuana.

IMPACT/DISCUSSION: As synthetic marijuana is not detected on standard urine drug screens, its use is increasing. Often, substances are added to increase or prolong its euphoric state. One such additive is brodifacoum, a coumadin-derived rodenticide. It inhibits the enzyme vitamin-K-epoxide reductase (VKOR), as mediator in the production of factor II, VII, IX, and X, resulting in low factor levels. Toxicity typically occurs by ingestion of laced-marijuana and symptoms directly correlate with amount ingested. Treatment is focused on repletion of Vitamin K with the addition of FFP for severe toxicity. During 2018, there have been publicized outbreaks of laced marijuana resulting in multiple deaths.

CONCLUSION: It is critical that internists are able to identify when patients present after ingestion of laced-illicit drugs—not only does this allow for appropriate workup and treatment, it is also essential in identifying public health emergencies.

A CASE OF VITAMIN D MEDIATED HYPERCALCEMIA IN LYMPHOMA: CALCITONIN RESISTANCE?

Priyanka Majety; Seda Babroudi; Feyza Erenler; Richard Siegel. Tufts Medical Center, Boston, MA. (Control ID #3184551)

LEARNING OBJECTIVE #1: There are multiple mechanisms of hypercalcemia in malignancies and treatment should be tailored accordingly to be effective

CASE: An 82-year-old male with history of hypertension presented with one month of generalized malaise, two weeks of shortness of breath and constipation. Physical exam and labs on admission were notable for moderate ascites, Cr 2.29mg/dL, LDH 253IU/L, Calcium (Ca) 12.8mg/dL, Hemoglobin 12.8g/dL. Calcium level 6 months prior to admission was normal. Parathyroid hormone (PTH) was 7pg/mL (low). Vitamin D 25OH D3 was 29ng/mL (normal). Workup was not suggestive of Multiple Myeloma. In the light of worsening renal function, he was started on Calcitonin that only decreased the Ca from 12.8mg/dL to 12.6mg/dL. PTHrP was 14pg/mL (normal) & 1,25 OH Vitamin D was 58pg/mL which was inappropriately normal in the setting of suppressed PTH. There was no evidence of hyperthyroidism or Vitamin A toxicity. Paracentesis showed cloudy fluid

and triglyceride level of 237mg/dL, consistent with chylous ascites raising the possibility of malignancy. CT abdomen revealed lymphadenopathy and inguinal lymph node biopsy confirmed angioimmunoblastic T-cell lymphoma. He received steroids as a part of the treatment, that decreased the Ca level. He was started on appropriate chemotherapy.

IMPACT/DISCUSSION: We discuss the management of hypercalcemia in a patient with new diagnosis of T-Cell lymphoma. Hypercalcemia occurs in about 20-30% of patients with cancer. It occurs with both solid tumors and hematologic malignancies. The most common cancers associated with hypercalcemia in the US are breast, renal, lung cancer & multiple myeloma. The main mechanisms involved are parathyroid hormone related protein (PTHrP) secretion, osteolytic metastases with cytokine release, vitamin D-mediated and ectopic PTH (very rare). Our patient had non-PTH related hypercalcemia and a trial of calcitonin (which decreases serum Calcium level by inhibiting osteoclasts & promoting bone resorption) failed, prompting that the mechanism here was not osteoclast mediated. His PTHrP level was normal ruling out humoral hypercalcemia. Although his 1,25 OH Vitamin D level was normal, it was inappropriately high normal given the low PTH (responsible for 1-hydroxylase enzyme upregulation) suggesting it is Vitamin D mediated. The hypercalcemia in lymphoma is due to PTH-independent extrarenal production of 1,25-dihydroxyvitamin D in malignant lymphocytes that causes increased intestinal absorption of Calcium. Steroids decrease the intestinal absorption of Calcium & decrease calcitriol production in mononuclear cells. His Calcium level decreased to 10.1 after a course of steroids establishing the Vitamin D mediated mechanism. Anti-resorptive treatments are probably limited in treating hypercalcemia in lymphomas due to the underlying mechanism.

CONCLUSION: Understanding the pathophysiology and mechanisms of hypercalcemia in malignancy is important. This helps us choose the most effective treatment.

A CASE REPORT DEMONSTRATING THE DIFFICULTIES IN DIAGNOSING ADULT TUBERCULOUS MENINGITIS

Yi-Chia Wu¹; Laila Dadvand². ¹Mount Sinai Beth Israel, New York, NY; ²Icahn School of Medicine at Mount Sinai, Hoboken, NY. (Control ID #3185333)

LEARNING OBJECTIVE #1: Recognize the difficulties in diagnosing tuberculous meningitis

CASE: A 72 year-old female with history of hypertension and coronary artery disease presented with one month of worsening headache, described as a generalized sharp pain associated with nausea and vomiting. She had no neurological deficits, fevers, neck stiffness, confusion, nor recent travel. Vital signs were stable. Physical exam and labs were unremarkable; ESR and CRP were normal. Brain magnetic resonance imaging (MRI) with angiogram and venogram were also unremarkable. There was a concern for intractable migraine, so the patient was given several treatments, including benadryl, reglan, and toradol, without relief. Initial cerebral spinal fluid (CSF) showed lymphocytic pleocytosis, elevated protein, and normal glucose. CSF smear and culture were negative. A repeat CSF was performed a week later and revealed similar results except with elevated opening pressure and low glucose. The results were concerning for tuberculous meningitis (TBM). CSF adenosine deaminase (ADA) was obtained and was 2.1 U/L. On further questioning, the patient revealed her son had tuberculosis many years prior although she self-reported having had negative PPD testing. Given her history of tuberculosis exposure, non-resolving headache, and the CSF results, the patient was treated empirically for TBM with rifaximin, isoniazid, pyrazinamide, and ethambutol (RIPE) prescribed for six months. After a few doses of RIPE, the patient felt better and was discharged with follow-up at the tuberculosis clinic.

IMPACT/DISCUSSION: Diagnosing TBM is difficult given its nonspecific presentation in addition to slow and low sensitivity laboratory

identification methods. Adult TBM often presents with worsening headache with vomiting and confusion for greater than 6 days. Studies show that TBM results in increasingly abnormal CSF composition and pressure with time, typically with high opening pressure, elevated leukocytes and protein, and low glucose. Current laboratory methods include CSF smear and culture, which are most commonly used. Although the acid-fast smear is quick and inexpensive, it requires about 10,000 organisms for a positive result, resulting in poor sensitivity. Studies have shown that a majority of TBM cases have a negative CSF smear. CSF culture takes 10-14 days to result and is highly dependent on laboratory expertise. Other methods include biochemical analysis, such as measuring CSF ADA, which helps to improve the diagnosis of TBM especially when bacterial meningitis is ruled out. ADA values >10 U/L has high specificity >90% for TBM; however, for ADA <10 U/L, studies have demonstrated a wide range of sensitivities, which limit the diagnostic use of this test.

CONCLUSION: Therefore, given that there is a lack of reliable and rapid diagnostic tests for TBM and late treatment of TBM leads to poorer outcomes, one should consider treating TBM empirically if there is a suspicion for the disease.

A COLD CASE OF A COLD ABSCESS

Christine Park; Ian A. Downs; Rachel Simmons. Boston Medical Center, Boston, MA. (Control ID #3185774)

LEARNING OBJECTIVE #1: Recognize the broad differential of cold abscesses and utilize host risk factors in assessing a patient with an unusual infection

LEARNING OBJECTIVE #2: Explore *Klebsiella pneumoniae* as a causative agent for a cold abscess

CASE: A 47-year old Vietnamese woman with a history of latent tuberculosis treated 21 years prior was admitted for a slow growing, tender, non-erythematous right anterolateral abdominal wall mass after a brief febrile respiratory illness 6 weeks prior. She was afebrile, hemodynamically stable and exam was unremarkable aside from the mass. Hematology and chemistry were unremarkable. CT scans of the chest, abdomen and pelvis showed pulmonary nodules, right middle lobe bronchiectasis, and large pleural, abdominal wall, and right upper quadrant subperitoneal rim-enhancing collections, concerning for a tracking abscess. Two induced sputum samples were negative for acid-fast bacteria. Cultures, cytology and pathology of aspirated abdominal wall fluid were negative for anaerobes, aerobes, fungi, mycobacteria or malignancy. Percutaneous drains were placed in the abdominal wall, and IV penicillin G was initiated for empiric *Actinomyces* species coverage. The abdominal wall collections improved but the pleural collection remained stable. Thoracentesis 25 days after initial presentation resulted in a culture positive for *Klebsiella pneumoniae*. Levofloxacin was started, and the abdominal wall mass improved, but with limited follow up.

IMPACT/DISCUSSION: Our patient presented with bronchiectasis and pleural effusion, which appeared to communicate with the "cold" intra-abdominal and abdominal wall abscesses. Given her history, both tuberculosis and melioidosis were considered, but testing was negative. *Acintomyces spp.* infection is a cause of indolent pulmonary infections that can readily cross tissue planes, and this organism can be difficult to isolate from culture. After testing was unrevealing, *Actinomyces* treatment was started empirically but was ineffective. *K. pneumoniae* was the only agent isolated from numerous cultures. It is known to cause pulmonary, blood, intra-abdominal and urinary tract infections. In Taiwan, 21% of cases of lung abscesses were found to be due to *K. pneumoniae* and patients presented with >30 days of symptoms in 9 of 28 cases; however, the ability to cross tissue planes is not a typical feature, absent a necrotizing infection. Our ability to assess if *K. pneumoniae* was the causative agent is limited due to lack of patient follow up. We would expect a response to fluoroquinolone treatment. Of note, although active pulmonary tuberculosis was ruled out and fluid and biopsy cultures were negative for mycobacteria, it is difficult to definitively rule out extrapulmonary tuberculosis.

CONCLUSION: •The differential for cold abscesses is broad, and may require extensive workup to confirm diagnosis •It is critical to rule out tuberculosis given the patient's immigration history, though extrapulmonary tuberculosis is difficult to exclude

A COLD CASE OF DIGITAL ISCHEMIA

Ryan Khodadadi; Muneeb Rehman; Absar Tahir; Delamo Bekele; Eric L. Matteson. Mayo Clinic, Rochester, MN. (Control ID #3171697)

LEARNING OBJECTIVE #1: Recognize type 1 cryoglobulinemia as a cause of digital ischemia in addition to other more common causes of vascular insufficiency.

LEARNING OBJECTIVE #2: Distinguish between the differing types of cryoglobulins, their respective associations, and unique approaches to treatment.

CASE: A 59 year-old Alaskan male with a history of nicotine dependence, coronary artery disease, hypertension, hyperlipidemia and multiple amputations presented for further evaluation of recurrent digital ischemia. A year prior, he experienced progressive bluish discoloration of the lower extremities with associated pain, swelling, and eventual digital necrosis resulting in the amputation of 3 digits despite normal vascular studies. Pathology revealed pauci-inflammatory small vessel occlusion by PAS-positive homogeneous pink-purple material. Ten months after smoking cessation, he had recurrence of his symptoms with new left great toe necrosis, bilateral lower extremity ulceration, and intractable pain. Physical exam revealed amputated left 4/5th and right 5th toes, black/blue discoloration of the left great toe, and periungual infarcts most prominent in the fingers without Raynaud's phenomenon. CT imaging, echocardiogram, and repeat vascular studies were unremarkable. Autoimmune serologies were negative but further workup revealed an elevated ESR and CRP, a SPEP with an increased M-spike in the gamma globulin portion, elevated total protein with elevated kappa free light chains (2.8) and a 10% type 1 cryoglobulin component.

IMPACT/DISCUSSION: Cryoglobulinemia is characterized by the precipitation of proteins including immunoglobulins and complement proteins in the blood below 37°C. Type 1 cryoglobulinemic (10-15% of cases) precipitate tends to be monoclonal in origin, related to an underlying lymphoproliferative disorder whereas a polyclonal cryoprecipitate is implicated in mixed cryoglobulinemia and classically associated with an underlying rheumatologic disorder or viral infections. Clinically, type 1 manifests with signs and symptoms of vascular insufficiency including digital ischemia, skin necrosis, and livedo reticularis. A diagnosis is established by laboratory isolation of cryoprecipitate and cryocrit measurement with treatment directed toward the underlying disorder to prevent hyperviscosity and further vascular injury.

CONCLUSION: It's important for the internist to recognize common causes of vascular insufficiency as well as type 1 cryoglobulinemia which is often driven by an underlying lymphoproliferative disorder, warranting further investigation and appropriately-targeted therapy. Prognosis and complications in patients with type 1 cryoglobulinemia correlate with the underlying hematologic disorder and its treatment course. This patient's bone marrow aspirate and biopsy revealed a CD-20 negative kappa-expressing monoclonal plasma cell population. He ultimately underwent apheresis with resolution of cryoglobulinemia and treatment with prednisone followed by bortezomib for an underlying lymphoproliferative disorder (MGUS).

A COMMONLY USED ANTIBIOTIC WITH A RARE, SEVERE, CUTANEOUS ADVERSE REACTION

Shahrzad Shidfar. umassmemorial, Worcester, MA. (Control ID #3186317)

LEARNING OBJECTIVE #1: Recognize and distinguish clinical presentation of AGEP

CASE: 44 year-old paraplegic man was admitted for left second toe osteomyelitis. He had open wound on left second toe, normal vital signs and white blood cell counts. He was started on vancomycin intravenously and underwent amputation of left second toe on hospital day 3. His antibiotic was changed to doxycycline 100 mg by mouth every 12 hours with the first dose given evening of operative day. The next morning patient complained of mild itchiness around the neck which he attributed to "not used to hospital sheets". There were no visible rash. He had normal vital signs and minimal pain at the surgical site. CBC showed leukocytosis of 11000 per microliter which was attributed to stress. Patient was discharged home on doxycycline. Later in that evening patient noted increase pruritus around the neck and upper body. The next morning (post-operative day 2) he noted erythematous rash around the neck spreading to extremities and trunk. He also felt swollen painful "glands" on his neck. Patient was readmitted to the hospital. He had normal vital signs. There was a diffuse pink morbilliform rash with confluent erythema and scattered pustules over the back, chest and the medial aspects of bilateral thighs. There were 2 tender enlarged right-sided cervical nodes. There were neither genital or oral mucosal involvement nor facial edema. He had a Leukocytosis of 15000 per microliter without bandemia or eosinophilia. Liver function tests were normal. Skin punch biopsy showed acute generalized exanthematous pustulosis (AGEP). Doxycycline was discontinued and patient was started on triamcinolone 0.1% topical ointment twice daily.

IMPACT/DISCUSSION: Acute generalized exanthematous pustulosis (AGEP) is a rare, severe cutaneous adverse reaction characterized by the rapid development nonfollicular, sterile pustules on an erythematous base. It is attributed to drugs in the majority of cases with Antibiotics being considered as the most common cause. Fever and peripheral blood leukocytosis are usually present. The time period from drug exposure to reaction onset is typically within 48 hours, with antibiotics having a median of 24 hours. Generally, with prompt discontinuation of the offending agent and general supportive care, prognosis for patients with AGEP is excellent. Our patient was exposed to vancomycin and doxycycline both but treatment with doxycycline started later than the treatment with vancomycin and signs and symptoms of AGEP appeared within 1 day after the start of doxycycline therapy which make doxycycline as more likely the cause of the AGEP.

CONCLUSION: Although AGEP is rare, its manifestations can be prone to misinterpretation. In contrast to most drug reactions, AGEP is manifested as pustules, thus, it is easily confused with other pustular eruptions and infectious processes. A thorough knowledge of the disease process of AGEP is important to avoid the dangerous continuation of the offending antibiotic.

A COMPLEX CASE OF MYOCARDIAL BRIDGING

Omar Hadzipasic¹; Ahmed Nagy¹; Adedotun Ogunusa²; Owusu Asamoah². ¹University of Massachusetts Medical School, Shrewsbury, MA; ²University of Massachusetts Medical School, Worcester, MA. (Control ID #3161489)

LEARNING OBJECTIVE #1: Distinguish myocardial bridging from coronary artery disease

LEARNING OBJECTIVE #2: Manage recurrent angina in myocardial bridging

CASE: A 58-year-old man with a history of hypertension and hyperlipidemia presented to the Emergency Department with anterior substernal chest pressure which started while he was cleaning his grill. EKG was notable for ST segment elevation in the anterolateral leads with elevated troponin to 25.5. He underwent emergent coronary angiography which showed an anterolateral STEMI caused by a mid left anterior descending (LAD) 100% thrombotic occlusion and had successful thrombectomy and balloon angioplasty of the mid-LAD. He was started on Aspirin and Ticagrelor and treated with a Tirofiban IV infusion for 48 hours. Two days later, he underwent Ocular coherence tomography/Intravascular ultrasound (OCT/IVUS) of the LAD which demonstrated severe myocardial bridging in the mid-LAD. The patient presented to the hospital again two weeks later with the same chest pain. It

was not relieved with nitroglycerin and he had not missed any doses of his DAPT therapy. EKG was notable for anterior lead Q waves with T wave inversions, troponin elevated to 6.02. Repeat coronary angiography again demonstrated myocardial bridging of the mid-LAD without occlusion. Recommendation was made for maximizing his Metoprolol dose and continued treatment with Aspirin, Ticagrelor, and Atorvastatin.

IMPACT/DISCUSSION: Myocardial bridging is an uncommon medical disorder that must be considered in the differential diagnosis for recurrent anginal chest pain. In this condition, the coronary artery traverses through an intramycardial course and is compressed during systole. Although most instances are of limited clinical significance, our patient had experienced repeat infarctions over time and developed an ischemic cardiomyopathy with reduced ejection fraction of 40%. Medical therapy is aimed at reducing heart rate and myocardial contractility through the use of beta blockers and calcium channel blockers, as well as procedural intervention via coronary artery stenting. For persistent symptoms, surgical intervention with myocardial bridge resection can be performed. Importantly, nitrates are contraindicated given the risk for reflex increase in contractility. Although similar in presentation to acute coronary syndrome from classic coronary artery disease, myocardial bridging differs in medical and interventional therapy. This case highlights how crucial it is to recognize and distinguish myocardial bridging from coronary artery disease to avoid recurrence and sequelae of continued myocardial infarction.

CONCLUSION: Myocardial bridging is an uncommon condition which presents as acute coronary syndrome and can be diagnostically indistinguishable from myocardial infarction until coronary angiography is performed. Initial medical therapy is aimed at the use of beta blockers and calcium channel blockers. Nitrates are contraindicated given the risk for reflex increase in contractility.

A COMPLICATED CASE OF PSEUDOMONAS ENDOCARDITIS PRESENTING AS A SUBARACHNOID HEMORRHAGE

Pedro Covas¹; Alexander E. Aldrich²; Adrienne N. Poon³. ¹George Washington University, Washington, DC; ²The George Washington University Hospital, Washington, DC; ³George Washington School of Medicine and Health Sciences, Clifton, NJ. (Control ID #3149722)

LEARNING OBJECTIVE #1: Neurological sequela of infective endocarditis

LEARNING OBJECTIVE #2: Diagnosis and treatment of Pseudomonas endocarditis

CASE: A 60 year-old woman with intravenous drug use (IVDU), presented with a week of cough, shortness of breath, and lower extremity edema. The patient was afebrile, tachycardic, and tachypneic. Lower extremity edema and bibasilar crackles were present, but had a normal cardiac examination. Labs were significant for leukocytosis to 18,000, platelets of 69, hemoglobin of 7.6, creatinine of 2.9, and BNP of 11,000. CT chest revealed bilateral septic emboli to the lungs and transthoracic echocardiogram (TTE) revealed vegetations on the tricuspid valve. Transesophageal echocardiogram (TEE) was unable to be performed. CT head revealed a subarachnoid hemorrhage (SAH). MRA was negative for aneurysm. Broad spectrum antibiotics were initiated for infective endocarditis (IE) and after blood cultures returned positive for *P. aeruginosa*, antibiotics were adjusted to meropenem and ceftazidime. Blood cultures remained positive for 10 days until renal function improved and gentamicin was added. Surgical management was not pursued given SAH and she completed 6 weeks of intravenous antibiotics. She was later readmitted for reoccurrence of *P. aeruginosa* IE when TEE revealed an aortic vegetation and tricuspid vegetation. Her condition rapidly deteriorated and died from sepsis and multiorgan failure.

IMPACT/DISCUSSION: *Pseudomonas Aeruginosa* is a rare cause of IE seen most often with concomitant IVDU. Recognizing that IE may have multiple neurological sequelae is essential in management as treatment and prognosis varies significantly depending upon involvement. Ischemic

strokes commonly result from embolization, but SAH is a rarer complication, especially spontaneous, as most result from mycotic aneurysm rupture. *Pseudomonas* endocarditis is a rare form of IE and treatment is not clearly established, but generally includes an aminoglycoside with a secondary pseudomonal agent and consideration of surgical resection of the vegetation. The role of echocardiography in IE is extremely helpful for diagnosis and TEE should be pursued if TTE not indicative. Our patient had progression of her IE with new left-sided involvement. Mortality is higher with left sided endocarditis and surgery should urgently be pursued if possible. We were able to confirm that the vegetation decreased in size with a repeat echocardiogram, but serial echocardiograms could be useful in surveillance with antibiotic therapy to confirm resolution of the vegetations as *P. aeruginosa* endocarditis has no established antibiotic duration. One can consider echocardiograms to confirm resolution to prevent reoccurrence, as it occurred with our patient. Further research is needed to establish optimal antibiotics therapy.

CONCLUSION: We present a case of *Pseudomonas* endocarditis that highlights recognizing SAH as an uncommon neurological sequelae of IE, treatment with the importance of an aminoglycoside, and the role of echocardiography in IE.

A COMPLICATED CASE OF PV

Hanyuan Shi; Tulane University School of Medicine, New Orleans, LA.
(Control ID #3185271)

LEARNING OBJECTIVE #1: Demonstrate a complication of polycythemia vera

LEARNING OBJECTIVE #2: Illustrate diagnostic testing for ischemic colitis

CASE: A 63-year-old female with a history of polycythemia vera (JAK2 mutation and hypertension presented with acute onset of diffuse colicky abdominal pain and hematochezia. She had no prior weight loss, weakness, or anorexia. The patient described liquid bowel movements with overt blood. She had been managed with aspirin 325 mg daily, dipyridamole 50 mg TID, hydroxyurea 200 mg daily at home. She underwent monthly phlebotomies that had been uncomplicated per her outpatient hematology provider. Her vitals were stable, albeit for mild hypertension at 152/76. Initial labs were significant for WBC 6.9, hemoglobin 13.8, and platelets of 447. INR was normal at 1.1. CT abdomen/pelvis showed thickening of the gastroesophageal junction and adenomyomatosis. Infectious stool studies were negative. She had a screening colonoscopy two months ago that was negative for colonic abnormalities, only non-bleeding internal hemorrhoids. During her admission, she underwent a flexible sigmoidoscopy. Findings included congested, erythematous, inflamed and ulcerated mucosa in the descending colon, sigmoid, and rectum likely secondary to colon ischemia. The hematology service was consulted for phlebotomy and the patient had 500 ml of blood removed with resolution of symptoms. Confirmation biopsies came back a week later showing descending colon and rectum with atrophic colonic epithelium consistent with ischemic changes. The biopsy was negative for evidence of chronic colitis, as well as negative for dysplasia or malignancy.

IMPACT/DISCUSSION: Polycythemia vera (PV) is a myeloproliferative disorder characterized by increase in red blood cell, white blood cell, and platelets. Thrombotic complications are unfortunately not rare, and can include cerebral infarction, thrombophlebitis, myocardial infarction, and ischemic colitis. Here we demonstrate an acute case of ischemic colitis (IC) (biopsy-proven) from PV, only the 4th documented case in the literature, that occurred 1-2 months after a normal colonoscopy. Ischemic colitis from PV is reversible but requires quick and precise diagnostic effort. Although enhanced abdominal CT and CT enterography are the gold standards for IC, a colonoscopy or a flexible sigmoidoscopy can also be used for definitive histopathological diagnosis. In patients with PV, biopsies of colonic lesions can more accurately differentiate IC from chronic inflammatory bowel diseases. Treatment of IC relies on controlling the primary cause. In this case, that involved expedited

phlebotomy for PV; other therapies have included anticoagulation with LMWH and initiation of mesalazine.

CONCLUSION: Internists are often asked to coordinate care from different subspecialty services. This case highlights a complication of polycythemia vera and the use of consultant services to aid in diagnosis and management of this patient.

A COOL CASE REPORT: SPONTANEOUS PERIODIC HYPOTHERMIA

Hayley N. Price; Jennifer Jacobs; Alexander Hajduczok; Ami DeWaters. Penn State Hershey Medical Center, Hershey, PA. (Control ID #3185792)

LEARNING OBJECTIVE #1: Describe the etiologies and evaluation of hypothermia.

LEARNING OBJECTIVE #2: Discuss the pathophysiology of spontaneous periodic hypothermia and how that may guide treatment options.

CASE: A 66-year-old man with dementia was transferred to the hospital from a local skilled nursing facility with recurrent hypothermia. On presentation, he was obtunded and unable to provide a history. He had been hospitalized twice that same year with a similar presentation. An extensive workup had been done during those admissions and was unrevealing. On admission, his temperature was 32 degrees Celsius, with a pulse of 44, and blood pressure of 92/56. On physical exam, he was obtunded. Pupils were equal, round, and reactive to light; more complete neurologic exam was deferred due to inability for him to participate. Laboratory testing demonstrated chronic anemia with a hemoglobin of 7.2 and chronic kidney disease with a creatinine of 2.3, with a normal TSH and morning cortisol. A urine toxicology screen was negative. He was treated with a Bair Hugger blanket as well as supportive care. His temperature spontaneously returned to normal after two days and the Bair Hugger was discontinued. His mental status improved with resolution of hypothermia, and he was discharged back to his facility with the presumptive diagnosis of spontaneous periodic hypothermia.

IMPACT/DISCUSSION: Hypothermia has multiple etiologies presenting a diagnostic challenge. Causes of hypothermia are commonly divided into the following categories: exposure, metabolic, infectious, and central. Exposure can be both intentional, for instance in an operating room, or unintentional, such as accidental cold water immersion. These etiologies can be determined by history. Metabolic etiologies include hypothyroidism, adrenal insufficiency and hypopituitarism. Sepsis can result in hypothermia. Central causes include trauma or stroke. Therefore, the evaluation of hypothermia should include TSH, morning cortisol, full infectious work-up with cultures, and head imaging, including MRI. If no etiology is discovered, the differential may need to be expanded further, as in this case. Spontaneous Periodic Hypothermia is a rare cause of hypothermia characterized by recurrent episodes of hypothermia thought to be mediated by central nervous system pathology without a clearly identifiable brain lesion. Though the exact pathophysiology is unclear, the cyclic nature of episodes has led to the thought that the pathophysiology may be similar to epilepsy. Treatment with antiepileptic medications has been trialed with success in a number of case reports. Further research is necessary to determine if these medications are truly effective.

CONCLUSION: Evaluation of a patient with hypothermia mandates consideration of a broad differential, particularly in cases in which a clear etiology is not evident. Spontaneous Periodic Hypothermia is a rare cause of hypothermia that may respond to treatment with antiepileptic medications.

A COUGH MAY JUST BE THE TIP OF THE ICEBERG

Ian Cormier; Michael P. Smith. University of Nebraska Medical Center, Omaha, NE. (Control ID #3186036)

LEARNING OBJECTIVE #1: Develop an approach to liver abscesses

LEARNING OBJECTIVE #2: Recognize the association of pyogenic liver abscesses and occult malignancy

CASE: A 61-year-old man presented with two weeks of cough. His cough was productive of yellow sputum with associated shortness of breath. He was initially diagnosed with a viral syndrome and treated conservatively. His symptoms worsened, and he developed new onset frontal headaches, fevers up to 103F, myalgias and chills. He had a past medical history of malignant melanoma excised in 2006 and pyogenic liver abscess (PLA) treated in 2008. The patient was afebrile with normal vitals. He had normal cognition, poor dentition, and diminished breath sounds with crackles noted in the right lung base. His white blood cell count was elevated with bandemia and a procalcitonin of 12. Chest x-ray revealed bilateral lower lung and right midlung infiltrates. The patient was given intravenous vancomycin and piperacillin-tazobactam and was admitted for community acquired pneumonia (CAP). He was transitioned to intravenous levofloxacin for CAP. Overnight, the patient became febrile to 102.8, tachycardic and tachypneic. Vancomycin and piperacillin-tazobactam were restarted. Blood cultures were drawn and a computed tomography (CT) of the chest, abdomen and pelvis revealed multiple bilateral pulmonary nodules with early cavitation concerning for septic emboli and a large multilocular hepatic hypodensity in the right lobe of the liver concerning for liver abscess. Gram stain of the abscess was positive for gram-negative rods. Anaerobic cultures grew Fusobacterium nucleatum. Blood cultures were negative. A peripherally inserted central catheter line (PICC) was placed and the patient was discharged on ampicillin-sulbactam along with an outpatient colonoscopy to evaluate for occult malignancy.

IMPACT/DISCUSSION: Pyogenic Liver abscesses, which are typically polymicrobial. Other causes of liver abscess include malignant, iatrogenic, and other infectious sources with overlap between the three categories being common. Many pyogenic liver abscesses result from portal vein pyemia, usually related to bowel leakage and peritonitis. Biliary, Pelvic, and other intraperitoneal sources are the most common source of infection in hepatic abscesses along with hematogenous spread. Fusobacterium spp. are anaerobic gram negative rods that occur as normal oral flora and have been associated with periodontal infections. However, they are uncommon causes of pyogenic liver abscesses. Pyogenic liver abscesses have a known association with GI malignancies and Fusobacterium nucleatum has recently been shown to promote colorectal carcinogenesis by affecting genes associated with the adenoma-carcinoma sequence. The oral cavity could be a potential source of infection for this patient, however, occult GI malignancy must be ruled out.

CONCLUSION: The general internist must diagnose and treat a pyogenic liver abscess and understand its implications for evaluation for malignancy

A CURIOUS CASE OF CARDIAC TAMPONADE WITHOUT TACHYCARDIA

LU CHEN¹; Uta Guo³; PARAG MEHTA²; Tristan Tanner⁴. ¹NEW YORK PRESBYTERIAN - BROOKLYN METHODIST HOSPITAL, Brooklyn, NY; ²NewYork-Presbyterian BMH Hospital, Brooklyn, NY; ³SUNRISE GME CONSORTIUM, LAS VEGAS, NV; ⁴New York Presbyterian - Brooklyn Methodist, Brooklyn, NY. (Control ID #3186251)

LEARNING OBJECTIVE #1: Diagnosing and managing subacute cardiac tamponade

CASE: A 67-year-old female with a past medical history of hyperthyroidism and total thyroidectomy, presented with progressive confusion and respiratory distress over the past three months. Patient became more lethargic and confused over the past month, with episodes of hallucination. She became bed bound a week prior to admission. Patient stopped taking her levothyroxine over a year ago. On admission, she was afebrile at 98.0F, with blood pressure of 147/84 with heart rate of 70. Physical exam was significant for lethargy, facial swelling, and macroglossia. Decreased breath sounds in the left lung base were noted along with bibasilar crackles. No murmurs, clicks, gallops or rubs were appreciated on the cardiac exam. Laboratory finding was

significant for a serum sodium level of 133 mmol/L, Thyroid Stimulating Hormone (TSH) at 58.5 ng/dL, and Free Thyroxine (T4) of 0.19 ng/dL. Electrocardiogram (EKG) showed low voltage QRS complexes with electrical alternans. Chest Radiography (CXR) was significant for consolidation, atelectasis or effusion in the area of left middle and lower lung region. Patient was started on levothyroxine and hydrocortisone. Echocardiogram (Echo) showed normal systole function of the left and right ventricles. No valvulopathy was identified. A large pericardial effusion with swinging of the heart in the pericardial sac was noted. Significant chamber collapse of both atria, as well as the right ventricle, was also noted. Inferior Vena Cava was dilated and showed no decrease in size with inspiration. Patient received pericardiocentesis with 1300ml serous straw-colored fluid drained. Analysis of pericardial fluid was negative for malignant cells. Acid-fast bacilli stain and culture were negative. Patient was discharged on levothyroxine. Serial TSH and T4 measurements over two months showed normalization of both hormone levels. Repeat echo showed diminishing pericardial effusion.

IMPACT/DISCUSSION: Subacute Cardiac Tamponade (SCT) develops over weeks to months and can have a subtle presentation. The most common sign of SCT is sinus tachycardia. Due to the slow development of the pericardial effusion, patients may not be hemodynamically compromised despite the presence of a large effusion. In our patient, tachycardia was possibly masked by baseline bradycardia from myxedema coma secondary to hypothyroidism. Additional physical findings associated with SCT include hypotension, pulsus paradoxus, and elevated jugular venous pressure. EKG, CXR, and Echo should be obtained to aid diagnosis and facilitate treatment.

CONCLUSION: Thorough physical exam and a high level of clinical suspicion are needed to prevent a delay in diagnosis of subacute cardiac tamponade, especially in the setting of myxedema coma.

A CURIOUS CASE OF EOSINOPHILIA

Elizabeth Thottacherry¹; Ali Hassoun². ¹University of Alabama School of Medicine, Huntsville, AL; ²Alabama Infectious Diseases Center, Huntsville, AL. (Control ID #3186072)

LEARNING OBJECTIVE #1: Recognise rare presentations of eosinophilia

LEARNING OBJECTIVE #2: Differentiate infectious, immunological and hematological causes of eosinophilia

CASE: A 62 year old female from India on dialysis for 2 years presented with chest pain occurring in dialysis. Chest pain was midsternal, occurring with dialysis and had started the week prior. Examination revealed an alert female, comfortable on room air and afebrile. Her cardiac exam was normal and no rashes or lymphadenopathy were noted. Labs reflected a white count of 43.7 x 103/uL (reference: 4.1-12.2 x 103/uL) and absolute eosinophil count of 37.2 x 103 (reference: 0.0-0.5 x 103/uL). Her cardiac enzymes were unremarkable and her kidney function was at baseline. Blood and stool cultures, ova and parasite screens and IgE levels were sent as well as a strongyloides and filarial panel given her Indian background. While cultures and parasite screen were negative, her IgE levels resulted grossly elevated. Peripheral smear and flow cytometry were inconclusive. Cardiac investigation revealed nonobstructive coronary disease. Bone marrow biopsy resulted showing eosinophilia and neutrophilia lacking malignancy. The patient attempted to continue dialysis, however again experienced chest pain. At this point a variety of differentials were considered with a discussion about recent lifestyle changes. The patient noted that she recently changed dialyzer membranes from polyarylethersulfone to polysulfone. Steroid therapy was started and her dialyzer membrane was changed back with immediate cessation of symptoms. Her eosinophilia improved and a polysulfone allergy was recorded.

IMPACT/DISCUSSION: Eosinophilia can be categorised into primary/ clonal, secondary/reactive or idiopathic. Diagnosis can be challenging due to the differentials present. After a detailed history is obtained, initial work

up includes a complete blood count, liver and kidney function, peripheral smear, c-reactive protein, erythrocyte sedimentation rate and bone marrow biopsy. While investigating the above case, causes of secondary eosinophilia were examined while ruling out primary eosinophilia. With the patient's subtropical background, infectious and parasitic causes were initially ruled out. Her elevated IgE prompted investigation into allergic causes and drugs. Primary clonal eosinophilia and malignancies were ruled out with a bone marrow biopsy. The temporal association of symptoms with dialysis led us to question changes in dialysis causing her symptoms. Polysulfone diasylate membranes are associated with increased incidence of hemodialysis associated eosinophilia with resolving eosinophilia noted after membrane change. The rapid response with oral steroids as well as changing the diasylate membrane further confirmed that the patient may be having an immune mediated reaction to the Polysulfone membrane.

CONCLUSION: Eosinophilia is seen in a variety of different clinical scenarios. A meticulous history and thorough investigation is key to forming a diagnosis and carrying out appropriate treatment.

A CURIOUS CAUSE OF ABDOMINAL PAIN IN A PATIENT WITH ANAPLASMOSIS

Julia Cooperman, Beth Israel Deaconess Medical Center, Boston, MA. (Control ID #3173639)

LEARNING OBJECTIVE #1: Diagnose and manage atraumatic splenic rupture non-operatively.

LEARNING OBJECTIVE #2: Recognize atraumatic splenic rupture as a complication of tickborne illness.

CASE: A 35 year old gentleman with a history notable for a spontaneous splenic hemorrhage and splenectomy in 2012 presented to the emergency department with fevers, myalgias and arthralgias 5 days after a deer tick bite. He was febrile. Initial labs were notable for a normal WBC count with neutrophil predominance. No parasites were seen on a parasite smear. He started Ceftriaxone and was admitted to the medical service. Overnight he complained of 10/10 peri-umbilical pain, diarrhea, and emesis. Labs showed bandemia of 14% and hemoglobin drop from 13.2 to 9.2. CT scan with IV contrast showed a large amount of hemorrhagic free fluid in the left upper quadrant around the splenic remnant, with a curvilinear area of hyperdense blood highly suspicious for active hemorrhage. He received 2 units of packed red blood cells and underwent emergent splenic arteriogram which did not reveal a source of active hemorrhage. He remained hemodynamically stable and required no further blood transfusions. He was found to have a positive Anaplasma PCR. Patient defervesced and felt improved. The remainder of his tickborne panel was negative. He was discharged with oral doxycycline.

IMPACT/DISCUSSION: Atraumatic splenic rupture is uncommon. Its exact incidence is unknown and there are no systematic studies defining its clinical presentation, but it is an important entity to recognize as mortality can be up to 12%.¹ Most common causes identified are neoplastic, infectious, and inflammatory. Clinical presentation can include left sided abdominal pain and/or left shoulder-tip pain from diaphragmatic irritation and signs of hemorrhage. Rupture is confirmed by either CT scan, ultrasound, or laparotomy in hemodynamically unstable patients. With increasing availability of angiography, current practice is trending toward non-operative management.² Therefore, diagnosis and management of splenic rupture is an increasingly important skill for general medical providers. Patients may not present with abdominal pain or any history of trauma, which may delay diagnosis if clinicians are not on alert for this potentially fatal complication. One case of Anaplasmosis associated with splenic rupture has been described.³ There are more reports of Babesiosis associated with splenic rupture.⁴ Any practitioner may encounter a patient with tickborne illness and should be familiar with its potential complications. 1. Renzulli et al. (2009) 2. Miller et al. (2014) 3. Khan and Ali (2018) 4. Li et al (2018)

CONCLUSION: Atraumatic splenic rupture is a potentially fatal complication in conditions commonly encountered by general medical practitioners. Its management is increasingly non-operative, and as such, important for providers to diagnose and manage. It is also important to recognize atraumatic splenic rupture as a potential complication of tickborne illness, even in post-splenectomy patients.

A DANGEROUS WEB

Nikita Agrawal¹; Daniel Labovitz². ¹Montefiore Medical Center (Moses & Weiler), New York, NY; ²Montefiore Medical Center, Bronx, NY. (Control ID #3184787)

LEARNING OBJECTIVE #1: Recognize carotid web as a cause of stroke.

LEARNING OBJECTIVE #2: Recognize imaging findings consistent with carotid stroke and other diagnosis with similar findings.

CASE: A 42-year-old woman with no known stroke risk factors woke up with slurred speech and left arm paresis. MRI brain and MRA head/neck demonstrated MCA infarction with insular cortex involvement and mild stenosis of the proximal right cervical internal carotid artery. CTA of the carotid demonstrated a low density filling defect along the posterior wall of the proximal right internal carotid artery. Carotid web (CaW) was suspected based on imaging features. She was placed on IV heparin followed by carotid endarterectomy confirming the presence of a CaW, which was removed. Patient was discharged on dual antiplatelet therapy for a three month course and lifelong aspirin and statin.

IMPACT/DISCUSSION: Carotid web (CaW) is an under recognized cause of stroke in young patients without classical risk factors. This case illustrates the importance of considering CaW as a cause of anterior circulation ischemic stroke. CaW is a variant of fibromuscular dysplasia that appears in the posterior aspect of the carotid bulb at the origin of the internal carotid artery. CaW can be diagnosed using imaging including US CTA, MRI or digital subtraction angiography (DSA). On imaging CaW appears as a shelf like structure. Whereas atherosclerotic lesions are irregular with a thickening of the carotid wall, CaW is distinguished by smooth borders of the lesion itself and of the vessel wall. Moreover, CaW can be mistaken for arterial dissections as the shelf on the web can appear as a dissection flap. In comparison arterial dissections classically affect the middle or distal cervical segments of the ICA and present with irregular borders. Moreover, dissections may include enlargement of the arterial diameter whereas CaW is associated with normal bulb shape. Currently epidemiologic data on CaW is limited as it remains an underrecognized pathology. At large, CaW is more common in young women. Currently there have not been studies examining the genetic propensity for the pathology. For ischemic strokes in CaWs, there is currently no optimal secondary stroke prevention strategy. Initial data has demonstrated that antiplatelet monotherapy may be insufficient in preventing recurrent ischemic events with reoccurrence of events occurring in nearly one third of patients. Revascularization with surgical resection has increasingly been used in prevention of carotid webs with no case reports of reoccurrence following resection. Carotid artery stenting has also been described as an alternate to surgical resection with a study demonstrating no reoccurrence in a 12 month follow up.

CONCLUSION: It is important to consider CaW as an etiology of stroke in young patients with limited risk factors. Given the life altering nature of strokes, prevention of repeat events with appropriate therapy is imperative. Strokes associated with CaW may be better managed with surgical intervention.

A DEADLY MYX: HYPOTHYROIDISM AND AMPHETAMINES

Syeda A. Raza. Methodist Health Systems Dallas, Dallas, TX. (Control ID #3168551)

LEARNING OBJECTIVE #1: Recognize that myxedema coma can be precipitated by amphetamine use

CASE: A 56- year old male presented with encephalopathy after being found unresponsive at home. On examination, patient's vitals were notable for blood pressure of 90/74mmHg, pulse of 43, and temperature of 97.6 degrees Fahrenheit. Physical exam revealed an obtunded, disheveled male with bilateral periorbital edema. Labs were notable for pancytopenia and elevated liver function tests. Further lab tests demonstrated TSH of 10mU/L with Free T4 of 0.25 mU/L. A subsequent urine drug screen was positive for amphetamines. Patient was admitted to the ICU and was treated for myxedema coma presumed to be triggered by recent amphetamine use. Patient was treated with warming blankets, IV hydrocortisone, and IV levothyroxine. He had improvement of his mentation and subsequent labs over the next few days showed resolution of pancytopenia and transaminitis. TSH also noted to downtrend appropriately. As patient became more alert, he was questioned and admitted to history of hypothyroidism with non-compliance to medication. He further reported recent use of amphetamine prior to hospitalization.

IMPACT/DISCUSSION: Myxedema coma is an extreme but rare manifestation of hypothyroidism, resulting in life-threatening secondary systemic decompensation. It is usually precipitated by an inciting event, such as infection, stroke, trauma, substance use, or cold exposure. In our case, the inciting event was noted to be secondary to recent amphetamine use. It is important for clinicians to develop broad differential diagnosis to prevent premature closure. Our patient's case was initially concerning for drug overdose but was found to be due to myxedema coma.

CONCLUSION: Myxedema coma is a medical emergency that necessitates immediate care. Management is necessary prior to confirming diagnosis as delay in treatment is associated with high mortality rates. It is important for clinicians to be aware of amphetamine use as a possible trigger for myxedema coma.

A DIAGNOSIS OF MGUS, A COMMON BUT COVERT DISEASE, IN A PATIENT WITH RECENT MYOCARDIAL INFARCTION
 Daniel Clement¹; Eun Ji Kim². ¹Northwell Health, Manhasset, NY;
²Northwell Hofstra School of Medicine, Lake Success, NY. (Control ID #3172918)

LEARNING OBJECTIVE #1: Diagnose MGUS and differentiate it from other plasma cell disorders

LEARNING OBJECTIVE #2: Recognize the association between thrombotic disease, including myocardial infarction, and MGUS

CASE: 76 year-old African American female with diabetes mellitus, hypertension, hyperlipidemia, and coronary artery disease presented for establishment of care after a recent hospitalization for NSTEMI. She was a lifelong non-smoker and denied family history of malignancy. Physical examination was within normal limits. Laboratory studies were relevant for a hemoglobin of 10.5g/dL (normal 11.5-15.5) with normal platelets and leukocytes. Total protein was elevated at 8.6g/dL (normal 6.0-8.3). The patient's liver function, creatinine, albumin, and calcium were within normal limits. Serum and urine protein electrophoresis were obtained because of her anemia and elevated protein level. These were relevant for an elevated level of Gamma-migrating paraprotein with M-spike in the serum with no evidence of a paraprotein in the urine. The patient was referred to hematology for further evaluation. Repeat serum protein electrophoresis confirmed the presence of a paraprotein. A skeletal survey showed no evidence of lytic lesions. Given these findings, the patient was diagnosed with Monoclonal Gammopathy of Unknown Significance (MGUS). She is currently scheduled for a bone marrow biopsy.

IMPACT/DISCUSSION: Diagnosis of MGUS is defined as the presence of an M-spike on serum protein electrophoresis less than 3g/dL, fewer than 10% plasma cells on bone marrow biopsy, and the absence of hypercalcemia, renal insufficiency, severe anemia, and bony lesions. MGUS is a common disease and affects higher percentages of elders (3.2% 50 years or older, 5.3% 70 years or older, and 7.5% 85 years or older). The prevalence of this disease is also higher in the African

American population (in one study, 8.6% of the participants in this ethnic group had an M-spike). MGUS is important to diagnose because there is a 1% chance of progression to multiple myeloma, lymphoma, Waldenstrom's macroglobulinemia, or AL amyloidosis every year after diagnosis. Current guidelines do not recommend screening the general population for MGUS. However, patients who have elevated total protein or immunoglobulins, unexplained anemia, elevated ESR, hypercalcemia, or renal failure should be screened. Once a diagnosis is established, the patients should be monitored with regular laboratory studies. This should initially occur six months after diagnosis followed by every two to three years thereafter. In this case, having an NSTEMI increased our suspicion for hematologic disease as having MGUS is associated with a 2-fold increase in the risk of developing both arterial and venous thrombosis.

CONCLUSION: In elderly patients with anemia and elevated protein level, serum and urine protein electrophoresis should be performed to evaluate for plasma cell disorders such as MGUS. Subsequently, patients with MGUS should be monitored closely for progression to other hematologic diseases.

A DYSFUNCTIONAL DIAGNOSIS FOR ABDOMINAL PAIN

Kevin Zheng; Jay J. Chudow; Darlene LeFrancois. Montefiore Medical Center, Bronx, NY. (Control ID #3186040)

LEARNING OBJECTIVE #1: Recognize sphincter of Oddi dysfunction as a common cause of post-cholecystectomy pain syndrome

LEARNING OBJECTIVE #2: Diagnose functional biliary sphincter disorder using the Rome IV criteria

CASE: A 31-year-old obese woman presented five months ago with recurrent epigastric pain. She underwent cholecystectomy with pathology showing chronic cholecystitis. Since then, she presented and was admitted multiple times for similar, near daily epigastric pain. The pain was worse after meals, lasted for hours at a time, and did not improve with antacids or ranitidine. She denied smoking and rarely drank alcohol. Exam revealed tachycardia as well as tenderness in the epigastrium and RUQ. Liver tests were elevated with AST 552 and ALT 612. Bilirubin, alkaline phosphatase, and pancreatic enzyme levels were within normal limits. EGD revealed mildly erythematous gastric mucosa and CT abdomen and pelvis was unremarkable. Abdominal ultrasound and MRCP did not reveal ductal dilatations or stones. She underwent ERCP and had biliary sphincterotomy without preceding manometry. Her symptoms improved and she was discharged. She has not returned since for a similar issue.

IMPACT/DISCUSSION: Sphincter of Oddi dysfunction (SOD) should be suspected in patients with recurrent biliary-type pain after cholecystectomy. The prevalence of SOD among these patients is 9-14%. After cholecystectomy, there is loss of a cholecystosphincteric reflex that is responsible for sphincter relaxation when the gallbladder is distended. This results in increased resistance to bile outflow and a subsequent rise in biliary pressure that is perceived as pain. Other theories include an increased sensitization of nociceptors to biliary pressure that remains after cholecystitis. The term functional biliary sphincter disorder (FBSD) is now used for patients with post-cholecystectomy biliary pain and some objective findings of sphincter dysfunction. According to the Rome IV criteria, a diagnosis of FBSD is established when either epigastric or RUQ pain satisfies all of the following: 1) lasts for 30 minutes or longer, 2) recurs at different intervals (not daily), 3) is severe enough to interrupt daily activities or lead to an emergency department visit, 4) is not significantly related to bowel movements, and 5) is not significantly relieved by postural change or acid suppression. In addition, patients must have elevated liver enzymes or a dilated bile duct, but not both, and have absence of bile duct stones or other structural abnormalities. Sphincter manometry is recommended to predict response to treatment with sphincterotomy but is often forgone in clinical practice due to the risk of pancreatitis associated with ERCP.

CONCLUSION: SOD is important to consider as a cause of postcholecystectomy pain syndrome. By the Rome IV criteria, FBSD is diagnosed by having biliary-type pain with either elevated liver enzymes or a dilated bile duct.

A FAILING HEART: A NEW DIAGNOSIS OF HEART FAILURE DUE TO HYDROXYCHLOROQUINE-INDUCED CARDIOMYOPATHY

Alexander Ghincea¹; Justin Allsop²; Daniel W. Groves⁶; Mona Rizeq⁴; Monica P. Revelo⁵; Sridharan Raghavan³. ¹University of Colorado School of Medicine, Denver, CO; ²University of Colorado, Aurora, CO; ³Denver VA Medical Center, Denver, CO; ⁴VA medical Center (ECHCS), Denver, CO; ⁵University of Utah, Salt Lake City, UT; ⁶University of Colorado School of Medicine, Aurora, CO. (Control ID #3180736)

LEARNING OBJECTIVE #1: Diagnose hydroxychloroquine-induced cardiomyopathy in patients with complex multi-organ-system medical history.

LEARNING OBJECTIVE #2: Recognize the importance of early diagnosis and medication cessation in hydroxychloroquine-induced cardiomyopathy.

CASE: A 43-year-old woman presented with acute shortness of breath, dry cough, and chest pain. She had a history of seronegative inflammatory arthritis treated with hydroxychloroquine (HCQ) 200 mg twice daily for 8 months and cystic lung disease. Pulse was 128 bpm and oxygen saturation 89% on room air. She had distant heart sounds and diffuse inspiratory crackles. White cell count was $12.7 \times 10^9/L$, hemoglobin 15.2 g/dL, and platelets $297 \times 10^9/L$. Comprehensive metabolic panel was normal. Pro-Brain Natriuretic Peptide (pBNP) was 3539 pg/mL, and troponin peaked at 0.05 ng/mL. Infectious and autoimmune workup was negative. Ferritin was 91 ng/mL and thyroid stimulating hormone was 0.35. She had sinus tachycardia with inferior T-wave flattening and lateral T-wave inversions on electrocardiogram (ECG). Computed tomography revealed ground glass opacities and bilateral pleural effusions. Echocardiography revealed global systolic dysfunction without ventricular hypertrophy and an ejection fraction of 20-25%. Cardiac magnetic resonance imaging (CMR) revealed dilated cardiomyopathy, and no focal inflammation, edema, infarction, or fibrosis. HCQ was discontinued, and her oxygen requirement resolved with diuresis. Coronary angiography was normal and endomyocardial biopsies (EMB) taken. She discharged in stable condition after optimization of guideline directed medications for heart failure. Histopathology and electron microscopy revealed non-specific myocyte hypertrophy, no evidence of iron or amyloid deposition, and no lymphocytic or granulomatous infiltrate, but did show myelinoid bodies consistent with HCQ toxicity.

IMPACT/DISCUSSION: HCQ is commonly used in patients with connective tissue diseases. Cardiotoxicity is rare, and is thought to be underrecognized. We present a patient without prior cardiac history who developed severe heart failure after only 8 months of HCQ therapy. High doses, long-term exposure, female sex, and pre-existing heart disease are risk factors. Cardiac complications include conduction disease and restrictive or dilated cardiomyopathy. EMB with histopathology and electron microscopy is essential to the diagnosis, and should be undertaken in any patient receiving HCQ presenting with new or unexplained cardiac abnormalities. CMR and echocardiography are important adjuncts to the diagnosis. Withdrawal of HCQ is the cornerstone of management owing to potential reversibility of cardiac complications.

CONCLUSION: Identification of adverse drug reactions and timely intervention are paramount for internists. Screening with ECG and echocardiography should be performed in all patients receiving HCQ. HCQ should be discontinued in all patients with confirmed or suspected cardiotoxicity to reduce the morbidity and mortality of these devastating complications.

A FATAL BUT UNCOMMON CAUSE OF HEADACHE

Matthew Langston²; Michael T. Vest¹. ¹Christian Care Health System, Wilmington, DE; ²Christian Care Health System, Newark, DE. (Control ID #3185766)

LEARNING OBJECTIVE #1: Consider etiologies of headache with potentially serious consequences.

LEARNING OBJECTIVE #2: Treat cerebral venous thrombosis.

CASE: A 57-year-old female was brought to the emergency department found unresponsive at home. She missed work due to a headache the day of admission. She had a history of breast cancer diagnosed in 2007 and treated with chemotherapy and mastectomy. A bone scan three months prior revealed a sclerotic left parietal lesion suspicious for metastatic disease. She was having headaches for several months. Her outpatient evaluation included magnetic resonance (MR) imaging of head four months prior, revealing sinus opacification. She was felt to have sinus headaches and underwent a right maxillary antrostomy and ethmoidectomy one week prior to admission. She was intubated in the emergency department for airway protection, where a urine drug screen was positive for cocaine, cannabinoids, and benzodiazepines. Head computed tomography with angiography (CTA) showed lack of opacification of the intracranial dural venous sinuses with enhancement of cortical veins. Further evaluation with MR venography revealed venous hypertension and ischemia of the deep grey nuclei secondary to extensive venous thrombosis involving the torcula, deep venous system, and bilateral transverse sinuses. Anticoagulation with intravenous heparin was started. An emergent thrombectomy was performed and the evacuated thromboses were felt to be chronic due to their density. Despite this intervention, she developed progressive neurologic deterioration due to increased intracranial pressure and ultimately died.

IMPACT/DISCUSSION: Headache is the most frequent symptom of cerebral venous thrombosis (CVT). High clinical suspicion for CVT is needed as general neuroimaging not protocolled appropriately may not detect this diagnosis and early diagnosis improves outcomes. Retrospective studies have indicated an incidence of cerebral venous thrombosis higher than previously expected. We suspect that her months of headaches were the result of CVT rather than sinus disease. Metastasis of recurrent malignancy could have played a role in her presentation. Treatment focuses on anticoagulation, however more recent endovascular therapies are being employed, as in our patient. This case underscores the importance of not prematurely attributing altered mental status entirely to substance abuse without searching for other causes in patients with positive urine drug screens.

CONCLUSION: Cerebral vein thrombosis is a challenging diagnosis as an uncommon etiology of headache. The inclusion of CVT remains an important consideration in the differential of an obtunded patient with headache history.

A FATAL CASE OF SEPTIC SHOCK CAUSED BY ACINETOBACTER BACTEREMIA ACQUIRED FROM A PLATELET TRANSFUSION

Christopher Nevala-Plagemann¹; Patrick Powers¹; Mustafa Mir-Kasimov²; Richard Rose². ¹University of Utah, Salt lake City, UT; ²Veterans Affairs, Salt Lake City, UT. (Control ID #3182679)

LEARNING OBJECTIVE #1: Prompt initiation of broad spectrum antibiotic therapy is essential in suspected septic transfusion reactions

LEARNING OBJECTIVE #2: Septic transfusion reactions are most commonly associated with platelet transfusion

CASE: A 67 year old male with a history of type II diabetes and alcoholic cirrhosis was admitted for medical optimization prior to a transarterial chemoembolization procedure for recently diagnosed hepatocellular

carcinoma. The patient was feeling well at the time of admission. Admission vitals were unremarkable and his labs were notable only for chronic thrombocytopenia. In anticipation of his upcoming procedure, two units of platelets were ordered. Shortly after initiation of the first platelet transfusion, the patient complained of chills and was noted to have a temperature of 100.8°F. The transfusion was stopped and the patient was administered acetaminophen and diphenhydramine. Approximately 1 hour later, the patient developed tachycardia, tachypnea, and hypotension. The patient was transferred to the intensive care unit where he was started on vasopressors and broad spectrum antibiotics. Within a few hours of admission to the ICU the patient developed severe disseminated intravascular coagulation (DIC). Blood cultures revealed Acinetobacter bacteraemia. Cultures obtained from the unit of transfused platelets grew the same species of Acinetobacter. Antibiotic coverage was broadened to tobramycin and meropenem. Unfortunately, over the subsequent 24 hours, the patient's vasopressor requirements continued to rise. Given his clinical deterioration further aggressive treatment was felt to be unlikely to improve his condition. Aggressive care was withdrawn and the patient expired shortly after.

IMPACT/DISCUSSION: Septic transfusion reactions caused by bacterial contamination of blood products have long been known to be a problem in transfusion medicine. The risk of a sepsis is highest with the transfusion of platelets due to storage at room temperature. Bacterial contamination rate of platelets is around 1 in 5000 transfusions, with a risk of transfusion associated sepsis around 1 in 100,000 transfusions. Death related to transfusion of contaminated platelets remains rare with only 10 fatalities reported by the Food and Drug Administration from 2012 to 2015. Clinicians must be able to recognize the signs of a septic transfusion reaction which include fever, chills, hypotension, and DIC. It may be difficult to differentiate sepsis from other types of transfusion reactions such as acute hemolytic reactions. In order to assist with diagnosis, the blood bank should be contacted immediately so that proper laboratory testing can be performed, including ABO compatibility and culture of the transfused product. Administration of antibiotics should be considered in any decompensating post transfusion patient.

CONCLUSION: Septic transfusion reactions are a relatively rare but important complication of blood product administration that clinicians must be able to recognize.

A FEBRILE CASE OF PRIMARY HEPATIC NEUROENDOCRINE TUMOR

Manojna Konda¹; swathi subramany¹; GAYATHRI KRISHNAN^{2, 1}; Richa Parikh¹; Kulsum Bano¹. ¹University of Arkansas for Medical Sciences, Little Rock, AR; ²UAMS, Little Rock, AR. (Control ID #3185685)

LEARNING OBJECTIVE #1: Recognize that fever could be an atypical presentation of primary hepatic neuroendocrine tumor.

LEARNING OBJECTIVE #2: Recognize that diagnosis can be challenging due to their common radiologic characteristics with other liver lesions.

CASE: A 54 year-old previously healthy male presented with one-week duration of fevers, abdominal pain, and diaphoresis. The patient was febrile to 102 F with otherwise normal vital signs. The patient was jaundiced on examination with tenderness in RUQ. Lab work showed white count of 17.4k/ μ L. LFTs were also elevated with total bili of 3.2 mg/dL, Direct bili 1.6 mg/dL, ALP 176 U/L, GGT: 231 U/L AST: 52 U/L ALT: 40 U/L. Abdominal CT showed multiple hypodense lesions in the liver concerning for abscesses. Empiric antibiotics were started as he was febrile with leukocytosis and imaging findings. Blood cultures, hepatitis, entamoeba and echinococcus tests were negative. Targeted FNA biopsy of one of the liver lesions was done. Final pathology revealed well-differentiated neuroendocrine tumor and was negative for any organisms. Antibiotics were discontinued. Octreotide scan showed increased activity only in the liver with no abnormal activity outside the liver. This was suggestive of the patient having primary hepatic neuroendocrine tumor

with multiple liver metastases. Serum chromogranin A was high at 50ng/mL, serum serotonin was elevated at 3333 ng/ml and urine 5-HIAA was high at 156.9 mg/day. The patient was started on somatostatin analogue lanreotide and mTOR kinase inhibitor everolimus with dramatic resolution of his fevers. His most recent imaging showed improvement in the size of his liver lesions.

IMPACT/DISCUSSION: This case adds to the literature about the rare presentation of primary hepatic neuroendocrine tumor which has previously not been described. It also highlights the importance of distinguishing various liver masses. While more than 80% of neuroendocrine tumors found in the liver are metastatic, primary hepatic neuroendocrine tumors are extremely rare with less than 100 cases reported worldwide. While most of the tumors are solitary and functionally silent, less than 10% cases have been described as being functional with flushing, diarrhea and wheezing. Although hypothetical, fevers may have been a result of high levels of serotonin. Diagnosis is often challenging based on radiological appearance as it can mimic other liver masses. Biopsy can confirm the diagnosis. Octreotide scan is a useful tool in differentiating primary hepatic neuroendocrine tumors from other primary sites with liver metastases. While surgical resection is the preferred treatment, in cases of unresectable disease use of somatostatin analogues has shown to have good results with overall prognosis being better than other types of liver cancer.

CONCLUSION: Clinicians need to be aware of fever as an atypical presentation of primary hepatic neuroendocrine tumors. While challenging to diagnose by conventional imaging, exclusion of other primary lesions and liver biopsy is strongly warranted.

A GREAT IMITATOR OF POSITIONAL VERTIGO

Priya Chopra¹; Ericson Stoen¹; Chi Zheng². ¹University of Colorado School of Medicine, Aurora, CO; ²Denver Health, Denver, CO. (Control ID #3158950)

LEARNING OBJECTIVE #1: Recognize neurosyphilis as a cause of recurrent falls

LEARNING OBJECTIVE #2: Understand the difference between otosyphilis and neurosyphilis

CASE: A 73-year-old woman presented after a fall at home resulting in a forehead hematoma in the setting of a four-month history of progressive dizziness and recurrent falls. She described the dizziness as "room spinning" exacerbated by changes in position; she also had a two-year history of right-sided tinnitus and progressive hearing loss. Her past medical history was notable for atrial fibrillation, type 2 diabetes mellitus with peripheral neuropathy, and hypertension. Medications included warfarin, NPH insulin, lisinopril, metoprolol, baclofen, tizanidine, and hydrocodone. Vital signs including orthostatics were normal. Cardiopulmonary exam was normal. Neurologic examination showed terminal dysmetria and deficits in bilateral lower extremity proprioception. Hemoglobin, glucose, troponin, TSH, B12, and HIV were all normal, and her INR was therapeutic. ECG showed sinus rhythm, and interrogation of the patient's loop recorder placed for her falls was unremarkable. CT and MRI of the brain were unremarkable. A prior audiometry report showed isolated right-sided neurosensory hearing loss. *Treponema pallidum* antibody was positive, with subsequently positive RPR at 1:2 and a positive confirmatory FTA-ABS. Cerebrospinal fluid (CSF) protein was elevated at 58, and CSF VDRL was non-reactive. As she had a negative RPR 11 years prior and scored 18/25 on a partially completed Mini-Mental State Examination, the patient was treated for neurosyphilis with continuous penicillin G infusion for 14 days with improvement in her vertigo and tinnitus but not hearing.

IMPACT/DISCUSSION: Over 800,000 patients are hospitalized each year due to falls, and the possible etiologies of recurrent falls are numerous. Our patient had several potential causes for her falls, and many of which were systematically excluded from the differential, but her neurologic and vestibular symptoms gave concern for neuro and oto-syphilis.

Syphilis can present with both hearing loss and vertigo. This occurs when *T. pallidum* invades the cochleovestibular system resulting in otosyphilis, or the cerebrospinal fluid (CSF) resulting in neurosyphilis. In neurosyphilis, extra-otic symptoms such as impaired proprioception, stroke, and dementia may also be present. To differentiate neurosyphilis from otosyphilis, a lumbar puncture should be performed. Making this distinction is important, as the treatment may differ. The literature currently suggests intravenous penicillin G treatment for neurosyphilis; however, there is controversy regarding treatment for otosyphilis. Some studies suggest that three doses of intramuscular penicillin is sufficient, while other experts recommend the same treatment as neurosyphilis due to concerns of incomplete eradication.

CONCLUSION: This case exemplifies the importance of a thorough diagnostic evaluation after recurrent falls and peripheral vertigo, including ruling out "the great imitator."

A HARBINGER OF MALIGNANCY: PARANEOPLASTIC CEREBELLAR ATAXIA

Michael H. Nguyen, California Pacific Medical Center, San Francisco, CA. (Control ID #3185948)

LEARNING OBJECTIVE #1: Recognize the clinical features that suggest a paraneoplastic process in patients with ataxia

LEARNING OBJECTIVE #2: Manage patients with paraneoplastic ataxia

CASE: A 73 year old female with a remote 25 pack per year smoking history presented to an emergency room 12/26 with 3 weeks of headache, blurry vision, and slurred speech. She was discharged home with negative workup including a CT scan. She received an outpatient MRI on 12/29 that was negative for acute pathology and subsequent work up with an ophthalmologist was also unrevealing. One week later, she presented to CPMC on 1/2 with progressive bilateral upper extremity weakness and ataxia. Lumbar puncture (LP) was only remarkable for elevated protein. She received a PET CT 1/3 that showed evidence of a 1.4 cm left upper lobe (LUL) nodule and hypermetabolism in her mediastinal lymph nodes. She underwent biopsy on 1/5 that revealed nonsquamous cell lung cancer that is subsequently positive for PD-L1 expression (20%). Her CSF also later comes back positive for Purkinje cell cytoplasmic antibody (PCA-1). At this point she was diagnosed with paraneoplastic cerebellar ataxia (PCA). Over the ensuing months, she underwent plasma exchange 1/5-1/7, external radiation 1/25-3/7, and chemotherapy 1/31-4/4 with no remission in her symptoms and was now wheelchair bound. A PET CT 4/10 reveals resolved hypermetabolism in her mediastinal lymph nodes but persistence of her 1.4 cm LUL nodule. A MRI 5/31 reveals cerebellar atrophy consistent with cerebellar degeneration. The patient underwent another round of plasmapheresis 6/12-6/20 with no improvement of her symptoms and she was discharged to hospice.

IMPACT/DISCUSSION: Ataxia is a common complaint in the ER. When imaging and initial laboratory tests are negative, differentials must be widened to include autoimmune and malignant processes. The cause of ataxia can even be a combination: in PCA, there is severe loss of cerebellar Purkinje cells as a result of onconeural antigens. This case demonstrates the diagnostic challenge of PCA and the devastating consequences of late treatment. The patient's negative MRI, negative LP, and acute presentation delayed her diagnosis of PCA. While it is a rare complication of malignancy, PCA often precedes the diagnosis of cancer and is a clue to diagnose malignancy at an early treatable stage. If given early enough, there is evidence for immunotherapy. However, in most cases the diagnosis is delayed rendering treatment ineffective. A patient with worsening ataxia over weeks with unremarkable brain imaging and laboratory tests must be considered for an autoimmune process. If there are any risk factors for malignancy, a paraneoplastic process should be • PCA commonly precedes the diagnosis of cancer, marking a critical

time to diagnose malignancy • It is thought the cerebellar damage is irreversible in PCA because interventions are too late • If a patient presents with worsening ataxia with negative imaging and lab tests, an autoimmune process should be considered

A HEALTHY HEART?

Magued W. Haroun; Vladyslav Dieiev; Pakhi Goel; Karishma Kitchloo. Montefiore Medical Center, Bronx, NY. (Control ID #3185968)

LEARNING OBJECTIVE #1: Recognize prevalence of early repolarization pattern (ERP) on electrocardiogram (ECG) among young, healthy athletes

LEARNING OBJECTIVE #2: Distinguish between ERP and ST segment elevation myocardial infarction (STEMI)

CASE: A 40 year-old Hispanic man presented with two episodes of palpitations. He had no significant past medical history; he was an athlete who ran three marathons during the preceding two-weeks period. Palpitations were non-exertional, lasted for ten minutes and resolved by the time of presentation. His initial ECG revealed STE in leads V3 and V4 that extended to lead V5 twelve hours later, and T-wave inversions (TWI) in leads III and V3 that extended to leads V4 and aVF six hours later and completely resolved on EKG at twelve hours. There were no ST depressions in reciprocal leads. Serial Troponin T was <0.01. Patient remained asymptomatic throughout the admission. Echocardiography revealed no abnormalities. Coronary angiography and left heart catheterization revealed patent coronary arteries.

IMPACT/DISCUSSION: Dynamic changes in ST segments is a worrisome clinical finding which raises suspicion for an acute coronary process but it is important to consider these findings in clinical context and to use specific ECG criteria. In our case, the ECG pattern and morphology, lack of chest pain, electrolyte disturbances or troponin elevation were consistent with ERP in anterior leads. Invasive evaluation confirmed absence of an underlying disease process which may have caused the changes described. ERP has always been considered a normal ECG variant. It is characterized by J-point ST elevation and manifests either as terminal QRS slurring (the transition from the QRS segment to the ST segment) or notching (a positive deflection inscribed on terminal QRS complex) associated with concave upward ST-segment elevation and prominent T waves in at least two contiguous leads. ERP is more prevalent in competitive athletes and its prevalence increases after intense physical training. ERP is not associated with structural left ventricular measurement, including chamber volume or wall thickness, both of which are well-established components of the "athlete heart" suggesting that exercise-related ERP may be an isolated electric phenomenon that develops parallel to, but not as a result of, structural myocardial remodeling.

CONCLUSION: While STE may reflect occlusion of the coronary artery and ongoing necrosis of myocardium, in the appropriate clinical scenario other etiologies should be considered. Internists need to be able to discern ERP from STEMI and to expect a higher prevalence of ERP in athletes.

A HEARTY INFECTION

MATTHEW WEBER¹; Pinky Jha². ¹Medical College of Wisconsin, Wauwatosa, WI; ²Medical College of Wisconsin, Milwaukee, WI. (Control ID #3185978)

LEARNING OBJECTIVE #1: Report a case of disseminated mucormycosis involving lungs and heart in an immunocompromised patient.

LEARNING OBJECTIVE #2: Show prophylaxis choice can be a clue for earlier diagnosis of mucormycotic infections.

CASE: 57 YO F diagnosed with myelodysplastic syndrome. Admitted for pre-transplant chemotherapy and matched unrelated allogenic PBSCT.

Prophylaxis included acyclovir, fluconazole, ciprofloxacin and Augmentin. Successful PBSCT on day 7. She began having sharp, pleuritic, left-sided chest pain. CXR showed lingular infiltrate in left upper lobe. CT showed bilateral ground glass and alveolar opacities over coarse interstitial disease. Broad infectious work was negative. She was switched from fluconazole to micafungin, and antibiotics broadened. On day 13 bronchoscopy showed normal lungs. BAL negative for bacterial, viral, and fungal infection. Day 14, began requiring 1-2 L of O₂. Work of breathing increased as she developed atrial fibrillation with RVR and hypotension requiring norepinephrine. Upon arrival to ICU she was sedated, intubated, and started on norepinephrine drip. Amphotericin B was started. Lingula biopsy obtained showing rhizopus. On day 25, CT surgery performed left upper lobectomy, resected pericardial fat, and pericardial window which revealed dark serous fluid. Pathology on the pericardial fat showed Rhizopus and Aspergillus, lung lobe showed Rhizopus. That night she became hypotensive, refractory to fluid, norepinephrine and vasopressin drips. Patient's family requested comfort cares only - the patient died a few hours later.

IMPACT/DISCUSSION: PBSCT patients are at high risk for infection. It is impossible to provide coverage for every possible infectious entity but being able to make quick a diagnosis can lead to early treatment and intervention. Mucormycosis is not typically the infection prioritized in prophylaxis selection. One study showed 875 patients with fungal infections: 43% with aspergillosis, 28% candidiasis, and 8% mucormycosis. The ASBMT Guidelines for Preventing Infectious Complications among PBSCT Recipients recommend prophylaxis targeted with fluconazole which has no mucor coverage. In patients at higher risks for mold infections (ie high risk for GVHD) they recommend voriconazole. Patients with voriconazole prophylaxis are actually *more* prone to breakthrough mucormycosis. Additionally, use of fluconazole or itraconazole therapy is associated with a fourfold increase in incidence of mucormycosis compared posaconazole. Pulmonary mucormycosis is a rapidly expanding disease that causes necrosis and can, on rare instances, invade the mediastinum and heart. Quick diagnosis can expand the window of treatment. Diagnosis requires histopathology evidence and positive cultures which often requires biopsy. Treatment involves surgical debridement and amphotericin B.

CONCLUSION: Using prophylaxis as a clue, providers can raise their index of suspicion for mucormycosis in the setting of progressive pneumonia in PBSCT patients.

A HEMATOLOGIC EMERGENCY MASQUERADE AS AN NSTEMI

Andrew B. Dicks; Bess Flashner; Jonathan D. Goldman. Beth Israel Deaconess Medical Center, Boston, MA. (Control ID #3177560)

LEARNING OBJECTIVE #1: Recognize an abnormal presentation of thrombotic thrombocytopenic purpura (TTP)

CASE: A 48 year old female with history of scleroderma and vitiligo presented with chest pain. The pain was sudden onset, sharp, and radiated to her back. There was no positional or pleuritic component, and no inciting event. Presenting vital signs and physical exam were unremarkable. ECG showed T-wave inversions in leads II and V1. Troponin-T and CK-MB trended upward, peaking at 0.28 ng/mL and 16 ng/mL, concerning for NSTEMI. CTA chest demonstrated no evidence of pulmonary embolism or aortic dissection. Coronary angiography demonstrated no CAD. She was subsequently admitted to the medicine service for evaluation of her chest pain. Presenting labs were also notable for Hgb 9.5 g/ dL and platelet count 87 K/uL, down from 12.0 g/dL and 264 K/uL nine months prior. Additional work up demonstrated absolute reticulocyte count 0.18 m/uL, haptoglobin <10 mg/dL, LDH 516 IU/L, and a peripheral blood smear with 2+ schistocytes, consistent with microangiopathic hemolytic anemia. Given concern for TTP, ADAMTS13 activity level was

sent. While awaiting the result, she was risk stratified for TTP using the PLASMIC score (defined by 7 variables including platelet count <30 K/uL, MCV <90 fL, INR <1.5, creatinine <2.0 mg/dL evidence of hemolysis, lack of active cancer, and lack of organ or stem cell transplant). She scored 6 out of 7, indicating high likelihood of TTP and was urgently started on plasma exchange and prednisone, with eventual addition of rituximab. Her laboratory parameters and chest pain improved with treatment, and she was discharged home with hematology follow up. ADAMTS13 activity returned at <5%, confirming the diagnosis of TTP. Her presentation of NSTEMI was felt to be the first clinical manifestation of her TTP.

IMPACT/DISCUSSION: TTP causes extensive microscopic thromboses of small blood vessels which can lead to dysfunction of nearly any organ system, including the cardiovascular system. Microvascular occlusions of the heart can result in MI, arrhythmias, heart failure, or cardiogenic shock. Cardiac dysfunction is a rare initial presentation of TTP as other sequelae are usually present, making this case an atypical and unique presentation of TTP. TTP has a high mortality rate and treatment should not be delayed if suspicion of TTP is high. ADAMTS13 activity may take several days to result, and the PLASMIC score can therefore be used to predict the likelihood of ADAMTS13 activity and guide initiation of therapy while awaiting definitive diagnosis (1). 1. Bendapudi PK, et al. Derivation and external validation of the PLASMIC score for rapid assessment of adults with thrombotic microangiopathies: a cohort study. *The Lancet Haematology*. 2017;4(4):e157-e164.

CONCLUSION: Patients with TTP can present with end organ damage of nearly any organ system, including the cardiovascular system. Treatment of TTP should not be delayed while awaiting definitive testing if probability of TTP is high based on PLASMIC score

A HOLE IN OUR LOGIC: USING BAYESIAN PROBABILITIES TO OVERCOME ANCHORING BIAS

Rachel P. Shah¹; Meredith H. Lora². ¹Emory University School of Medicine, Atlanta, GA; ²Emory, Atlanta, GA. (Control ID #3185695)

LEARNING OBJECTIVE #1: Review anchoring bias and its effect on diagnostic error

LEARNING OBJECTIVE #2: Apply Bayesian analysis to overcome anchoring bias

CASE: A 50-year-old homeless man with a recent incarceration presented to a hospital with hemoptysis. He reported two months of productive cough, pleuritic chest pain, and B symptoms. Physical exam showed temperature 39.2 degrees C, pulse 115, oxygen saturation 96% on room air, and normal lung exam. Labs showed white blood cell count 19,000 (86% neutrophils) and negative HIV test. Chest CT revealed an 8cm RUL cavitary lesion with surrounding consolidation and no associated lymphadenopathy. The differential diagnosis included tuberculosis (TB), necrotizing bacterial pneumonia, invasive fungal infection, and malignancy. Empiric community acquired pneumonia treatment was started. Respiratory culture grew two strains of *Pseudomonas aeruginosa*, interpreted by the team as superimposed pseudomonas infection on a cavitary lesion. Ciprofloxacin was added. Tuberculosis workup included three negative sputum acid fast bacilli (AFB) smears, negative sputum TB PCR, and weakly positive QuantiFERON-TB Gold. Due to suspicion for smear-negative TB, the patient was started on empiric RIPE therapy. He developed drug-induced liver injury and symptoms worsened. Bronchoscopy yielded negative AFB smear and TB PCR. BAL culture grew levofloxacin-resistant *Pseudomonas*. Repeat CT chest showed enlargement of the cavitation to 13cm. Patient was treated with cefepime for six weeks and underwent RUL lobectomy. Pathology showed organizing pneumonia without evidence of TB.

IMPACT/DISCUSSION: This case highlights the risk of anchoring bias in patients with classic presentations of disease. While there is a broad differential for cavitary lung lesions, this patient had a presentation typical

of TB. Empiric treatment for TB was initiated and continued despite mounting evidence that decreased the probability of cavitary TB. This patient suffered from iatrogenic liver injury and a high-risk surgery that potentially could have been avoided through earlier diagnosis. About 75% of diagnostic errors have a cognitive component. Anchoring bias is the tendency for clinicians to stick with a diagnosis even as new contradictory information becomes available. To avoid anchoring, clinicians can employ Bayesian reasoning. While calculation of post-test probabilities using likelihood ratios can be daunting, a practical nomogram can aid in rapid utilization. If the pretest probability of TB in this patient was 70%, the posttest probability of TB after three negative sputum AFB smears and PCR dwindled to 20%, necessitating additional workup. Increased cognitive awareness through utilization of these probabilities can overcome anchoring bias and decrease errors.

CONCLUSION: 1. Cavitary lung lesions may result from microorganisms including but not limited to TB. 2. Anchoring bias can delay correct clinical diagnosis and increase risk of morbidity. 3. Bayesian analysis can be used to minimize the effects of anchoring bias.

A HORSE IN A ZEBRA COSTUME

Elaine Buckholtz; Michael P. Smith. University of Nebraska Medical Center, Omaha, NE. (Control ID #3186127)

LEARNING OBJECTIVE #1: Develop a systematic approach to the work-up for hypoglycemia.

LEARNING OBJECTIVE #2: Understand the importance of early detection of factitious hypoglycemia

CASE: A 20 year-old woman presented with extreme lethargy and was found to have a blood sugar of 49. She was admitted for recurrent and profound hypoglycemia of unknown etiology that had been ongoing for several months. She also had admissions for seizures related to hypoglycemia in the past. Due to increased sensitivity to even small doses of insulin, the patient reports that she stopped taking basal insulin altogether three weeks ago, which was interesting given her history of type 1 diabetes and hereditary pancreatitis which required a pancreatectomy. She was found to have undetectable levels of pro-insulin and c-peptide, but an elevated level of insulin. Insulin antibody levels were also elevated. IGF-1 and IGF-2 were normal. ACTH stimulation test was normal. A CT abdomen showed a mass suspicious for a neuroendocrine tumor. A DOTATE scan was also mildly positive which increased suspicion for a neuroendocrine tumor. An exploratory laparotomy yielded a tissue sample of the mass that was negative for neuroendocrine tissue. The patient improved without further intervention and tolerated a modest regimen of insulin without recurrence of hypoglycemia. The patient suffered from severe depression with prior suicide threats in addition to difficult social circumstances. It became evident that she had several risk factors and exhibited signs concerning for factitious hypoglycemia.

IMPACT/DISCUSSION: Recurrent hypoglycemia, outside of an acutely ill patient, requires a systematic approach from the general internist. It is important to implement a methodical approach to hypoglycemia as the differential is vast and work-up can become complicated as well as costly. Certain drugs and alcohol should be ruled-out first as a cause. Adrenal insufficiency will usually present with symptoms outside of what would be typical for hypoglycemia. Distinguishing between endogenous versus exogenous insulin will also be a helpful clue, which can be assessed by measuring insulin and c-peptide levels in the blood. C-peptide levels will be high with endogenous secretion of insulin. A common cause of exogenous insulin would be accidental or surreptitious administration of insulin. If there is suspicion for factitious behavior, it is important to rule-out an insulinoma, as labs will appear similar when compared to excessive sulfonylurea administration. Identifying a person with factitious disorder can be elusive and the implications of missing this diagnosis are serious. Complications of hypoglycemia include seizures, coma, and even death. Additionally, the cost of searching for an alternative cause can be high and it may lead to invasive, unnecessary procedures.

CONCLUSION: The general internist needs to have an approach to hypoglycemia that minimizes unnecessary testing and interventions in order to rapidly diagnose and treat the appropriate etiology

A LEGION OF THEIR OWN: A CASE OF LEGIONNAIRE'S DISEASE

William Chastant¹; Phillip S. Bell¹; Robert Miller². ¹Tulane University School of Medicine, New Orleans, LA; ²Tulane University Health Sciences Center, New Orleans, LA. (Control ID #3184473)

LEARNING OBJECTIVE #1: Discuss the rationale behind Legionella urine antigen testing.

LEARNING OBJECTIVE #2: Describe the severity of Legionnaire's disease.

CASE: A 67-year-old native Hawaiian with a history of COPD and diet-controlled diabetes presented with one week of progressively worsening dyspnea and weakness. He reported associated subjective fevers, a non-productive cough, and episodes of drenching sweats. Additionally, he experienced multiple episodes of watery, non-bloody diarrhea for several days, which resolved the day prior to presentation. His dyspnea and weakness resulted in an inability to get out of bed. He denied drug or alcohol use. He worked as a groundskeeper at a naval base. On physical exam his temperature was 103, HR 102, BP 159/90, RR 20, O2 % 95 on 2L NC. He exhibited increased work of breathing, diffuse rhonchi bilaterally and was extremely diaphoretic, with pools of sweat forming behind his clavicles. His hemoglobin was normal. WBC count was 11.7 (4.8-10.8) with 19% bands. His sodium was 131, and his AST and ALT were 148 and 105. CRP was 24.01 (nl 0-0.6). Rapid flu was negative. The rest of the chemistry panel was normal. Patchy, multi-focal, bilateral, lobar opacities were noted on initial chest x-ray. Piperacillin/tazobactam was initiated and Medicine was consulted for admission. Legionella and S. pneumoniae urine antigen, sputum cultures and blood cultures were ordered. Chest CT demonstrated multi-focal pneumonia with emphysematous changes and bronchiectasis. Given his structural lung disease, risk factors & toxic appearance, levofloxacin was added for additional antipseudomonal coverage. He improved initially but later became increasingly dyspneic and required intubation. Legionella urine antigen resulted positive. His coverage was narrowed to levofloxacin. Blood and sputum cultures had no growth. The patient was subsequently extubated and discharged home with a diagnosis of Legionnaire's pneumonia.

IMPACT/DISCUSSION: The severity of Legionnaire's disease warrants consideration of Legionella spp. as the etiology of any pneumonia that presents to the hospital. Radiographically there is no distinction with typical pneumonia. The commonly taught distinguishing features of diarrhea, hyponatremia and elevated transaminases, while helpful, are often absent. Sputum culture remains the gold standard for diagnosis. However, up to 50% of patients with legionella pneumonia do not produce sputum, making a culture difficult to obtain. Legionella urinary antigen has a sensitivity of 70-80% with a specificity approaching 100%. Therefore, multiple organizations recommending Legionella urine antigen testing in all patients with severe pneumonia.

CONCLUSION: In 2015, pneumonia was the 5th most common principal diagnosis leading to hospitalization in the United States. 1-10% of these cases were caused by *Legionella* spp. with mortality rates reaching up to 10% even with treatment.

A MALIGNANT CURE: SECONDARY NEOPLASM PRESENTING AS A CANCER OF UNKNOWN PRIMARY IN A HODGKIN'S LYMPHOMA SURVIVOR

Carlos A. Lopez¹; Nirupa J. Raghunathan². ¹Memorial Sloan Kettering Cancer Center, New York City, NY; ²Memorial Sloan Kettering Cancer Center, New York, NY. (Control ID #3186118)

LEARNING OBJECTIVE #1: Recognize the increased risk of solid subsequent malignant neoplasms (sSMN) in patients that have received chest irradiation.

CASE: A 50 year old female presented for a routine exam and was noted to have new, painless abdominal distention. She had a previous history of Hodgkin's Lymphoma (HL) treated with mantle radiation therapy (RT) and chemotherapy (treated at age 24) and triple negative breast cancer treated with bilateral mastectomy and chemotherapy (treated at age 44). She had no exposure to tobacco, and the rest of her history was non-contributory. Her exam was notable only for a protruding soft abdomen without mass and a palpable liver edge. An abdominal and pelvic ultrasound identified a hypoechoic 2.6 x 2.4 x 2.1 cm mass separate from the liver within the right upper quadrant adjacent to the region of the pancreatic head. A CT of the abdomen and pelvis revealed a gastrohepatic node increased in size compared to prior imaging. Biopsy of the gastrohepatic mass suggested lung adenocarcinoma. A staging PET CT scan showed disease localized to the lymph node without evidence of a lung primary tumor, other lymph node involvement, or distant metastases, so she underwent local therapy via surgical resection of the lymph node only and was monitored with imaging every 3 months. CT scans of the chest, abdomen, and pelvis at 3, 6, and 9 months were negative for evidence of progression; at 12 months, however, surveillance PET CT scan showed a new perihilar foci in the right lung with post-obstructive atelectasis suspicious for malignancy and FDG-avid enlarged lymph nodes in the infrahilar paraesophageal and portacaval regions. Biopsy of the infrahilar lymph node confirmed the diagnosis of metastatic lung adenocarcinoma. She was started on carboplatin, pemetrexed, and pembrolizumab.

IMPACT/DISCUSSION: This case highlights that survivors of childhood cancers who undergo RT are at high risk of developing solid subsequent malignant neoplasms, and that new symptoms or signs on physical exam should be investigated carefully. The cumulative incidence of developing sSMN at 40 years after diagnosis of HL is about 26.4%. Women who receive chest RT are at high risk for breast cancer, with a cumulative incidence of breast cancer of about 45.3% by age 50. Chest RT also increases the risk of lung cancer, with an estimated cumulative incidence of 2.2% by 40 years from diagnosis of HL. Though the risk of lung cancer conferred by RT appears to be higher than that of smoking in the general population, there is insufficient evidence at this time to recommend low-dose CT-imaging based screening in these patients. Notably, due to absence of a primary lung mass at the time of diagnosis, screening our patient with lung imaging would have proved unhelpful.

CONCLUSION: Cancer survivors exposed to RT should communicate and engage with their providers if they have new findings that may warrant investigation of disease reoccurrence or new sSMN, even in the absence of other traditional risk factors.

A MYSTERY DIAGNOSIS IN A PATIENT WITH ALTERED MENTAL STATUS

Cristina Nguyen. Alameda Health System - Highland Hospital, Oakland, CA. (Control ID #3184741)

LEARNING OBJECTIVE #1: Assess when to treat bacterial meningitis with adjunctive Dexamethasone.

LEARNING OBJECTIVE #2: Recognize when to give antimicrobial chemoprophylaxis for bacterial meningitis.

CASE: A 51 year-old homeless man with a past medical history of methamphetamine use presented for altered mental status after being found lying in a bathtub. While en route, he complained of a headache. He had a temperature of 103.2 F, heart rate of 112 beats per minute, and oxygen saturation of 98% on room air. Exam was notable for nuchal rigidity and decreased level of consciousness. His WBC count was 22,000. CT head revealed chronic bifrontal encephalomalacia and

multifocal paranasal sinus fluid and mucosal thickening. Lumbar puncture revealed an opening pressure of 55 cm H2O. Cerebrospinal fluid analysis was remarkable for 1750 WBC's, 92% neutrophils, protein 578, and glucose <5. Urine toxicology was positive for methamphetamine. The patient was stated empirically on intravenous Ceftriaxone and Vancomycin for presumed bacterial meningitis. Dexamethasone and Rifampin were also added as adjuncts for *Streptococcal pneumonia* treatment. All staff members treating the patient received a single dose of Ciprofloxacin for prophylaxis. On hospital day 5, the patient's altered mental status improved. He was also found to have a reactive, reactive treponemal antibody, a serum RPR titer 1:64, and reactive CSF VDRL. However, the patient left against medical advice without treatment.

IMPACT/DISCUSSION: Understanding cognitive biases for the vulnerable population affects physicians' decisions. Implicit bias also plays a major role in health care settings in regards to socioeconomic disparities which affect clinical judgment and decision-making. Thus, considering the patients' perspectives, advocating for the vulnerable, and maintaining a broad differential for patients presenting with altered mental status will lead to improved health outcomes. Our patient had many possible causes of altered mental status, including intoxication, neurosyphilis, and bacterial meningitis. Based on studies, adjunctive Dexamethasone should be given at the same time or prior to antibiotics if there is a likelihood of pneumococcal meningitis to decrease the rate of hearing loss and mortality. It has no benefit if given after antibiotics. Unlike Vancomycin, Rifampin is not limited in crossing into the CSF by the decrease in inflammation with Dexamethasone and is often added when Dexamethasone is started. Both Vancomycin and Rifampin can be discontinued if the organism is susceptible to the cephalosporin. Postexposure chemoprophylaxis can prevent the spread of *N. meningitidis*, but not pneumococcal disease. It is indicated for those in close contacts with patients and is most effective within 24 hours of the exposure. Although healthcare workers are at increased risk of exposure, the absolute increase in risk is very small. Thus, prophylaxis is not recommended for those who have not had direct exposure to respiratory secretions

CONCLUSION: See above.

A NEARLY-MISSED OPPORTUNITY: DIAGNOSING EPIDURAL ABSCESS DURING RESOLVING ENCEPHALOPATHY

Steven Omansky¹; Patricia Dharapak². ¹Mount Sinai Beth Israel Hospital, New York, NY; ²Mount Sinai Beth Israel, New York, NY. (Control ID #3161458)

LEARNING OBJECTIVE #1: To understand the incidence, risk factors, warning signs, and diagnostic process of spinal epidural abscess in the hospital setting.

CASE: A 59 year-old woman with uncontrolled diabetes mellitus and end-stage kidney disease on hemodialysis presented with altered mental status and a suprapatellar abscess. Following irrigation and debridement, her course was complicated by septic shock. She was found with high-grade methicillin-sensitive *Staphylococcus aureus* bacteremia, and her blood cultures ultimately sterilized with IV cefazolin therapy. Despite hemodynamic stabilization and resolution of leukocytosis, the patient remained stuporous. Further investigation revealed septic emboli on brain MRI as likely culprits. In the following days, her mental status gradually improved such that she could answer questions. While she had been evaluated by five different providers on weekend coverage, a new complaint of left lower extremity paralysis was only identified by the primary team. An emergent MRI of the spine revealed osteomyelitis and an epidural abscess at C5-6. Resultant cord compression and edema were also noted. The patient was urgently transferred to an affiliate hospital with the capability of neurosurgical intervention.

IMPACT/DISCUSSION: Finding *S. aureus* bacteremia in the hospital setting should provoke vigilance for its sequelae, especially in patients

with risk factors such as diabetes mellitus and kidney disease on hemodialysis. *S. aureus* infection is the most common cause of spinal epidural abscesses through hematogenous spread; however, it is still rare and easily missed with an incidence of only 0.2–2.8 per 10,000 hospital admissions. An MRI with gadolinium contrast is the most sensitive modality for epidural abscess diagnosis but unfortunately, many other clinical and laboratory findings are nonspecific if MRI is not possible. The typical symptoms of fever, back pain, and focal neurologic deficit are not always observed at presentation and are uncommonly found together. An altered mental status makes the diagnosis challenging when sensorimotor function or a review of systems cannot be reliably assessed. If the patient cannot follow commands, observation of bladder and bowel dysfunction or depressed reflexes can support a diagnosis of spinal cord injury, although non-specific for an epidural abscess. For these reasons, around half of patients with an admission for epidural abscess are initially misdiagnosed, and 4–22% of patients will suffer irreversible paralysis in part due to delays in appropriate treatment.

CONCLUSION: Patients with *S. aureus* bacteremia are at particularly high risk for morbid or fatal complications and require vigilant monitoring, even when blood cultures have sterilized. The potential for epidural abscess should not be forgotten, although diagnosis can prove elusive. In this setting, continued surveillance is imperative to assess for clinical developments, especially those undetected prior to recovery from altered mental status.

A NEW ERA OF OPIOIDS - THE RISE OF FENTANYL IN US DRUG MARKETS

Ashley Engel¹; Amy H. Farkas^{1, 2}. ¹Medical College of Wisconsin, Milwaukee, WI; ²Milwaukee VA Medical Center, Milwaukee, WI. (Control ID #3182666)

LEARNING OBJECTIVE #1: Understand the initial approach to altered mental status

LEARNING OBJECTIVE #2: Recognize the rise of fentanyl use in the United States

CASE: A 57-year-old male with a past medical history of substance abuse presented with altered mentation following a motor vehicle accident. Family reported that he had been admitted to an outside hospital one-month prior for unknown reasons. On exam the patient was oriented to person only with a blunted affect and minimal engagement. No focal neurologic deficits were noted. Initial work up including infectious, toxic, and metabolic causes of his altered mentation were unremarkable. MRI demonstrated extensive, confluent, symmetric, bilateral hyperintense T2 signal abnormalities. EEG showed a mild degree of slowing and encephalopathic changes. One week into his admission, records from the previous admission were obtained. Per those records, patient was admitted to the ICU after being found nonresponsive secondary to a fentanyl overdose with a resultant anoxic brain injury. Patient records did not reveal any fentanyl prescriptions in the past 7 years. Given his prior admission and anoxic brain injury it was felt that his mental status represented a new baseline as a consequence of his fentanyl overdose. Patient was ultimately transferred to a long-term care facility.

IMPACT/DISCUSSION: Altered mental status is a common presenting complaint in internal medicine. A thorough review of the patient's medical record can help direct work-up. Best practices suggest that all patients with altered mental status should begin with an assessment of hemodynamic stability, history of trauma, past medical and substance abuse history, and history of present illness. Work-up should progress in a stepwise fashion to include basic infectious testing, toxicology screening, head imaging, EEG, LP, and evaluation of psychiatric disorders. It is important for clinicians to recognize the clinical impact of the opiate epidemic. With nearly 70,000 overdose deaths in 2016 and 2.5 million Americans battling addiction, the rise of illicit manufactured fentanyl is an increasing public health concern. Fentanyl is the leading cause of opioid

overdose related deaths in the United States. Heroin contaminated with fentanyl is 20-40x more potent and this increased potency increases the risk of overdose. Patients who survive overdose can be left with devastating lifelong health consequences.

CONCLUSION: 1. All patients with altered mentation should be assessed for metabolic, infectious, toxic, malignant, and neurologic causes 2. Fentanyl is the leading cause of opiate overdose 3. Survivors of opiate overdose can be left with significant health consequences References: Hedegaard H, Bastian B. Drugs Most Frequently Involved in Drug Overdose Deaths: United States, 2011 - 2016. National Vital Statistics Reports. 2018; 67(9): 1-13. Xiao H, Wang Y, Xu T, Zhu H, Guo S, Wang Z, Yu X. Evaluation and Treatment of Altered Mental Status in Patients in the Emergency Department: Life in the Fast Lane. WJEM. 2012; 3(4): 270-277.

A NON-CLASSICAL PRESENTATION OF CELIAC DISEASE

Ammu T. Susheela¹; Clyde L. Smith^{1, 2}. ¹Beth Israel Deaconess Medical Center, Boston, MA; ²Brigham and Women's hospital, Boston, MA. (Control ID #3186421)

LEARNING OBJECTIVE #1: Weight loss can be an initial only symptom of celiac disease. Celiac disease can be challenging to diagnose in an atypical presentation of non-European descent patients.

CASE: A 35-year-old Ethiopian female is presented with 50 lb weight loss over 7 months after her second pregnancy. Her appetite is decreased and significantly limited by bloating. She has history abdominal pain and black stools. Past history is significant for gastroesophageal reflux disease (GERD), thyroiditis, anemia, migraine headache, vitamin D deficiency, malaria, and human papillomavirus infection. Her family history is significant for mother diagnosed with diabetes mellitus and asthma. Physical examination was normal with the soft, non-tender and non-distended abdomen. Her free T4 was 0.9, but her TSH was normal at 1.3. Liver enzymes were slightly elevated with ALT at 63, the rest of her liver function tests were normal. Peripheral smear showed anemia. Her hepatitis core antibody was positive and surface antibody was also positive indicating a previously cleared hepatitis B infection. Her ultrasound showed a hepatic cyst. She was however also tested for celiac disease and her Tissue Transglutaminase Ab, IgA was greater than 100. Her esophagogastroduodenoscopy showed chronic focally active gastritis with marked architectural abnormalities-villous shortening/crypt elongation consistent with celiac disease. Surprisingly H-pylori was negative. A diagnosis of celiac disease was made. Patient education about celiac disease was done extensively. She was given counseling about food intake and was put on a gluten-free diet with a nutrition consultation. She was advised mind-body stress reduction. She has also advised a lactose-free diet. Her condition remarkably improved on putting on following a strict gluten-free- lactose-free diet. She started gaining weight and has no gastrointestinal distress. Her GERD symptoms completely subsided and she feels she is doing very well.

IMPACT/DISCUSSION: Celiac disease may present with a wide range of clinical symptoms and signs. Non-gastrointestinal symptoms have also been reported in patients. A new term called the silent celiac disease has been used to refer for patients who do not present with diarrhea and it has been reported that the silent variant of celiac disease is more common than the patients who present with diarrhea. Patients with one autoimmune disease is more susceptible to other autoimmune diseases such as celiac disease. Currently, the only treatment for celiac disease is the gluten-free diet. In this case, it took several months to diagnose this patient with celiac disease due to the non-classical silent presentation.

CONCLUSION: The presentation of celiac disease varies within a spectrum of classical symptoms to atypical and silent variety. This makes it a challenge to diagnose the disease in atypical presentations which can significantly delay the treatment and lead to benign and malignant complications.

A PARADOXICAL TURN OF EVENTS

Jimmy Mao; Neha Nidhi; Terin Sytsma; Brody Slostad; Iftikhar Kullo. Mayo Clinic, Rochester, MN. (Control ID #3179235)

LEARNING OBJECTIVE #1: Recognize clinical and diagnostic features of paradoxical emboli (PDE) causing myocardial infarction (MI)

LEARNING OBJECTIVE #2: Manage venous thromboembolism (VTE) in the setting of malignancy

CASE: A 71-year-old female with no known coronary artery disease (CAD) and recently diagnosed unprovoked pulmonary embolism in the setting of a probable right malignant ovarian mass found on subsequent imaging, on apixaban 5 mg twice daily, presented to the emergency department with new onset chest pressure and shortness of breath. She was found to have a normal electrocardiogram (ECG) but elevated high-sensitivity troponins (340 ng/L, 2-hour at 580 ng/L, 6-hour at 1051 ng/L), loaded with aspirin 324 mg plus clopidogrel 600 mg, and started on a high-intensity heparin nomogram for a presumed recurrence of VTE vs. new MI. A repeat ECG hours later showed new ST elevations in the inferior leads, and she was taken urgently to the cardiac catheterization lab. Coronary angiogram showed no evidence of significant atherosclerotic disease but revealed a distal occlusion in the left anterior descending (LAD) artery, suggestive of embolism. A transesophageal echocardiogram (TEE) revealed a patent foramen ovale (PFO) with a small bidirectional shunt at rest. A lower extremity ultrasound showed a new acute thrombus in the right gastrocnemius vein. These findings suggested that the etiology of the patient's symptoms was an MI secondary to a PDE to the LAD artery in the setting of likely apixaban failure. She subsequently was transitioned from apixaban to enoxaparin and underwent an exploratory laparotomy and right salpingo-oophorectomy days later. Histopathology revealed high-grade carcinoma of the right ovary with mixed serous, clear cell, and mucinous differentiation and peritoneal involvement. A follow-up appointment with medical oncology was made for further staging and management.

IMPACT/DISCUSSION: PDE to the coronary arteries should be considered in patients presenting with acute coronary syndrome (ACS) in the setting of recent VTE and minimal CAD risk factors. Once suspected, a TEE should be performed to assess for a PFO. Treatment should focus on manual aspiration of the thrombus if possible and prevention of recurrence with anticoagulation. Low molecular weight heparin (LMWH) has been shown to be superior to vitamin K antagonists in preventing VTE in cancer patients. Although emerging data suggest that certain direct oral anticoagulants (DOACs) are more convenient, affordable, and as effective as LMWH, VTE recurrence in the setting of medication compliance may warrant switching to a LMWH.

CONCLUSION: Patients with known VTE and minimal CAD risk factors presenting with ACS should be assessed for PDE to the coronary arteries. Medical management involves long-term anticoagulation. LMWH is preferred over vitamin K antagonists for VTE prevention in the setting of malignancy, while comparisons between LMWH and DOACs are currently undergoing investigation.

A PATIENT BETWEEN THE CRACKS: NAVIGATING HEALTHCARE BETWEEN HOMELESSNESS AND INCARCERATION

Maria Srour; Francis G. Wade; Jennifer Schmidt. Saint Louis University, Saint Louis, MO. (Control ID #3184624)

LEARNING OBJECTIVE #1: Recognize the challenges of providing quality health care to patients within the Medicaid coverage gap.

LEARNING OBJECTIVE #2: Highlight healthcare access disparities between low income citizens in non-Medicaid expansion states and correctional facility inmates.

CASE: A 27-year-old male with Crohn's disease presented from a correctional facility with worsening enterocutaneous fistulae and abdominal wall abscesses. Prior to incarceration, the patient was homeless and uninsured with very limited access to healthcare. He was unable to afford the recommended immunomodulator therapy. Once incarcerated, he qualified for Department of Corrections healthcare coverage and sought care. Definitive treatment for his disease required surgery with temporary colostomy. Concerned about returning to prison with an ostomy bag, he opted for a biologic agent, the inferior treatment option. Treatment required complete bowel rest and total parenteral nutrition therapy, extending his admission to 107 days. Due to ongoing treatment needs, the correctional facility enacted a compassionate release, terminating his healthcare coverage and jeopardizing access to further care. Eventually, the patient was enrolled in Missouri Medicaid due to disability but not before suffering significant morbidity due to preventable complications of his Crohn's disease.

IMPACT/DISCUSSION: Medicaid expansion is a key provision of the 2010 Affordable Care Act (ACA). Medicaid was guaranteed previously only to the elderly, blind or disabled, children, pregnant women, and low-income parents or caretakers if their income falls within certain limits of the federal poverty level (FPL). Medicaid expansion ensures eligibility for all adults aged 18-65 years old with incomes up to 138% of the FPL. 19 states, including Missouri, have not implemented Medicaid expansion, leaving a coverage gap for low-income adults who do not qualify for Medicaid nor the ACA's Marketplace subsidies. It remains a challenge for non-disabled low-income adults in non-expansion states to access reliable healthcare. Meanwhile, healthcare coverage for correctional facility inmates is guaranteed by the Missouri Department of Corrections. Our patient in the Medicaid coverage gap only became eligible for healthcare coverage once deemed a criminal. Paradoxically, his incarceration led him to choose an inferior treatment for his disease. His story highlights challenges in providing quality care to vulnerable populations in states without Medicaid expansion. It also illuminates an ethical dilemma about how our healthcare system addresses both poverty and criminality.

CONCLUSION: -Access to healthcare remains a challenge for many patients within the Medicaid coverage gap of non-expansion states. -Non-disabled, low-income adults without children in non-expansion states do not share the same rights to healthcare access guaranteed to correctional facility inmates. -Policy change in non-expansion states may lead to improved outcomes in low-income patient populations by improving healthcare access.

A PATIENT WITH TWO UNCOMMON CONDITIONS: CAN THIS BE CAUSE AND EFFECT?

Justin Oveyssi; Chester Choi; Alice Park. St. Mary Medical Center, Long Beach, CA. (Control ID #3172389)

LEARNING OBJECTIVE #1: Recognize the immunological manifestations of sarcoidosis.

LEARNING OBJECTIVE #2: Understand the pathophysiology of cryoglobulinemia and glomerulonephritis.

CASE: A 53 year old male with a history of uveitis caused by sarcoidosis presented with acute kidney injury (AKI) with hypertension, proteinuria, hematuria, edema, and vasculitic skin lesions. Diagnostic testing revealed a normocytic anemia and positive rheumatoid factor (RF) and qualitative cryocrit. His complement levels were mildly decreased and his ANA, ANCA, RPR, HbsAg, HepC ab, and HIV tests were all negative. He underwent kidney biopsy showing a membranoproliferative (MPGN) pattern consistent with mixed cryoglobulinemia. Immunofluorescence microscopy showed positive staining in mesangial areas and capillary walls for IgG, IgA, IgM, C1q, C3, and both kappa and lambda light chains. Corticosteroid therapy was instituted.

IMPACT/DISCUSSION: Glomerulonephritis (GN) is an uncommon manifestation of sarcoidosis, which more often causes interstitial

granulomatous nephritis (IGN). Cryoglobulinemia has not been previously reported with sarcoidosis. However, with the exclusion of other common causes of cryoglobulinemia and GN, the pathophysiology of sarcoidosis, which leads to a broad-based hypergammaglobulinemia, and the MPGN which can be caused by mixed cryoglobulinemia raise the likelihood that these conditions are linked. The immunoglobulins that may be produced include RF (an IgM directed against IgG) and this and others may act as cryoglobulins and may be the cause of this patient's GN. In a 2013 review of glomerular diseases associated with sarcoidosis, the GN often occurred years after the diagnosis of sarcoidosis; it could, however, precede the diagnosis, and it could occur in conjunction with IGN. Establishing a unifying diagnosis may be of benefit in terms of consolidating treatment and subsequent follow up. This may be the first case of documented mixed cryoglobulinemia, glomerulonephritis, and sarcoidosis.

CONCLUSION: Sarcoidosis is an uncommon disease and Idiopathic Membranoproliferative Glomerulonephritis with Cryoglobulinemia is even more rare; the probability that they would occur in the same patient is remote if they are independent variables. If they are dependent variables, the probability would be greater and such a conjoint occurrence could be consistent in our patient given the pathophysiology of these conditions. The difference may have relevance in terms of steroid treatment which may be indicated for extrapulmonary manifestations of sarcoidosis, whereas not all patients with idiopathic cryoglobulinemic MPGN require intervention with steroids.

A PERNICIOUS MIMICKER: B12 DEFICIENCY PRESENTING AS SPLENOMEGALY, PANCYTOPENIA AND HEMOLYTIC ANEMIA

Megan K. Cochran²; Angela Thinda¹; Elieth Martinez¹. ¹UCSF Fresno, Fresno, CA; ²UCSD, La Jolla, CA. (Control ID #3184924)

LEARNING OBJECTIVE #1: Recognize the common and rare clinical manifestations of B12 deficiency

LEARNING OBJECTIVE #2: Recognize clinical features of pseudo-thrombotic angiopathy secondary to B12 deficiency

CASE: A 76 year-old man with a mechanical mitral valve replacement and atrial fibrillation (on coumadin) presented with 1 month of dyspnea on exertion and 20 pound weight loss. Exam revealed irregular rhythm, scleral icterus, and a painless 23cm spleen. Labs were notable for WBC 1.9, Hgb 4.5 (MCV 108), and PLT 62. INR was 5.9. Blood smear showed macrocytosis, schistocytes, tear drops, and hypersegmented neutrophils. The patient was transfused pRBCs/FFP and was given oral vitamin K. INR decreased to 1.5. Hemolysis labs were positive (LDH 4500, haptoglobin <30, indirect bilirubin 5.2) and Coomb's test was negative. TTE showed a normal ejection fraction with normal mitral valve function. Bone marrow biopsy demonstrated a hypercellular marrow. Serum folate was normal while vitamin B12 was low at 62. Methylmalonic acid was elevated and intrinsic factor antibody was positive. After active bleeding was ruled out, the patient was started on coumadin with heparin bridge as he was also thrombogenic due to the mechanical valve and atrial fibrillation. He was started on B12 injections (1000 mcg daily) and was discharged in stable condition. The remainder of the workup was as follows: negative MDS FISH analysis, negative ADAMSTS13/PNH assays, and no clonal abnormality on cytogenetic analysis.

IMPACT/DISCUSSION: This case highlights several important diagnostic and management challenges. First, B12 deficiency manifests as a variable spectrum of disease. Although the classic features include megaloblastic anemia and neuropsychiatric symptoms, our patient presented with rare manifestations of splenomegaly, pancytopenia, and hemolysis. Second, the patient's elevated INR, hemolysis, and schistocytes seen on presentation prompted us to consider microangiopathic hemolytic anemia that led to an extensive workup such as obtaining ADAMSTS13 assay. This phenomenon is known as pseudo-thrombotic microangiopathy, and often leads to delay in diagnosis and delivery of blood products such as

FFP as seen in our patient. Our patient's subtherapeutic INR offered the secondary challenge of balancing the risk of anticoagulating a prothrombotic patient while ruling out a bleeding diathesis. Furthermore, while a hematological process was suspected such as myelodysplastic syndrome or myelofibrosis given his age, pancytopenia, and enlarged spleen, reversible and easily treatable etiologies should not be overlooked. Our patient's low serum B12 and elevated MMA levels ultimately lead to a diagnosis of pernicious anemia that was managed with B12 injections.

CONCLUSION: B12 deficiency due to pernicious anemia can rarely present with pancytopenia, hemolysis, and splenomegaly. Diagnostic evaluation of pancytopenia should emphasize testing for reversible and easily treatable conditions including B12 deficiency

A PREEMPTIVE STRIKE AT SUSPECTED PRIMARY ALDOSTERONISM IN A MEDICALLY UNDERSERVED PATIENT

Zachary S. Pinchover; Sam Bedri; Steven Taylor. Dell Medical School at the University of Texas Austin, Austin, TX. (Control ID #3155089)

LEARNING OBJECTIVE #1: Recognize the clinical presentation of primary aldosteronism (PA) in an acute care setting.

LEARNING OBJECTIVE #2: Detail the evaluation and management of suspected PA in a medically-underserved patient.

CASE: A 29-year-old uninsured male with untreated hypertension, inadequate access to outpatient care, and frequent emergency department (ED) visits presented to the ED with a two-day history of headaches, blurry vision, chest pain, and shortness of breath. He denied muscle cramps, prescription medication use, illicit drug use, or family history of hypertension. His physical exam showed a blood pressure (BP) of 280/140 mmHg, otherwise normal vital signs, and normal cardiopulmonary and neurologic exams. Initial lab studies revealed a low serum potassium (2.2 mEq/L) and elevated serum creatinine (1.4 mg/dL). ECG and serial troponin measurements ruled out acute MI. He was diagnosed with hypertensive emergency with acute kidney injury (AKI) and treated in an ICU setting with potassium repletion and continuous esmolol and nicardipine infusions. With suspicion for PA, morning serum samples for aldosterone and plasma renin activity measurement were collected. The patient was transitioned onto maximum doses of three anti-hypertensive agents and required continued potassium repletion. Though his AKI resolved his BP remained elevated and, on hospital day #4, he voiced a desire to be discharged at a time his lab evaluation for PA was still pending. With high concern for PA, he was prescribed spironolactone with subsequent improvement in BP and serum potassium. He was discharged with follow up in a local clinic for the uninsured, and his lab evaluation later returned confirming high suspicion for PA. Confirmatory biochemical testing for PA was deferred, CT imaging showed a 2.3 cm right adrenal adenoma, and arrangements were made for right adrenalectomy.

IMPACT/DISCUSSION: PA is an often underrecognized cause of secondary hypertension that carries significant morbidity. Treatment-resistant hypertension and spontaneous hypokalemia are cardinal features in PA that should prompt a diagnostic evaluation for it. This can be costly, time-consuming, and challenging, however. Medications, hypokalemia, and AKI can result in falsely elevated or suppressed results of biochemical tests used for PA case detection. Further, consensus guidelines indicate confirmatory testing—often to include adrenal venous sampling—should be pursued for many patients for whom PA is suspected based on biochemical case detection results. A patient-centered approach to the evaluation and treatment of PA is essential for medically-underserved patients for whom high clinical suspicion for this diagnosis exists.

CONCLUSION: Empiric treatment for PA may be considered in a medically-underserved patient with high clinical suspicion for PA while awaiting the results of biochemical tests for case detection. Confirmatory biochemical tests may be deferred in the setting of high clinical suspicion for PA.

A QUANDARY OF UNRESOLVING ORBITAL CELLULITIS

PRIYANKA BHUGRA¹; Abhishek Maiti². ¹University of Texas Health Science Center at San Antonio, San Antonio, TX; ²University of Texas Health Science Center at Houston, Houston, TX. (Control ID #3187157)

LEARNING OBJECTIVE #1: IgG4-related disease is an immune-mediated condition which can mimic infectious, malignant and inflammatory disorders.

LEARNING OBJECTIVE #2: Histopathology is the key to diagnosis and timely diagnosis can prevent severe end-organ damage, disabling tissue fibrosis, and even death.

CASE: A 50-year-old woman with history of asthma presented to emergency room with progressive swelling of her left upper and lower eyelids for 4 weeks. Examination showed severe edema and redness of left eyelids. Pupils were normal. Visual acuity was 20/20 in both eyes. Fundus examination was normal. Laboratory studies were unremarkable. Computed tomogram of the orbits and sinus showed left preseptal and orbital cellulitis, chronic pansinusitis and left ethmoid osteomyelitis. Swab and tissue culture from nasal and sinus endoscopy grew methicillin-sensitive *Staphylococcus aureus*. No improvement was noted after 2 weeks of IV antibiotics. Repeat imaging showed further progression of the inflammatory changes in left orbit and ethmoid. At this point, a left caruncular orbitotomy with biopsy showed dense lympho-plasmacytic infiltrate and fibrosis. Immunohistochemistry showed diffuse IgG positivity with >100 IgG4 cells/HPF and polyclonal kappa and lambda light chains. Diagnosis of IgG4-related disease (IgG4-RD) was established and patient was started on IV methylprednisolone. Dramatic improvement was noted over next few days and she was discharged on an oral steroid taper. At 6-month follow-up, she remained asymptomatic.

IMPACT/DISCUSSION: IgG4-RD is a recently-recognized, immune-mediated condition that is characterized by fibro-inflammatory lesions rich in IgG4-positive plasma cells. It can affect one or more organs with tumefactive lesions, synchronously or metachronously. It can masquerade as a neoplastic or inflammatory condition. The pathogenesis is poorly understood but involves multiple immune-mediated mechanisms with autoimmune as well as allergic components. Tissue diagnosis is the gold standard for diagnosis. The chief pathologic features include lymphoplasmacytic infiltration and storiform pattern of fibrosis. High number of IgG4 positive plasma cells on immunostaining is the hallmark for diagnosis. This may or may not be accompanied by elevation of serum IgG4 levels. All patients with symptomatic and active IgG4-RD require treatment. Majority cases are responsive to glucocorticoids which are the first line of treatment. Disease recurrence is common. Glucocorticoid sparing agents may be used in cases of contraindication to steroids, failure of steroids, or for remission maintenance but their efficacy has not been studied.

CONCLUSION: IgG-RD has a wide spectrum of presentation with single or multi-organ involvement. Early diagnosis can help prevent serious organ damage and death as most of the cases are responsive to steroids.

A QUINKE COMPLICATION OF TRANSJUGULAR LIVER BIOPSY

Grant Pickett; Nathan C. Nowalk. Baylor College of Medicine, Houston, TX. (Control ID #3186241)

LEARNING OBJECTIVE #1: Identify hemobilia as a potential complication of trans-jugular liver biopsy

LEARNING OBJECTIVE #2: Formulate the appropriate management of hemobilia

CASE: A 56 year-old female with adult polycystic kidney disease and recurrent ascites underwent transjugular liver biopsy to evaluate for cirrhosis. Pre-procedural imaging was significant for multiple hepatic cysts, largest at 8 cm in diameter. Four core biopsies were collected with no immediate complications recognized. Following the procedure, the

patient had several episodes of large volume hematemesis. Emergent esophagogastroduodenoscopy demonstrated a large amount of blood in the stomach and duodenum without a recognized source of bleeding. Despite blood transfusions, her hemoglobin continued to fall prompting further investigation. Endoscopic retrograde cholangiopancreatography showed active bleeding from the ampulla. Interventional Radiology performed angiography with embolization of a 1cm pseudoaneurysm arising from the pancreaticoduodenal vessels. Following embolization, she demonstrated no further evidence of hemorrhage.

IMPACT/DISCUSSION: In patients undergoing liver biopsy, percutaneous liver biopsy is considered the gold standard. Contraindications to percutaneous biopsy include morbid obesity and ascites, such as seen in our patient. In these cases, a transjugular approach is considered, which some literature has reported to have comparable outcomes both for specimens and patient safety relative to a percutaneous approach. Hemobilia is a rare complication of transjugular liver biopsy with an incidence of 0.04%. Quinke's triad of hemobilia is acute gastrointestinal bleed, jaundice, and right upper quadrant pain, although the full triad is uncommon. Definitive diagnosis of hemobilia is made by visualization of bleeding from the ampulla. As seen in our patient, acute hemobilia is most commonly iatrogenic from direct injury to intrahepatic blood vessels or bile ducts during instrumentation. Angiographic intervention is the preferred method of managing active hemobilia. In one study, success rates with angiography were greater than 95%. However, this same study acknowledged that successful embolization will be dependent on the skill of the interventional radiologist.

CONCLUSION: Transjugular liver biopsy is the preferred method for patients with morbid obesity or ascites. It is important for physicians to be able to recognize post-procedural complications such as hemobilia and initiate early and appropriate management. In patients with hemobilia, first-line treatment is transcatheter arterial embolization, which has shown high rates of success.

A RARE AUTO-IMMUNE-LIKE SYNDROME ASSOCIATED WITH NIVOLUMAB THERAPY

Eugene N. Quaye. University of Oklahoma School of Community Medicine, Tulsa, OK. (Control ID #3183619)

LEARNING OBJECTIVE #1: Recognize autoimmune related adverse effects of check-point inhibitors

LEARNING OBJECTIVE #2: Treat autoimmune related adverse effects of check-point inhibitors

CASE: A 63 yo male with medical history of atrial fibrillation, hypertension, and stage III metastatic melanoma on immunotherapy with nivolumab presented for evaluation of a five day history of dyspnea with onset shortly after his second chemotherapy treatment. He also endorsed orthopnea, paroxysmal nocturnal dyspnea, diplopia which resolved upon closing the right eye, and right eye lid droop at the time of presentation. Examination was significant for tachypnea, and tachycardia with an irregular rhythm. There were no neurological deficits. Laboratory work revealed AST of 818 and ALT of 358, troponin of 13.1 and CPK of 16,493. EKG showed atrial fibrillation with rapid ventricular rate. Treatment initiated with heparin drip, aspirin and ticagrelor. Hepatic thrombus was ruled out with testing. ECHO ruled out cardiac wall abnormalities. Acute intervention for possible ACS was decided against due to possible myocarditis associated with his immunotherapy. He had positive acetyl-choline binding antibody, but anti-MUSK antibody returned negative. His troponin, CPK and transaminase levels improved after initiation of immune suppressive therapy with steroids and plasmapheresis. However, he had a decline in respiratory function necessitating intubation. He later developed GI bleeding due to biopsy proven duodenitis. His case was further complicated by varying degrees of heart block, bradycardia and ultimately hemodynamic instability. He failed to improve despite aggressive measures, ventilator support and continued steroid therapy. His

family ultimately made the decision to pursue comfort care. The rapid improvement of his troponin, CPK and transaminitis with steroids and plasmapheresis, and positive acetylcholine binding antibody supported our suspicion for autoimmune involvement as a side effect of this immunotherapy.

IMPACT/DISCUSSION: Check point inhibitors such as nivolumab act by binding PD 1 receptor with subsequent blockade of PD 1 and PD 2 ultimately causing improved antitumor response that has been beneficial in the treatment of metastatic melanoma and renal cell carcinoma. However, nivolumab has been reported to cause an autoimmune like syndrome of myocarditis, hepatitis, myasthenia gravis, endocrinopathies and pneumonitis. Our case highlights an autoimmune-like syndrome of de novo myasthenia gravis, hepatitis, duodenitis and myocarditis with each having a less than 1% occurrence. Initial therapy involves the use of glucocorticoids and immunomodulators to curb further injury to the patient. Ultimately, supportive care remains the corner stone of medical therapy.

CONCLUSION: There is an increasing number of case reports describing autoimmune syndrome associated with check point inhibitors, thus early recognition and routine follow-up is critical in improving quality of life of patients initiated on therapy.

A RARE CASE OF C. DIFFICILE ENTERITIS; A COMMON BUG IN AN UNCOMMON PLACE

Amreet K. Aujla¹; Shivaraj Patil¹; Nha Duong¹; Alexander Potashinsky².
¹UConn Health, Hartford, CT; ²UConn Health, Farmington, CT. (Control ID #3180776)

LEARNING OBJECTIVE #1: To recognize signs and symptoms of atypical Clostridium Difficile infection (CDI) in order to improve disease related mortality and morbidity

CASE: Patient is a 55-year-old male with history of Crohn's disease status post total colectomy with end ileostomy on mesalamine therapy, chronic osteomyelitis on suppressive therapy with doxycycline, ESRD on hemodialysis who presented to the emergency department with symptoms of increased ostomy output and abdominal pain for two days. Physical exam was significant for tachycardia, hypotension, and a diffusely tender abdomen. The ileostomy was viable and a small amount of fluid noted in the ostomy bag. Laboratory examination revealed a white blood cell count of 10,900 cells/mm³ and a serum lactate of 2.2 mg/dL, with negative blood cultures. Stool studies from his stoma grew C. difficile and he was treated with oral metronidazole with improvement in ostomy output. He was discharged with metronidazole to complete a 10-day course. Three months later, the patient presented with a four-day history of increasing ostomy output with watery stools and epigastric abdominal pain. Vitally, patient was hemodynamically stable and on physical examination, patient had epigastric abdominal tenderness. Laboratory examination were significant for a white blood cell count of 14,200 cells/mm³. CT abdomen and pelvis with oral contrast showed bowel thickening with minimal stranding suggestive of enteritis along with enlarged peritoneal lymph nodes. Stool studies were positive for C. difficile and lactoferrin. Patient was started on oral vancomycin and improved. He was discharged to complete a 12-week course.

IMPACT/DISCUSSION: Isolated small-bowel involvement is exceedingly rare but is more commonly seen in patients with colectomy. The diagnosis of *C. difficile* enteritis requires a high index of suspicion. As many patients may not initially raise suspicion of *C. difficile* infection, CT scan may provide supportive evidence. Ascites and fluid-filled small bowel in the presence of mild mesenteric stranding is often consistent with *C. difficile* enteritis. Analogous to colonic infection, antibiotics such as metronidazole and vancomycin are the corner stone of treatment, along with supportive therapy.

CONCLUSION: CDI is the major identifiable cause of antibiotic-associated diarrhea and is responsible for 15-25% of all cases. CDI has

increased in incidence, particularly among patients with inflammatory bowel disease. Normally manifesting as infectious colitis, small bowel involvement known as CDI enteritis is a very rare condition and is associated with a mortality rate of approximately 30%. In addition, it is also coupled with increased morbidity, length of stay, health care cost and poor quality of life. CDI involvement of the small bowel is rare, however, it appears that the incidence is increasing. High index of suspicion and early identification of *C. difficile* in the small bowel is imperative for early intervention in order to improve outcomes.

A RARE CASE OF GI BLEED ASSOCIATED WITH NEUROFIBROMATOSIS TYPE 1

Ricci Kalayanamitra¹; Jose Chu Luo¹; Zainab Shahid²; Neal Shah³; Ravi Patel³; Rohit Jain³. ¹Penn State College of Medicine, Hershey, PA; ²Lake Erie College of Osteopathic Medicine, Erie, PA; ³Penn State Milton S. Hershey Medical Center, Hershey, PA. (Control ID #3165746)

LEARNING OBJECTIVE #1: Recognize the association between neurofibromatosis type 1 and gastrointestinal stromal tumor.

CASE: A 21-year-old male with PMHx of NF1 presented with SOB, lethargy, and 1 episode of melena. He was admitted to an OSH 2 weeks prior with similar symptoms and found to be anemic due to a GI bleed. Colonoscopy and EGD were negative. He was then scheduled for an outpatient capsule endoscopy but this was not done due to his abrupt rehospitalization at said OSH, where he was found to be tachycardic and anemic with Hgb of 6g/dl. He underwent an abdominal CT, was transfused with 3 units of pRBCs, and was transferred to our institution. Patient reported continued lethargy and denied abnormal bowel movements between his 2 hospitalizations. His abdominal and rectal exams were unremarkable and skin exam revealed cafe-au-lait spots on the right arm. Hgb and t-bili were 8.5mg/dl and 2.3mg/dl, respectively. Vital signs were stable. The CT-scan from the OSH was initially reaffirmed as normal, but it was later re-examined with the patient's history of NF1 in mind. This revealed a 2.1 x 2.1 x 3.2cm well-circumscribed ovoid mass adjacent to a loop of small bowel in the left upper quadrant, which was subsequently resected, biopsied, and confirmed as a low-grade GIST.

IMPACT/DISCUSSION: The differential diagnoses of patients who present with anemia are broad. In the setting of anemia and melena, CT-scans, EGDs, and colonoscopies are often ordered. If these exams are non-revealing, patients may be subjected to repeat studies or more specialized studies, such as capsule endoscopies and push or double balloon enteroscopies. This adds a physical and financial burden to the patient and may still fail to identify the underlying etiology of their symptoms. After admitting this patient to our institution, our plan was to repeat testing with a push enteroscopy and a capsule study. We were able to avoid this course by taking a thorough history of his NF1, researching its link to GIST, and correlating this with our suspicious findings on imaging. According to the American Society of Clinical Oncology, the annual incidence of GIST is 6.8 cases per million people in the US. Of these, 5 percent of patients have a familial AD syndrome, such as NF1, familial GIST syndrome and Carney-Stratakis. In fact, patients with NF1 are 34 times more likely to develop GIST than unaffected individuals. Imatinib is an effective treatment for GIST; it has shown improvement in 54% of GIST patients within 6 months and an increase in survival of GIST patients from 18 to 57 months in a phase 2 clinical trial. Despite its rarity, providers should consider GIST in patients with a history of NF1 who present with GI symptoms, especially because there is an effective treatment for it.

CONCLUSION: -Have clinical suspicion for GIST in patients with NF1 presenting with GI symptoms. -The primary team should conduct thorough history taking and provide adequate contexts when ordering imaging. -GIST is treatable and therefore a prompt diagnosis is essential.

A RARE CASE OF GONOCOCCAL CELLULITIS IN A PATIENT WITH SEVERE SOFT TISSUE INFECTION

Marissa Fox¹; Veronica Scott¹; Patrick Pham²; Molara Alexis³; Thida Win³. ¹University of California Riverside, Riverside, CA; ²University of California Riverside School of Medicine, Riverside, CA; ³St. Bernardine's Medical Center, San Bernardino, CA. (Control ID #3184188)

LEARNING OBJECTIVE #1: Inquire about sexual history and screen at-risk individuals for sexually transmitted infections.

LEARNING OBJECTIVE #2: Assess for potential sexually transmitted infections in patients with evidence soft tissue infection with joint involvement.

CASE: A 47 year old female with diabetes presented to the Emergency Department with progressive redness, pain, and swelling of the right foot and left knee over the course of five days. She had extensive erythema and swelling on the right foot as well as left proximal calf, left knee, and left distal thigh. She also experienced pain with flexion of the left knee. On admission she was afebrile and vital signs were stable. CT scan revealed gas along the subcutaneous tissue and deep in the fascial planes of the proximal calf and distal thigh along with joint effusion. Her laboratory studies were significant for an elevated White Blood Count of 28,700. The patient was started on broad spectrum antibiotics and was evaluated by a general surgeon. She was taken to the Operating Room for incision and debridement to rule out necrotizing fasciitis. The surgeon noted extensive induration of the posterior calf and thigh with serous fluid without evidence of necrosis or purulence along the fascial planes. The debrided subcutaneous tissue from the Operating Room was sent to the laboratory for culture and returned with gram negative diplococci, that was later confirmed to be Neisseria Gonorrhea. Upon further assessment, the patient stated she was sexually active with multiple male partners and had inconsistent condom use in the past year. She was unsure of her last screening for sexually transmitted infections. She denied any symptoms of urethritis or vaginal discharge. Her urine gonococcal and chlamydia screen was negative, however, the patient had already received five days of IV Ceftriaxone which likely eliminated the infection prior to urine screening.

IMPACT/DISCUSSION: This case highlights a unique clinical finding that has scarcely been described in the literature. Given the patient's sexual history and lack of screening, she likely had an untreated gonococcal infection for an unknown period of time. We diagnosed her with severe cellulitis related to disseminated Neisseria gonorrhoea infection. This highlights the importance of adequate sexual history taking in all sexually active patients as well as screening those at-risk individuals to prevent severe and life-threatening complications of untreated infections.

CONCLUSION: Gonococcal cellulitis is an extremely rare clinical finding that has been scarcely reported in the literature. Screening at-risk individuals for sexually transmitted infections can prevent detrimental complications of untreated infection.

A RARE CASE OF INVASIVE NON-TYPHOIDAL SALMONELLA CAUSING EMPHYSEMATOUS OSTEOMYELITIS

Rohan B. Parikh; Muhammad U. Khalid; Krupa K. Solanki; Lance Blau; Munir Shah. Western Reserve Health Education, Youngstown, OH. (Control ID #3185931)

LEARNING OBJECTIVE #1: We present a rare case of emphysematous vertebral osteomyelitis due to Non-typoidal salmonella (NTS) in an immunocompetent adult. NTS commonly causes foodborne diarrheal illness but rarely causes fulminant invasive infections. There is a six fold higher risk of invasive infection with NTS when compared with other bacterial causes of gastroenteritis. There should always be a high degree of suspicion in presence of particular risk factors which would aid in reducing morbidity and mortality.

CASE: Our patient is a 51-year-old male who presented to the ED in acute distress with worsening back pain for four weeks. Associated symptoms included shortness of breath, sharp chest pain, high grade fever, and chills. His significant medical history included type II diabetes mellitus, hyperlipidemia, and peripheral vascular disease. His medications were aspirin, cilostazol, insulin glargine, losartan, and fenofibrate. He had a 30-pack year smoking history but denied any illicit drug use. He owned a mobile petting zoo and was in close contact with many animals on a daily basis. Examination revealed oxygen saturation of 84% on room air, bilaterally diminished breath sounds, and point tenderness around the first lumbar vertebra. His laboratory studies were significant for platelet count of 103, ESR of 88, sodium of 129, creatinine of 1.94, and total bilirubin of 1.7. Blood cultures were drawn. Chest x-ray showed bilateral extensive multifocal airspace opacities, and an MRI of spine showed emphysematous osteomyelitis of the L1 vertebral body with small amounts of gas in the retroperitoneum. The patient was started on supplemental oxygen, vancomycin, cefepime, and levofloxacin. Over the next two days, his oxygen requirement increased, and he eventually required non-invasive ventilation in the ICU. On day four, blood cultures grew gram negative rods which finalized to pansensitive group D salmonella. He was treated with intravenous ceftriaxone for six weeks. Neurosurgical intervention was deemed unnecessary, as there were no signs of necrosis or abscess formation on serial imaging. At three-month follow up, the patient reported complete resolution of his symptoms.

IMPACT/DISCUSSION: Extraintestinal infections of NTS species are well reported in immunocompromised patients; however, they are rare in immunocompetent patients such as ours. Invasive NTS is also associated with diabetes and atherosclerosis. Along with our patient's comorbidities, repeated exposure to animals in his petting zoo likely culminated in his extraintestinal, invasive infection. Due to disease rarity, management of emphysematous osteomyelitis can prove difficult as optimal antibiotics and the need for surgery have not yet been established. Although there has been development in the field of invasive NTS vaccines, none have shown much promise in clinical trials.

CONCLUSION: There should be an increased awareness amongst physicians to reduce morbidity associated with NTS emphysematous osteomyelitis.

A RARE CASE OF LIFE-THREATENING HYponATREMIA FROM A SWOLLEN HEART

Shaunak Mulani; Margaret C. Lo. University of Florida College of Medicine, Gainesville, FL. (Control ID #3185939)

LEARNING OBJECTIVE #1: Recognize the clinical presentation of acute hyponatremia secondary to pericardial tamponade

LEARNING OBJECTIVE #2: Identify the risk factors and disease markers for acute hyponatremia secondary to tamponade

CASE: A 76-year-old female presented with three weeks of lightheadedness, substernal, non-radiating chest pain and self-reported syncopal episodes. Medical history includes rheumatoid arthritis and GERD. Exam revealed tachypnea, hypotension, irregularly irregular rhythm and rate (140s), jugular venous distension and 1+ pitting edema in bilateral legs. EKG showed new onset atrial fibrillation with rapid ventricular rate (RVR). CBC, BMP and TSH were normal on admission. ProNT BNP was elevated at 408. CTA Chest noted a moderately sized pericardial effusion but no PE. TTE showed a newly depressed EF of 35% and a pericardial effusion but no tamponade physiology. Patient was stabilized by diuresis for CHF and metoprolol for rate control. On hospital days 4-6, she developed worsening dyspnea, increasing hypoxia, recurrent hypotension refractory to IVF and atrial fibrillation with RVR refractory to IV metoprolol and digoxin. Labs noted acute kidney injury (AKI) and acute hyponatremia worsening in 48 hours (creatinine 1.1->2.1 mg/dL, Na 136->122mEq). The hyponatremia did not respond to fluid restriction or salt tablets. Repeat TTE showed worsening pericardial effusion with tamponade physiology. Urgent pericardiocentesis removed

1200mL bloody, exudative fluid likely due to recent anticoagulation for atrial fibrillation. Within 24 hours of pericardial drainage, her clinical picture improved with rapid resolution of hyponatremia and AKI.

IMPACT/DISCUSSION: Hyponatremia is a common electrolyte abnormality often caused by medications, hormonal imbalance, liver or cardiac failure. This case adds to the limited literature of acute hyponatremia from tamponade, often overlooked as another potential cause. It teaches the dangers of anchoring and premature closure as diagnostic heuristics in the work-up of hyponatremia. Diagnostic clues include abrupt clinical deterioration and rapid progression of hyponatremia refractory to standards of therapy. Literature suggests monitoring NT-pro BNP as a marker of disease severity in tamponade. Cases are mostly in malignancy and rarely hemorrhagic from anticoagulation or nonmalignant like our case. Pathophysiology is not well-understood but likely due to inappropriate release of ADH from the low-flow state of tamponade. Prompt pericardial drainage improves systolic blood pressure, decreasing ADH production, increasing ANP production and resulting in rapid recovery of hyponatremia, as cited in most cases.

CONCLUSION: Consider tamponade in cases of unexplained hyponatremia, particularly in the setting of malignancy, existing pericardial effusion and/or hyponatremia refractory to empiric treatment. Reversal of hyponatremia after pericardial drainage is rapid and spontaneous so prompt diagnosis of tamponade is imperative and life-saving.

A RARE CASE OF RECURRENT ENDOCARDITIS DUE TO CANDIDA PARAPSILOSIS

Daniel Tsang; Misa Hyakutake; Kevin Andujar. Mount Sinai Beth Israel, Bronx, NY. (Control ID #3183552)

LEARNING OBJECTIVE #1: Recognize the importance of long-term suppressive therapy in patients with a history of fungal endocarditis.

CASE: A 51 year old man with a history of active inhaled cocaine use and former intravenous heroin use presented with dyspnea and fevers for 2 weeks. Patient denied taking any medications other than methadone. He last used cocaine 3 days ago and quit intravenous heroin use 8 years ago. Physical exam was notable for mild jugular venous distention, a 3/6 systolic murmur, 1/6 diastolic murmur, and 1+ pitting edema in his lower extremities. No skin or nail abnormalities were observed. Laboratory test showed WBC 7.6 K/UL, B-Type Natriuretic 506.2 PG/ML. Urine toxicology was positive for cocaine and methadone. Chest X-ray showed pulmonary vascular congestion and interstitial edema. Transthoracic echocardiogram and subsequent transesophageal echocardiogram showed a mobile 1 x 0.5 cm echodensity on the aortic valve and severe aortic regurgitation. All 3 sets of blood cultures that were drawn grew Candida parapsilosis. He underwent successful aortic valve replacement and completed a 3 week course of intravenous caspofungin. He was discharged with a 90 day supply of oral fluconazole and planned outpatient follow up. Approximately 4 months later, he presented again to the ED complaining of left sided abdominal pain and left chest pain. CT of the abdomen showed large areas of splenic infarctions. Transesophageal echocardiogram revealed multiple new vegetations on the bioprosthetic aortic valve with the largest measuring 3.4 cm. He underwent successful redo aortic valve replacement. Blood cultures and cultures from the aortic root vegetations again grew Candida parapsilosis and he was continued with caspofungin. Upon further questioning, patient admitted that he had not been compliant with his suppressive fluconazole, only taking it for 2 weeks. He was eventually discharged with 6 weeks of IV caspofungin, followed by planned lifelong fluconazole therapy.

IMPACT/DISCUSSION: Recurrence rates of fungal endocarditis after surgical and antifungal treatment have been estimated to be around 30-40% and occur more frequently in those who stop suppressive therapy. There have been reported cases of recurrence several years after the initial

valve replacement. Fungi have been shown to be present in replaced valves decades after placement. Given the rarity of fungal endocarditis (about 2% of all infectious endocarditis cases), there are no definitive guidelines on anti-fungal treatment duration after valve replacement. This report demonstrates a case of a rare infection and the possible effects of an abbreviated treatment course. Taking into account the high recurrence rates of fungal endocarditis, it is reasonable to consider lifelong suppressive therapy.

CONCLUSION: - There are no definitive guidelines as to treatment duration for fungal endocarditis because of its rarity. - Given the high mortality rate and high rate of recurrence, lifelong suppressive therapy should be considered for fungal endocarditis.

A RARE CASE OF RECURRENT PNEUMONIA

Belaal Sheikh; Dipesh Ludhwani. Chicago Medical School, McHenry, IL. (Control ID #3185779)

LEARNING OBJECTIVE #1: Important considerations when assessing causes of recurrent pneumonia.

CASE: A 63 year old Caucasian female presented to our hospital with a complaint of dyspnea for a few days. Her past medical history was significant for multiple sclerosis, quadriplegia and recurrent pneumonia. A month prior to presentation, the patient was discharged from the hospital on antibiotics for her third episode of aspiration pneumonia in the last 8 months. Patient had a normal bronchoscopy 6 months ago. Physical exam on admission revealed a low grade temperature with hypoxia and coarse breath sounds. Initial lab work showed an elevated leukocyte count of 15.4 and normal serum chemistry. CT chest revealed progression of bilateral chronic lower lobe infiltrates with right upper lobe infiltrates now lower in density compared to previous imaging. Patient was started on broad spectrum antibiotics and underwent bronchoscopy with Broncho-alveolar lavage and Transbronchial biopsy. Cytopathology from right upper lobe revealed reactive bronchial cells and foamy macrophages consistent with a diagnosis of Lipoid pneumonia. Careful investigation of her medication list revealed mineral oil use for chronic constipation. Mineral oil was stopped and patient was continued on supportive antibiotic therapy. Her symptoms improved and patient was discharged to a skilled nursing facility. Follow up CT scan performed outpatient revealed a complete resolution of upper lobe infiltrates and improvement in lower lobe opacities.

IMPACT/DISCUSSION: Lipoid pneumonia should be considered in all cases of recurrent pneumonia especially in patients at high risk of aspiration. Detailed history and thorough medication review are imperative in making the diagnosis. CT scan in lipoid pneumonia characteristically shows fat attenuation as low as -30HU within consolidative opacities. Presence of superimposed inflammation can confound diagnosis by increasing attenuation and obscuring fat component. Imaging with histologic confirmation is gold standard in diagnosis of lipoid pneumonia. Distinction between endogenous and exogenous pneumonia plays a big role in management of such cases. Endogenous pneumonia is commonly associated with lung malignancy. Treatment for lipoid pneumonia is supportive. Historically corticosteroids, immunoglobulins and whole lung lavage have all shown successful results.

CONCLUSION: Pneumonia remains a leading cause of mortality and morbidity worldwide. Lipoid pneumonia is a rare presentation of pneumonia seen in 1-2.5% cases. Lipoid pneumonia results from accumulation of lipid in alveoli and can either be exogenous or endogenous in nature based on the source of lipid. Mineral oil with long chain saturated hydrocarbons can induce inflammatory reaction in alveoli. These oils are phagocytosed by macrophages and coalesce to form a mass also known as paraffinoma. Successful identification and treatment of lipoid pneumonia can decrease morbidity, mortality, and unnecessary interventions for patients.

A RARE CASE OF SYSTEMIC AMYLOIDOSIS: AN UNDERDIAGNOSED DISEASE

Syeda A. Raza¹; Somtochi I. Okafor². ¹Methodist Health Systems Dallas, Dallas, TX; ²UT Southwestern Medical School, Dallas, TX. (Control ID #3185729)

LEARNING OBJECTIVE #1: Recognize primary systemic amyloidosis in elderly patients with no evidence of preceding or coexisting disease in elderly patients

LEARNING OBJECTIVE #2: Diagnose primary systemic amyloidosis based on clinical features and laboratory studies

CASE: An 81-year old man with no known past medical history presented to the hospital via emergency medical services for altered mental status. On physical exam, patient was awake but only oriented to person. He had multiple purpuric lesions around the eyelids and upper chest wall. He also had a distended abdomen with bilateral lower extremity pitting edema. Initial labs were notable for sodium of 117 mmol/L and a creatinine of 1.91 mg/dL. He was admitted to the ICU for treatment of his hyponatremia that was corrected with 3% hypertonic saline. However, patient remained volume overloaded despite aggressive diuresis. A transthoracic echo showed normal systolic function but impaired diastolic relaxation. As the patient remained volume overloaded in setting of renal dysfunction, decision was made to initiate patient on hemodialysis. A renal biopsy was obtained showing Congo red positive amyloid deposition. During the hospitalization, the patient continued to deteriorate and developed an ileus that did not improve with supportive care. A subsequent endoscopy and colonoscopy were performed to help with decompression. Gastric, colonic, and rectal biopsies that were taken showed Congo red positive amyloid deposition consistent systemic amyloidosis. At this point the patient's clinical status had not improved. Multiple family meetings were held to discuss treatment and prognosis. However, the family revealed that the patient had advanced directives in place and would not want aggressive treatment. He was transitioned to palliative care and ultimately passed away.

IMPACT/DISCUSSION: Amyloidosis constitutes a plasma cell dyscrasia and consists of a subset of various diseases to which primary systemic amyloidosis belongs. Primary systemic amyloidosis involves deposition of monoclonal immunoglobulin light chain proteins throughout the body tissues and typically occurs without existence of prior amyloid disease or concurrent chronic inflammatory conditions. Clinical manifestations often include macroglossia, mucocutaneous lesions, restrictive cardiomyopathy, kidney failure, and edema. Laboratory workup involves CBC, SPEP/UPEP, and biopsy of the affected organ to identify amyloid deposition. Treatment involves targeted therapy of affected organs as well as systemic chemotherapy. In rapidly progressive cases, in depth conversation with family regarding treatment, prognosis, and patient's wishes remain imperative to ensure effective communication and compassionate care.

CONCLUSION: Primary systemic amyloidosis may manifest as rapidly progressive systemic organ failure prompting immediate treatment. Treatment and management of primary systemic amyloidosis include a combination of targeted organ therapy and chemotherapy or palliative care depending on patient's wishes

A RARE CASE OF THROMBOTIC MICROANGIOPATHY IN THE SETTING OF SEVERE HIV/AIDS PRESENTING AS ATYPICAL HEMOLYTIC UREMIC SYNDROME

Garima Gupta. Jewish Hospital of Cincinnati, Blue ash, OH. (Control ID #3186367)

LEARNING OBJECTIVE #1: Thrombotic microangiopathy (TMA) is a clinical syndrome that can present as thrombotic thrombocytopenic purpura (TTP) or hemolytic uremic syndrome (HUS). Among these conditions, atypical HUS is now recognized to be a disease of alternative complement pathway dysregulation. TMA occurs when insults to the vascular wall of small vessels trigger formation of microvascular

thrombosis. Clinically, patients with HUS present with thrombocytopenia, microangiopathic hemolytic anemia and fever. TMA is a known but rare complication of human immunodeficiency virus (HIV) and is suspected to play a role in the pathogenesis of HIV by direct endothelial cell damage. TMA is a medical emergency and can cause significant morbidity and mortality if not promptly diagnosed.

CASE: A 65-year-old male presented with a two-week history of generalized weakness and 20-pound weight loss. He was found to have acute kidney injury as well as pancytopenia. Few schistocytes were noted on the peripheral blood smear with elevated lactate dehydrogenase and low haptoglobin. The patient underwent plasmapheresis due to concerns of atypical HUS while his ADAMTS13 level was pending, which was later noted to be within normal limits. A renal biopsy was performed which showed thrombotic microangiopathy. The patient was immunized appropriately in anticipation to start eculizumab outpatient. The patient was brought to the hospital five days later with altered mental status. He was febrile and his laboratory studies demonstrated worsening pancytopenia and acute kidney injury. He was started on eculizumab inpatient. He required urgent hemodialysis due to worsening renal function. His HIV screen was positive with a CD4 count of less than 1 and viral load elevated at 1,400,000 copy/ml. Urine histoplasma antigen and serum antibodies were noted to be positive and yeast was seen on the peripheral blood smear. Patient was treated with amphotericin B for disseminated histoplasmosis. He was started on HAART after 21 days of therapy for histoplasmosis and discharged to a long term care facility.

IMPACT/DISCUSSION: In the setting of HIV associated TMA, AIDS defining illnesses can play a significant role in accelerating the terminal outcome of this disease. Our patient initially presented with non-specific symptoms and was diagnosed with atypical HUS which was confirmed with renal biopsy. It was not known until his readmission that he was discovered to be infected with HIV complicated by disseminated histoplasmosis. He was treated promptly and aggressively once his diagnosis was confirmed, which yielded positive outcomes.

CONCLUSION: Early treatment of HIV with HAART has led to a decrease in the development of TMA. However, it remains a life threatening condition that can present as a rare complication of HIV. Eculizumab is now considered an important treatment of complement-mediated TMA, and patients with prompt diagnosis and treatment now have improved morbidity and mortality outcomes.

A RARE CAUSE OF HEADACHE

Chandralekha Ashangari¹; Waqas Hafeez¹; Anuja Kamat¹; Praveen Tumula². ¹TTUHSC, Amarillo, TX; ²Texas Oncology, Amarillo, TX. (Control ID #3181526)

LEARNING OBJECTIVE #1: Leukemia, and leukostasis, in particular, is a very uncommon etiology of headaches in the emergency department. This case highlights the importance of keeping the differential diagnosis broad, taking an adequate and detailed history, and pursuing a more thorough workup when no etiology for subacute or chronic headaches is identified.

LEARNING OBJECTIVE #2: This case also identifies hematologic malignancy as a potential cause of subacute headaches, one that may require emergent intervention.

CASE: A 56-year-old Caucasian female with a past medical history of chronic headaches presented to the emergency department with a thunderclap headache for 2 days, sudden in onset and continuous. The pain was aggravated with cough and bright light, briefly relieved with tylenol and was associated with vision disturbances. Vital signs and the physical examination were unremarkable at the time of presentation; a fundoscopic exam was normal. Laboratory studies showed a WBC count of 87100 with a neutrophilic predominance (82.7%) with significant metamyelocytes. Serum LDH was 797. Lumbar puncture was done which ruled out meningitis with an opening pressure of 30 cm H2O. Concern shifted to leukemia as the likely etiology of headache, with potentially a blast crisis causing leukostasis. Hematology/oncology were consulted. On repeat

history after laboratory studies, the patient endorsed unintentional weight loss. Peripheral smear showed multiple mature leukocytes with occasional blasts and had findings consistent with chronic CML. Bone marrow biopsy and aspirate showed hypercellular marrow with features consistent of myeloproliferative neoplasm with only 1-2% blasts. BCR-ABL test was positive. The final diagnosis of chronic phase of CML was made and the patient was recommended starting on Imatinib.

IMPACT/DISCUSSION: Gross leukocytosis and subsequent leukostasis resulted in this patient's presentation of a chronic headache with vision changes. This is an uncommon headache etiology. The clinical manifestations of leukostasis most commonly manifest within the central nervous and respiratory systems. Neurologic symptoms range from headaches, tinnitus, or dizziness, to blurry vision, confusion, and decreased mentation. Respiratory symptoms are nonspecific as well, including dyspnea, hypoxemia, tachypnea, and respiratory failure. It is also possible to have manifestations of ischemia from leukostasis, including myocardial infarction, limb ischemia, and bowel ischemia. Marked leukocytosis in CML is most commonly attributed to a blast crisis but can result from advanced chronic disease.

CONCLUSION: Headaches are common, though leukostasis secondary to malignancy is an extremely rare etiology. Overall, a thorough history of the present illness with a physical examination can help diagnose even the rarest of disorders.

A RARE COMPLICATION OF DIVERTICULITIS

Brenden S. Ingraham; Maryam Mahmood. Mayo Clinic - Rochester, Rochester, MN. (Control ID #3159402)

LEARNING OBJECTIVE #1: Pylephlebitis should be considered when there is pain inconsistent with the primary site of infection or when the pain or fever persists despite treatment.

LEARNING OBJECTIVE #2: Recognition is critical as pylephlebitis requires a prolonged duration of antibiotic therapy and sometimes systemic anticoagulation to prevent significant morbidity and mortality.

CASE: 59-year-old female with minimal medical history presented to the ED with severe left lower quadrant abdominal/pelvic pain and nausea. CT of the abdomen/pelvis showed findings of acute diverticulitis. She was admitted and managed medically with bowel rest and IV ciprofloxacin and metronidazole. She was discharged on oral antibiotics. Unfortunately, two days after discharge she returned to the ED with right upper quadrant pain and fever. Labs were notable for leukocytosis and transaminitis. CT showed portal venous gas, thrombus in the portal vein and inferior mesenteric vein (IMV), and a small abscess in the pelvis. She was initiated on IV ciprofloxacin, metronidazole, and heparin. Blood cultures grew *candida albicans* and *C. dubliniensis*, and anidulafungin was initiated. Despite antimicrobials, the pain worsened over the subsequent days with persistent fevers. She was broadened to meropenem and daptomycin. Repeat imaging showed septic thrombophlebitis, phlegmon around the IMV, and bowel ischemia without perforation. She was urgently taken to the OR for washout, colectomy, colostomy, and drain placement. Fluid collections drained intraoperatively grew *Streptococcus anginosus*, *Lactobacillus rhamnosus*, *L. paracasei*, and *C. albicans*. She was discharged on piperacillin-tazobactam IV for 3 weeks, anidulafungin for 6 weeks, and apixaban for 6 months.

IMPACT/DISCUSSION: Mesenteric pylephlebitis is suppurative thrombophlebitis of the portal vein. It is a rare diagnosis that complicates only 0.6% of intraabdominal infections. It is usually nonobstructive but can result in extension of the thrombus to the mesenteric and splenic veins, bowel ischemia, hepatic abscess, septic pulmonary emboli, and, rarely, acute portal hypertension with variceal hemorrhage. Bacteremia occurs in 44-88% of cases, and it is usually polymicrobial. The most common organisms are *E. coli*, *Bacteroides fragilis*, and streptococcus. CT with IV contrast is the best study for diagnosis and monitoring. Treatment includes 4-6 weeks of antibiotics. Anticoagulation is controversial but usually unnecessary. It may be considered if there is progression of the thrombus or persistent fevers/bacteremia. Mortality ranges between 11% and 32%.

CONCLUSION: Pylephlebitis is an exceedingly rare complication that can occur following infection of any portion of the GI tract drained by the portal system. It typically presents with right upper quadrant abdominal pain and fever in a patient with another intraabdominal infection. Recognition is critical as the infected thrombus requires a prolonged duration of antibiotic therapy and sometimes systemic anticoagulation to prevent significant morbidity and mortality.

A RARE COMPLICATION OF EPIDIDYMOORCHITIS AND MANAGEMENT

Jaepil E. Yoon²; Meghana Anugu¹; Dave R. Gupta¹; Rafael L. Jurado¹. ¹Emory, Atlanta, GA; ²Emory University School of Medicine, Atlanta, GA. (Control ID #3186331)

LEARNING OBJECTIVE #1: Recognize the clinical presentation, workup, and treatment of acute epididymoorchitis.

LEARNING OBJECTIVE #2: Identify symptoms of testicular infarction and its management options.

CASE: A 64 year old male presents with acute onset, severe, left scrotal pain. Medical history was notable for benign prostatic hypertrophy requiring intermittent catheterization and prior urinary tract infections (UTIs). He denied nausea, vomiting, fever, urinary frequency, dysuria, or hematuria. Exam revealed left scrotal tenderness and edema. Laboratories were notable for Cr 1.2, WBC 14,000, and urinalysis with WBC 36 and RBC 111. Scrotal ultrasound (US) revealed a heterogeneous left epididymis with increased vascularity. Ceftazidime was initiated for presumed UTI. Urine culture grew *Klebsiella pneumoniae*. He continued to report intermittent left scrotal pain and was diagnosed with acute epididymoorchitis. On hospital day four, he developed suprapubic tenderness. Repeat US revealed decreased echogenicity of the left testis with diminished, nearly absent vascular flow, consistent with testicular infarction. Surgical intervention was not recommended as continued fertility was not a concern and his right testis could provide adequate testosterone levels. He was treated with a two week regimen of oral Levofloxacin. Following resolution of his epididymoorchitis, urology recommended suprapubic catheter for prostatic rest and an open prostatectomy.

IMPACT/DISCUSSION: Acute epididymoorchitis (EO) is the most common cause of scrotal pain in men, accounting for 600,000 cases per year in the U.S. It presents as acute, unilateral scrotal tenderness and edema. EO is a clinical diagnosis, but Doppler US may reveal increased blood flow to an enlarged, thickened epididymis. In sexually active men aged 14 to 35 years old, *Neisseria gonorrhoea* and *Chlamydia trachomatis* are the most common pathogens. In older men, pathogens are often enteric bacteria that have migrated into the vas deferens by retrograde flow of urine due to obstruction. Most episodes of EO resolve with appropriate antibiotic treatment. However, progression to testicular infarction may occur due to inflammation in the epididymis or spermatic cord, causing compression of the arterial supply to the testicle. While there are no standard guidelines for treatment of infarction due to EO, most episodes resolve with outpatient treatment. Therefore, clinicians must be aware of rare complications like testicular infarction in the treatment of EO, given its consequences on fertility. Serial or periodic examination of testicular blood flow by US can enable early detection of infarction. Once diagnosed, treatment recommendations are not clear, but urology should be consulted for consideration of surgical decompression.

CONCLUSION: EO can progress to testicular infarction in patients with persistent symptoms despite antibiotic therapy. Serial US assessment may allow early detection of infarction. Urology should be consulted.

A RARE COMPLICATION POST-TRANSPLANT ATYPICAL HEMOLYTIC UREMIC SYNDROME (HUS)

Seda Babroudi¹; Cindy Varga². ¹Tufts Medical Center, Lincoln, MA; ²Tufts Medical Center, Boston, MA. (Control ID #3179428)

LEARNING OBJECTIVE #1: Recognize the clinical features of atypical HUS

LEARNING OBJECTIVE #2: Treat atypical HUS in a timely fashion

CASE: A 63 year-old Asian woman with a past medical history of end stage renal disease secondary to adult-onset polycystic kidney disease underwent deceased donor kidney transplant. She was initiated on tacrolimus, mycophenolate, and prednisone for immunosuppression. Post-transplant course was complicated by delayed graft function requiring dialysis, anemia, and thrombocytopenia. Laboratory studies were notable for elevated LDH, undetectable haptoglobin, and negative DAT. Peripheral smear revealed the presence of schistocytes, but ADAMTS13 was within normal limits and infectious work up was negative. Tacrolimus was discontinued without clinical improvement, so the patient was empirically started on eculizumab. The patient's renal function, anemia, and thrombocytopenia improved within 48 hours of initiation. Kidney biopsy later showed evidence of acute thrombotic microangiopathy (TMA) without rejection, and atypical HUS genetic panel was equivocal. The patient's graft function eventually recovered and she no longer needed dialysis.

IMPACT/DISCUSSION: This is a case of atypical Hemolytic Uremic Syndrome (HUS) in a post-renal transplant patient. Atypical HUS may be distinguished from classic HUS by the presence of renal failure, hemolytic anemia, and thrombocytopenia in the absence of an infectious source. TMA post-renal transplant is a complication that only occurs in approximately 0.5% patients annually, however it is associated with a 50% graft failure rate at two years and a 50% mortality rate at three years after diagnosis. Although calcineurin inhibitors have classically been implicated in the pathogenesis of atypical HUS post-transplant, calcineurin inhibitors are used commonly without incident. It has been postulated that calcineurin inhibitors, or even organ transplantation itself, act as triggers for acquired defects of the alternative complement pathway, which constitute the basis of genetic testing in suspected cases of atypical HUS. Genetic testing, however, remains neither sensitive nor specific in the diagnosis of atypical HUS. Given the risk of graft failure, it is imperative to recognize TMA syndromes early in the post-transplant course and withdraw all offending agents. If no clinical improvement is observed, and clinical suspicion of thrombotic thrombocytopenic purpura is low, empiric treatment for atypical HUS should be initiated. Eculizumab, an anti-C5 monoclonal antibody, is the treatment of choice for atypical HUS, and should be continued lifelong given the risk of graft failure and TMA syndrome recurrence.

CONCLUSION: Atypical HUS is a rare cause of post-transplant associated-TMA. Early recognition of atypical HUS is crucial to preserve donor graft function. First-line therapy for atypical HUS is the use of the monoclonal antibody eculizumab.

A RARE PRESENTATION OF CUSHING'S SYNDROME (CS): ECTOPIC ACTH SECRETION SECONDARY TO AN OLFACTORY NEUROBLASTOMA

Sumedha Chablani; Andrea Carter. University of Pittsburgh Medical Center, Pittsburgh, PA. (Control ID #3185431)

LEARNING OBJECTIVE #1: Recognize typical physical exam and laboratory findings of hypercortisolism secondary to CS

LEARNING OBJECTIVE #2: Diagnose and treat CS secondary to an ectopic ACTH secreting tumor

CASE: A 43 year-old man with a newly diagnosed olfactory neuroblastoma was admitted from home after he was noted to have hypokalemia (serum potassium level 2.1 mEq/L) on pre-operative laboratory evaluation. Admission physical examination revealed hypertension (blood pressure 162/94 mmHg), facial plethora, fat deposition in the dorsocervical area, and anasarca. Initial laboratory testing revealed significant metabolic alkalosis (blood gas pH 7.55, PaCO₂ 53 mmHg, HCO₃ 46 mEq/L) and hyperglycemia (serum glucose level 229 mg/dL). Given these findings,

CS was suspected, and further testing showed an elevated random cortisol level of 112 ug/dL and serum ACTH level of 565 pg/mL. A confirmation of CS was pursued with dexamethasone suppression testing, which failed to suppress the serum cortisol levels. Given our high suspicion of ectopic ACTH secretion, a pituitary MRI and CT of the chest, abdomen, and pelvis were performed to identify possible sources but these imaging tests failed to reveal additional masses beyond his olfactory neuroblastoma. As such, a presumptive diagnosis of CS secondary to an ACTH secreting olfactory neuroblastoma was made. Prior to tumor resection, patient's hypercortisolism was initially managed with ketoconazole and spironolactone, but he ultimately required an etomidate drip to decrease his serum cortisol levels. Patient underwent tumor resection with normalization of plasma cortisol and ACTH levels. Immunohistochemical testing is currently being performed to confirm whether the patient's olfactory neuroblastoma is positive for ACTH, and therefore the etiology of his CS.

IMPACT/DISCUSSION: CS is a rare condition of hypercortisolism, which affects approximately two to three persons per million per year. CS can result from ACTH dependent or independent causes. The most common etiology of ACTH dependent CS is pituitary hypersecretion of ACTH, followed by ectopic secretion of ACTH by non-pituitary tumors. CS secondary to an olfactory neuroblastoma is very uncommon, with less than ten cases discussed in the literature. The diagnosis of CS secondary to an olfactory neuroblastoma includes immunohistochemical staining of the tumor, as well as clinical and laboratory improvement subsequent to tumor resection. While the mainstay of treatment is tumor resection, hypercortisolism in the preoperative period may be treated with ketoconazole, spironolactone, and if not adequately controlled, an etomidate drip, as was required for our patient.

CONCLUSION: This case highlights distinguishing physical exam and laboratory features of hypercortisolism secondary to CS. This case also demonstrates the presentation, diagnosis, and treatment of a rare form of CS secondary to ACTH secretion from an olfactory neuroblastoma, while underscoring the importance of pursuing a thorough work-up of CS to evaluate for alternative etiologies.

A RARE RASH WITH A COMMON CAUSE: A CASE OF DRUG-INDUCED LINEAR IgA BULLOUS DERMATOSIS

Malik Darwish; Joseph M. Rocco; Ayako W. Fujita. University of Pittsburgh Medical Center, Pittsburgh, PA. (Control ID #3172636)

LEARNING OBJECTIVE #1: Identify Linear IgA bullous dermatosis (LABD) as a rare blistering disease that requires direct immunofluorescence to confirm the diagnosis

LEARNING OBJECTIVE #2: Recognize the most common offending agents of drug-induced LABD

CASE: A 73-year old woman with recent history of an intraabdominal infection on antibiotics presented with a blistering rash. Two months prior, she was admitted for acute pancreatitis complicated by polymicrobial peri-pancreatic abscesses, requiring drain placement and meropenem and vancomycin. After approximately one week of antibiotics, she developed an erythematous rash on her abdomen and legs with rapidly enlarging blisters. She was afebrile. Exam was notable for multiple tense bullae of various sizes filled with serous fluid on a base of tender, erythematous papules, with oral involvement. Nikolsky sign was negative. Total body surface involved was less than 20%. Skin biopsy revealed neutrophilic subepidermal blisters with linear deposits of IgA along the basement membrane zone consistent with linear IgA bullous dermatosis. Vancomycin was suspected as the most likely precipitating factor, so it was stopped. She was also started on a high-potency topical steroid. She initially continued to form new bullae and erythema, but three days after withdrawing the vancomycin, she had rapid improvement in her rash with shrinking borders, reduced erythema, and cessation of new bullae formation.

IMPACT/DISCUSSION: Linear IgA bullous dermatosis (LABD) is a rare disease, with an incidence of less than 0.5 to 2.3 cases per million

individuals per year. A classic pattern of presentation includes an acute eruption of an erythematous rash with tense bullae and mucosal involvement but negative Nikolsky sign. In the case of drug-induced LABD, onset usually begins within one month of drug initiation, and vancomycin has been identified as the offending agent in 46% of cases. Other drugs associated with LABD include lithium, captopril, and diclofenac. LABD is difficult to distinguish on exam due to its similar appearance to other blistering rashes that can present with bullae or vesicles, such as bullous pemphigoid or dermatitis herpetiformis. Therefore, skin biopsy is the gold standard. This includes both a biopsy of an entire vesicle or edge of a bullae for histology, as well as an unaffected, peri-lesional skin sample for immunofluorescence staining. Evidence of continuous linear IgA deposits along the basement membrane confirms the diagnosis. For idiopathic LABD, dapsone with high potency topical corticosteroids is first-line treatment. For drug-induced LABD, withdrawal of the offending agent leads to spontaneous resolution of the rash over several weeks, however new bullae may continue to form for a few days before improvement occurs.

CONCLUSION: Biopsy with immunofluorescence staining is necessary to diagnose and differentiate LABD from other blistering rashes. Vancomycin is the most common cause of drug-induced LABD.

A RETURN TO THE FOLD

Max Harris; Jacob Schulman; Susan B. Glick; Daniel Pohlman. Rush Medical College, Chicago, IL. (Control ID #3186157)

LEARNING OBJECTIVE #1: Recognize the importance of timely diagnosis of amyloidosis

LEARNING OBJECTIVE #2: Diagnose light chain (AL) amyloidosis based on its clinical presentation and laboratory features

CASE: A 60 yo man with AS presented with edema of the legs, hands and face x 6 wk. The edema improved with elevation. There was no shortness of breath, PND or chest pain. He consulted his cardiologist. ECHO revealed moderate AS and EF 60%. Furosemide was prescribed without improvement. PMH: Hypercholesterolemia. Medications: Metoprolol, atorvastatin, and aspirin. He worked in the entertainment industry and smoked tobacco. He appeared well. BP 99/69, HR 76, T 98.6. + Systolic ejection murmur without radiation to the carotids. No JVD. 1-2+ pitting edema 1/3 up the bilateral lower extremities. Exam was otherwise normal. Creatinine 0.92, albumin 1.5, cholesterol 465. CBC normal. UA: protein > 300 mg/dL, otherwise normal. Serum immunofix: monoclonal IgG lambda. Urine immunofix: monoclonal free lambda light chains. 24-hour urine protein 18 g. BNP 18. Troponin 0.01. Renal ultrasound, skeletal survey: normal. Bone marrow biopsy: 5% plasma cells, AL amyloid. Renal biopsy: amyloid nephropathy, AL, involving glomeruli and vessels.

IMPACT/DISCUSSION: Amyloidosis is caused by clonal plasma cells that produce amyloid, a misfolded protein that deposits in and damages tissue. Deposition may be systemic or localized; > 75% is due to AL amyloid. To prevent irreversible organ damage, prompt diagnosis and treatment are needed. The combination of macroglossia and periorbital purpura is pathognomonic for AL amyloidosis, though uncommonly seen. Cardiac deposition causes restrictive cardiomyopathy with JVD and edema. Renal involvement most often presents with heavy proteinuria due to glomerular deposition, though may present as worsening renal function without proteinuria due to vascular deposits or as tubular dysfunction due to tubular deposits. Neurologic involvement causes both peripheral and autonomic neuropathy. Soft tissue infiltration causes salivary gland enlargement and muscular pseudohypertrophy. Diagnosis requires confirmation of a monoclonal plasma cell disorder via serum and urine immunofix electrophoresis and measurement of serum free light chains. Congo red staining establishes the presence of amyloid. Demonstration of organ involvement and fibril type are also required. Treatment focuses on eradication of the plasma cell clone. Newer therapies under study target the amyloid deposits.

CONCLUSION: Prompt diagnosis and treatment of amyloidosis can prevent irreversible organ damage. Light chain amyloidosis causes restrictive cardiomyopathy (JVD, edema), nephropathy (edema, proteinuria, renal insufficiency, RTA), neuropathy (peripheral/autonomic) and soft tissue infiltration (macroglossia, muscular pseudohypertrophy). Diagnosis requires serum and urine immunofix electrophoresis and measurement of serum free light chains to confirm a monoclonal plasma cell disorder; Congo red staining to confirm amyloid; evidence of organ involvement; and fibril type.

A ROTTEN CASE OF HUS: THE EMERGING PATHOGENESIS OF SALMONELLA

Sarah Kurz; Kristin Christensen; Selen Uman. University of Pennsylvania, Philadelphia, PA. (Control ID #3185773)

LEARNING OBJECTIVE #1: Recognize the value and importance of a complete clinical history

LEARNING OBJECTIVE #2: Distinguish between forms of MAHA based on clinical and laboratory data

CASE: A previously healthy 27-year-old male presented with 1 week of nausea, vomiting, and abdominal pain, and was found to have a white blood cell count of 22 THO/uL, hemoglobin of 18.8 g/dL, a platelet count of 214 THO/uL, and a creatinine of 1.31 mg/dL. He underwent CT imaging which was notable for severe colitis from the cecum to the distal descending colon. He was started on broad-spectrum antibiotics for presumed colitis. The patient's history was remarkable for his girlfriend having similar symptoms following the consumption of eggs the couple had purchased and both eaten but her symptoms had resolved without intervention. Over the course of the next 4 days, patient developed rapidly progressive symptoms in addition to notable changes in his laboratory data, in particular thrombocytopenia with platelets of 34 THO/uL, renal failure with creatinine of 4.01 mg/dL, anemia with hemoglobin of 10.8 g/dL, and a persistent leukocytosis with white blood cell count of 19 THO/uL. Based on his clinical decline, the syndrome of microangiopathic hemolytic anemia (MAHA) was entertained. The three most common forms of MAHA are Thrombotic thrombocytopenic purpura (TTP), Hemolytic uremic syndrome (HUS), and Disseminated Intravascular Coagulation (DIC). While all have different causes, each is life threatening and characterized by the triad of small-vessel hemolytic anemia, thrombocytopenia, and renal impairment. Our patient's evaluation for the etiology of MAHA included evaluation for TTP with ADAMTS13 (activity of 55%, negative), DIC with slightly elevated fibrinogen of 463 mg/dL (low fibrinogen levels are seen in DIC), and a stool culture that was negative for EHEC O157:H7 via enzyme immune assay (EIA), but positive for salmonella via PCR testing. The patient remained in the ICU for 48 hours where he received 2 days of steroids. He received a total of 5 days of broad-spectrum antibiotics including Vancomycin, Zosyn, and Flagyl. Within the next few days, with continued fluids, his renal function improved, his WBC count downtrended and his platelets normalized. He was discharged home in good condition on Day 8.

IMPACT/DISCUSSION: This case illustrates the expanding body of clinical evidence that non-shiga toxin producing pathogens are capable of causing HUS. This growing link between non shiga-toxin producing pathogens and HUS opens opportunities for exploration of the underlying mechanisms and the potential role for novel therapies.

CONCLUSION: -A good clinical history is of high value especially when there is concern for an underlying infectious cause -Case reports indicate a sporadic association between salmonella gastroenteritis and HUS without clear etiology of pathophysiologic basis given lack of shiga-toxin production in salmonella infections

A SECOND OPINION FROM DR. GOOGLE: A FAMILY REQUESTS NON-BENEFICIAL TREATMENTS AT THE END OF LIFE

Kyle Cornell. Baystate Medical Center, Springfield, MA. (Control ID #3186416)

LEARNING OBJECTIVE #1: Recognize a family's request for non-beneficial treatment as well-intentioned advocacy for a dying loved one.

LEARNING OBJECTIVE #2: Utilize multidisciplinary family meetings to address medical questions and provide supportive outlets for continued advocacy.

CASE: An active 56-year-old female with diet-controlled hyperlipidemia presented to our hospital after an out-of-hospital cardiac arrest secondary to anterior myocardial infarction. The time from her arrest to high-quality compressions was over 10 minutes. Subsequent interventions included coronary revascularization and targeted temperature management. There was evidence of cerebral edema on imaging and she remained comatose with progressive loss of neurologic function. She was declared brain dead by day 5 of hospitalization. The patient's family including husband, 3 teenaged children and many extended relatives were present and understandably desperate for hope. After reading through various online articles, they insisted that treatment with hyperbaric oxygen be tried for their wife/mother. In response, a multidisciplinary team was convened to help explain the futility of that treatment whilst recognizing the family's efforts in providing her the best care possible.

IMPACT/DISCUSSION: Ubiquitous internet access provides the general public with an abundance of research articles which can be misconstrued without appropriate medical expertise and context. Desperate family members are particularly vulnerable to this phenomenon. Though the use of hyperbaric oxygenation in some types of brain injury is under review, there was no evidence for benefit in this case. The persistence of such requests despite a medical explanation can be challenging. The care team's approach to such cases is critical to validate advocacy, answer medical questions, and maintain family rapport. Multidisciplinary team meetings have been shown to improve quality of patient centered care. A consensus amongst involved providers is the most helpful approach to address such family concerns and ensure consistency and quality of care.

CONCLUSION: The emotional trauma of a sudden and unexpected critical illness can manifest in various forms of patient advocacy from grieving family members. Frequent requests for non-beneficial treatment are often inspired by readily available internet searches and require careful attention to acknowledge intentions while explaining futility. Multidisciplinary team meetings with the family are instrumental in responding to these concerns and creating an appropriate care plan. Direct reference to the family's specific internet resources and a unified consensus amongst the patient's providers has been found to be most helpful. Repetitive requests may indicate denial as part of the complex grieving process. Such delicate situations require a provider's best patience and understanding.

A SEVENTEEN-YEAR-OLD, IN HER FIRST TRIMESTER OF PREGNANCY, PRESENTING WITH A MYOCARDIAL INFARCTION

Amitabh Singh¹; David Evans²; Neil Evans¹; Jennifer Schmidt¹. ¹Saint Louis University, Saint Louis, MO; ²Unity Health, Searcy, AR. (Control ID #3185862)

LEARNING OBJECTIVE #1: Recognizing myocardial infarction in low risk patients

LEARNING OBJECTIVE #2: Understanding alternate mechanisms of thrombus formation in the coronary vessels

CASE: A 17-year-old female G1P0, at eight weeks gestation, presented with severe, sharp, substernal chest pain occurring at rest. The pain began

twenty minutes prior to arrival and is associated with dyspnea, diaphoresis, nausea and right arm pain and tingling. 1 Sublingual nitroglycerin relieved her pain. Vital signs were within normal limits. Initial EKG demonstrated normal sinus rhythm at 78 bpm, with a normal axis. and ST-segment elevation in leads II, III, AvF with reciprocal changes in leads V1-3. Labs showed CPK of 12 U/L, troponin I 0.01 ng/mL. Her urine drug screen was negative. Cardiac echocardiogram demonstrated hypokinesis of posterobasal and inferolateral segment of left ventricle. Subsequent coronary catheterization showed right-dominant circulation with complete occlusion of the distal circumflex artery (underwent balloon recanalization) and normal right coronary artery, left main coronary artery and the left anterior descending arteries Thirteen hours later troponin peaked at 29.83 ng/mL. She was discharged and experienced no further pregnancy complications.

IMPACT/DISCUSSION: Myocardial infarctions are the leading cause of death amongst adults. The pathophysiology is thought to be due to atherosclerotic plaque rupture. Once a plaque ruptures there is exposure to underlying endothelial tissue. The exposure to sub endothelial collagen promotes platelet aggregation. An occlusive thrombus is formed leading to a transmural infarction which may be seen on EKG as ST- segment elevations. Plaque rupture accounts for a majority of MIs however other pathophysiological mechanisms of MI exist. The differential diagnosis for non-atherosclerotic myocardial infarctions include coronary vasospasm, vasculitis, thrombi, and coronary dissection. In the pregnant population, coronary dissection is a common cause of myocardial infarction. Roth et al. suggest the rate to be at 27% of all MIs in pregnant patients. This patient did not have coronary vasospasm, vasculitis, and coronary dissection. She had developed a thrombus in the absence of any triggering mechanisms.

CONCLUSION: We present a case of a 17-year female G1P0 at eight weeks pregnancy with no clinical risk factors, who presents for evaluation of chest pain. There is concern for misdiagnosis or failure to diagnose by Internists given her lack of risk factor

A SHORT DIFFERENTIAL COMES UP SHORT IN A PATIENT WITH SHORTNESS OF BREATH

Duy Ha; Steven G. McKee. University of Arkansas for Medical Sciences, Little Rock, AR. (Control ID #3184724)

LEARNING OBJECTIVE #1: Identify premature closure as a powerful cognitive bias when addressing common respiratory symptoms

LEARNING OBJECTIVE #2: Utilize a broad differential diagnosis as a cognitive debiasing strategy

CASE: A 41-year-old male with chronic sinusitis and lung disease presented with worsening dyspnea and productive cough and internal medicine admission was requested for an exacerbation of chronic obstructive pulmonary disease (COPD). Chart review revealed two recent admissions treated as COPD flares. His chronic lung disease and episodic dyspnea began at age 29. Workup in the past included a normal alpha-1-antitrypsin level, pulmonary function tests with mid-flow-loop obstruction plus reduced diffusion capacity, and a non-diagnostic bronchial alveolar lavage (BAL). He reported night sweats, hemoptysis, and 10-pounds of weight-loss. He admitted five pack-years of smoking but quit 10 years previously. Prior to current incarceration he worked at a fertilizer factory. On examination, the patient was afebrile and thin. His respirations had a prolonged expiratory phase and polyphonic wheeze. Standard laboratory testing was unremarkable. Computed-tomography displayed central bronchiectasis. Repeat BAL cytology resulted with eosinophilia, but all other BAL tests were negative. Serum *Aspergillus fumigatus* IgE was positive (4.23 kU/L) and serum IgE was elevated (3868 kU/L). Allergic bronchopulmonary aspergillosis (ABPA) was diagnosed and his symptoms improved with itraconazole and prednisone.

IMPACT/DISCUSSION: Though dyspnea and wheeze are common complaints to internists, rare diseases lurk among the etiologies. If our initial differential diagnoses are not robust, physicians can fall prey to

premature closure and/or framing bias as likely occurred when this patient was repeatedly treated for COPD despite minimal smoking and a history of occupational hazards. ABPA is a form of hypersensitivity with airway damage triggered by *A. fumigatus* exposure. It is characterized by recurrent bouts of dyspnea, cough, and thick sputum. Wheeze, fever, and hemoptysis may occur. The diagnostic process of modern medicine still hinges on the practitioner's data gathering, hypothesis testing, and clinical reasoning. Yet, cognitive biases and flawed logic by physicians contribute to nearly one in five adverse events in healthcare. A thorough differential diagnosis is a key strategy to prevent errors, without which vital history and exam components will be overlooked and the provider will fail to consider alternative illnesses. Studies have shown that a broad differential diagnosis helps clinicians make timely, accurate diagnoses despite our limitations. As a course of habit, we find this a cost-effective method to avoid readmissions and enhance patients' quality of life.

CONCLUSION: Premature closure increases the risk of delayed or incorrect diagnoses. Establishing forced consideration of a variety of etiologies is an efficient strategy that can reduce diagnostic errors.

A SOUR CASE OF SWEET SYNDROME

Hao Chi; Lindsay Hammons. Mount Sinai Beth Israel, New York, NY. (Control ID #3182560)

LEARNING OBJECTIVE #1: Recognize clinical features that is required to establish the diagnosis of Sweet syndrome.

LEARNING OBJECTIVE #2: Understand the three subtypes of Sweet Syndrome

CASE: A 30 year-old Japanese male with no significant past medical history presented with two days of diffuse painful erythematous papules/plaques. The patient stated that the painful and pruritic papules appeared four days ago on his right knee and then spread to his upper and lower extremities, sparing his trunk, face, palms and soles. Last week, the patient recovered from a flu-like illness where he experienced achy joints, two episodes of watery, non-bloody diarrhea and a subjective fever. Twelve years ago, the patient had a similar episode of acute onset rash for which he was admitted to an outside hospital and treated for one day with an unknown medication. On exam, he was afebrile and his vital signs were stable. Physical exam was significant for diffuse, tender, raised erythematous papules/plaques 1-2 inches in diameter on the extensor surfaces of the lower extremity and extensor/flexor surfaces on bilateral upper extremities. Initial labs showed the following: ESR 84, CRP 432 and WBC 37. 8k/ μ L with 83% neutrophils. A skin biopsy was completed; histology showed atypical subcutaneous neutrophilic dermatosis. These findings, in addition to an elevated CRP/ESR, WBC count >8k/ μ L and neutrophil percentage >70%, met the diagnostic criteria for Sweet syndrome. The patient was started on IV steroids with rapid improvement of his rash.

IMPACT/DISCUSSION: Sweet syndrome (SS), also known as acute febrile neutrophilic dermatosis, is a rare inflammatory disorder characterized by fever, neutrophilia and painful, edematous, and erythematous papules, plaques, or nodules on the skin. Often seen in 30 to 60 year-olds, Sweet syndrome is most commonly associated with the following three etiologies: (1) infection, especially upper respiratory and gastrointestinal illnesses, (2) malignancies, acute myelogenous leukemia being the most prevalent, and (3) drugs, most notably after treatment with granulocyte-colony stimulating factor. About 80% of infection-associated SS cases are in women, whereas other types have no clinical gender bias. Speculated to be inflammatory in etiology, the exact pathogenesis of SS is still largely unknown. Factors theorized to contribute to the development of this disorder include hypersensitivity reactions, cytokine dysregulation, and genetic susceptibility. Genetically, it has been found that abnormalities in chromosome 3q, seen in people of Japanese descent, is linked to an increased predisposition for SS, as suggested by this clinical case.

CONCLUSION: This case highlights the importance of considering Japanese descent as a genetic risk factor for Sweet syndrome. It is also vital for the treating physician to determine the underlying cause of the disease, as early detection of malignancy is paramount.

A SPICE-Y CASE OF ANTIBIOTICS RESISTANCE

Chelsea F. Dahl; Joseph M. Rocco. University of Pittsburgh, Pittsburgh, PA. (Control ID #3185599)

LEARNING OBJECTIVE #1: Understand the clinical significance of the AmpC plasmid and know the most common bacteria that carry this gene for inducible -lactamase resistance.

LEARNING OBJECTIVE #2: Know the appropriate empiric antibiotic regimen to select when treating these organisms.

CASE: A 49-year-old man with history of alcoholic cirrhosis and chronic pancreatitis presented with obstructive pancreatitis requiring common bile duct stent placement. He was found to have a small hepatic liver abscess which was drained, and cultures grew pan-sensitive *Citrobacter freundii* complex and *Streptococcus anginosus*. His course was complicated by *S. anginosus* bacteraemia, and therefore he received 2-week course of ceftriaxone. Three weeks later, he returned with fevers, night sweats, and worsening lower back pain. Blood cultures grew *Citrobacter freundii* and sensitivities now demonstrated resistance to ceftriaxone as well as ampicillin-sulbactam, cefazolin, ceftazidime, and cefuroxime. CT imaging revealed a new lumbar discitis and epidural abscess. CRP was 5.3. He was initially started on cefepime, but after Infectious disease was consulted, he was broadened to ertapenem due to concern for inducible ampC resistance. Blood cultures cleared after two days and he received a 6-week course of ertapenem. Upon completion, his CRP downtrended to 1.2 and interval MRI imaging revealed no epidural abscess.

IMPACT/DISCUSSION: A common mnemonic for bacteria known to carry the AmpC plasmid is the "SPICE" organisms which include *Serratia*, *Pseudomonas*, indole-positive *Proteus*, *Citrobacter*, and *Enterobacter*. However, this list is not complete and others including *Acinetobacter*, *Providencia*, and *Morganella* can carry AmpC as well. AmpC -lactamases encode a cephalosporinase commonly found on the bacterial chromosome of *Enterobacteriaceae*. Production of this enzyme can be inducible only after exposure to penicillin-based antibiotics, and routine microbiologic testing is not sensitive enough to detect them. The initial drug sensitivities may report that the organism is susceptible to penicillins and cephalosporins. Additionally, AmpC -lactamases are not inhibited by -lactamase inhibitors such as clavulanic acid. However, after starting these antibiotics, repeat sensitivities will demonstrate resistance as seen in our case. Therefore, initial antibiotic selection is essential and often requires a carbapenem, especially in severe infections. Third generation cephalosporins must be avoided. Cefepime and piperacillin-tazobactam have a lower chance of inducing resistance but should be avoided when source control is lacking as demonstrated in our case.

CONCLUSION: The "SPICE" bacteria are known to carry AmpC inducible -lactamase resistance which can lead to treatment failure despite the organisms initially appearing susceptible to cephalosporins. Broad empiric therapy is required which should include a carbapenem in severe infections.

A SPONTANEOUS CASE OF ISOLATED CELIAC ARTERY DISSECTION

SAMEER PATEL; Amr Salama; Michael R. DiSalle. Unity Hospital, Rochester, NY. (Control ID #3184231)

LEARNING OBJECTIVE #1: Manage the acute and follow-up care for a patient with spontaneous isolated celiac artery dissection (SICAD)

CASE: A 59 year old non-smoking gentleman presented with a 3 day history of evolving chest pain, dysphagia and upper abdominal pain. The left lateral posterior chest pain was first described as pleuritic, non-

radiating, and stabbing in nature. The following day, the symptoms evolved into a radiating pain across the posterior chest between both shoulder blades. On presentation, he underwent a chest x-ray that was negative for any thoracic pathology, and had a negative cardiac workup (negative serial EKG's, negative troponin). Two days later, the patient presented back to the ED with unresolving abdominal pain, underwent a CT abdomen/pelvis, and was diagnosed with a focal dissection of the celiac artery with 50% of luminal narrowing. Vascular surgery recommended a non-surgical approach given the patient's hemodynamic stability. They recommended dual-antiplatelet therapy, blood pressure control, pain management, and serial abdominal examinations. The patient's symptoms improved and he was discharged with instructions to follow-up with the vascular team in the outpatient setting. He will be on dual antiplatelet therapy for 6 months, aspirin/statin for life, and will need yearly imaging follow-up.

IMPACT/DISCUSSION: SICAD is a rare diagnosis that affects primarily males (5:1) with the average age of 55 years. The etiology is usually iatrogenic or secondary to atherosclerosis, trauma, pregnancy, fibromuscular dysplasia, inflammatory or infectious diseases, or a congenital disorder of the vascular wall. SICAD usually occurs between the intima and the external elastic layer, whereas in aortic dissection, the cleavage plane is between the first and the second layer of the intima. Most patients with SICAD are asymptomatic while some patients may present with abdominal pain due to involvement of the splenic, renal or superior mesenteric arteries causing ischemia. Patients with ruptured aneurysms can present acutely with bleeding while chronic dissections can present with symptoms of intestinal angina. An extensive literature on this subject shows that for the majority of cases of SICAD, conservative management and observation is appropriate. Conservative management typically consists of blood pressure control, imaging surveillance, and lifelong antiplatelet therapy +/- a short course of anticoagulation therapy. If abdominal pain is persistent, endovascular stenting may stabilize or improve the pain, and surgical reconstruction can be done for aneurysmal degeneration. Close follow-up by surveillance imaging should be done in most cases and can be done by US to reduce radiation burden.

CONCLUSION: • SICAD is rare diagnosis with male predominance that can present with non-specific symptoms • The majority of stable patients with SICAD can be conservatively managed while surgical intervention can benefit patients with hemodynamic instability or persistent abdominal pain.

A STIFF WOMAN

FNU Srinithya¹; Saikrishna Gadde². ¹Brookwood Baptist, Birmingham, AL; ²Ochsner Medical Center, Birmingham, AL. (Control ID #3186163)

LEARNING OBJECTIVE #1: Recognize clinical features and laboratory finding of Stiff Person Syndrome (SPS)

LEARNING OBJECTIVE #2: Identify disorders associated with Stiff Person syndrome

CASE: A 37-year-old female with no significant past medical history presented with refractory stiffness and weakness. Initial symptom started 3 months ago with her right leg giving out while walking. She experienced a fall due to her symptoms, which resulted in fracture left foot. Denied similar episodes in the past. Social history and family history were unremarkable. Patient had unintentional weight loss of 15 pounds in last 4 months. Pap smear within the past year was negative. Review of systems was otherwise negative. Vital signs were within normal limits on arrival. Cardiopulmonary and abdominal exam was without abnormalities. Neurological examination revealed mild stiffness; lower extremity stiffness greater than upper extremity; no rigidity. Deep tendon reflexes were 2+; cranial nerves, sensation, cognition were all intact. Breast exam was normal. Initial laboratory findings revealed a normal complete blood count, thyroid studies, comprehensive metabolic, serum vitamin B12, urinalysis, urine drug screen, serum thiamine and autoimmune panel.

CT brain and EEG were normal. Her symptoms were attributed to psychogenic non-epileptic seizures and sertraline was initiated. She developed serotonin syndrome due to the addition of Tramadol, trazadone and flexeril to sertraline. MRI brain and pan spine revealed T2 hyperintensity within dorsal column in cervical spine and scattered foci on T2 flair within supratentorial white matter. Serum protein electrophoresis, CT chest abdomen pelvis with contrast and lumbar puncture were negative. Paraneoplastic workup revealed elevated titres for amphiphysin antibody indicative of SPS. The patient has since received IV immune globulin and methylprednisolone. Nuclear Medicine PET revealed abnormal nodes in the left axilla and a right upper lung nodule. Left axillary node biopsy was positive for Estrogen receptor carcinoma; suspicious for breast versus gynecologic malignancy.

IMPACT/DISCUSSION: This patient had profound stiffness and muscle weakness, which lead to the pursuit of testing for rheumatologic, neurologic, and paraneoplastic etiology. Stiff person syndrome (SPS) is a rare, progressive neurological syndrome. It is caused by increased muscle activity due to decreased inhibition of the central nervous system. Symptoms include extreme muscle stiffness, rigidity and painful spasms. The syndrome affects twice as many women as men. Treatment aims to control symptoms and improve mobility, involves benzodiazepines, muscle relaxants, and/or intravenous immunoglobulins.

CONCLUSION: SPS is associated most commonly with breast cancer but has been linked to Hodgkin's lymphoma and small cell cancer and autoimmune diseases like diabetes mellitus, vitiligo and pernicious anemia. Treatment aims to control symptoms and improve mobility, and may involve benzodiazepines, muscle relaxants, and/or intravenous immunoglobulins

A STROKE OF LUCK: SUPERIOR SINUS VENOSUS ATRIAL SEPTAL DEFECT DISCOVERED VIA A CRYPTOGENIC STROKE SHRUTI RAO MD, THOMAS WONG MD, ANDREW VU MD, SARA L. SWENSON MD

Shruti Rao; Thomas J. Wong; Sara L. Swenson. California Pacific Medical Center, San Francisco, CA. (Control ID #3186322)

LEARNING OBJECTIVE #1: Findings such as an abnormal P wave axis, right axis deviation, and incomplete RBBB are indicative of a superior sinus venosus ASD on EKG. Internists should be aware of these specific findings, which can prompt a TEE and accelerate the often lengthy workup of cryptogenic stroke to ultimately repair the ASD.

CASE: A 33-year-old male developed acute onset of vertigo after abruptly turning his head to the right. He then experienced pain in the right posterior neck, binocular diplopia, anisocoria, and ataxia. CTA of head and neck was negative for dissection or obvious infarct or hemorrhage, however given persistent symptoms, patient received tPA with improvement. MRI showed a paramedian thalamic and midbrain stroke. His ECG showed an abnormal P axis with right axis deviation, and incomplete RBBB indicating cardiac pathology. The decision was made to use transesophageal echocardiography instead of transthoracic echocardiography with agitated saline contrast injection to search for intra-atrial pathology. The study revealed a large sinus venosus ASD of 1.7cm, left-to-right shunting, and a Qp:Qs ratio of 2.5, raising suspicion of a paradoxical embolism. The rest of his workup for alternative stroke etiology was negative. He eventually underwent Baffle repair of PAPVR to the left atrium and ASD closure. He recovered completely with no residual deficits and remains on antiplatelet therapy with aspirin.

IMPACT/DISCUSSION: The diagnostic workup of cryptogenic strokes is often lengthy. Interestingly, a test as simple as an ECG was able to reveal the most likely cause of this patient's stroke. Findings such as an abnormal P wave axis, right axis deviation, and potential RBBB are indicative of a superior sinus venosus ASD due to intra-atrial remodeling from left to right shunt across the defect. Using the patient's ECG prompted correct selection of TEE over TTE as superior sinus venosus atrial septal defect can be missed with TTE because of its posterior

location. Presenting complications of large ASDs include right ventricular dilatation, tricuspid regurgitation, right heart failure, and pulmonary hypertension that can lead to right-to-left shunting. Indications for ASD closure include an embolic-appearing cryptogenic ischemic stroke and/or a large shunt ($Qp:Qs$ ratio > 2) without pulmonary hypertension. Although his stroke was unfortunate, timely surgical correction of his ASD will prevent him from developing the more advanced complications.

CONCLUSION: Superior sinus venosus is a rare form of ASD that can have unique presentations, including cryptogenic stroke. Providers should be aware of the findings that are highly suggestive of superior sinus venosus ASD on electrocardiography as it can aid in the timely diagnosis and management of this rare cardiac condition.

A SUBTLE PRESENTATION OF ADVANCED SMALL CELL LUNG CANCER

Sara Vidovic; Pakhadi Buddhadev. Medical College of Wisconsin, Wauwatosa, WI. (Control ID #3181473)

LEARNING OBJECTIVE #1: Recognize when to suspect ectopic Cushing's syndrome (ECS)

LEARNING OBJECTIVE #2: Distinguish ECS from other etiologies of Cushing's syndrome (CS)

CASE: A 66-year-old woman was admitted for hypokalemia (1.6 mmol/L) with associated metabolic alkalosis and hyperglycemia. She noted a few weeks of fatigue, generalized muscle weakness, and weight loss. She was a smoker and had a past medical history of chronic obstructive pulmonary disease and hypertension. Vital signs were significant for blood pressure of 197/87 mmHg. Physical examination showed skin atrophy and large bruises on the right hip. Remainder of exam was normal. Throughout admission patient was hypertensive despite increasing doses of three blood pressure medications. She was persistently hypokalemic requiring 120 mEq potassium and 150-200 mg spironolactone daily. Renin activity and aldosterone level were normal. Adrenocorticotrophic hormone (ACTH) (136.1 pg/ml), morning cortisol (99.1 ug/dl), and 24-hour urine free cortisol (11,081.1 ug) were markedly elevated as were adrenal hormones dehydroepiandrosterone-sulfate, testosterone, and androstenedione. MRI brain showed no evidence of pituitary lesion. Low dose dexamethasone suppression test was positive. CT chest, abdomen, and pelvis showed bulky necrotic mediastinal and right hilar adenopathy and possible lymphatic obstruction without discrete pulmonary mass. In the abdomen and pelvis were innumerable low-density hepatic lesions and a soft tissue nodule in the subcutaneous fat overlying the right gluteus musculature concerning for metastatic disease of unknown origin. High dose dexamethasone suppression test was positive suggesting ectopic ACTH secretion. Ultrasound-guided liver biopsy was consistent with small cell lung cancer (SCLC); salt and pepper chromatin with immunostaining positive for synaptophysin, chromogranin, and cytokeratin AE1/AE3.

IMPACT/DISCUSSION: CS occurs when the body is chronically exposed to high levels of glucocorticoids. CS can be divided into primary and secondary hypercortisolism depending on whether excess cortisol is dependent on ACTH. The differential diagnoses for secondary hypercortisolism include pituitary hypersecretion of ACTH and ectopic ACTH secretion from a neuroendocrine tumor. Ectopic ACTH secretion is responsible for 10% of all CS cases. Of these, 50% are attributed to neuroendocrine lung tumors including SCLC. Although it is well known that SCLC can secrete ACTH, only up to 5% of SCLC cases are associated with ECS. As in this case, ECS may present with electrolyte disturbances and resistant hypertension rather than classic cushingoid traits like central obesity, acne, striae, facial plethora, and enlarged supraclavicular fat pads. This makes the diagnosis of ECS easy to miss, requiring high clinical suspicion. This suspicion is warranted as ECS may be the first manifestation of malignancy and is a poor prognostic factor in SCLC.

CONCLUSION: Diagnosis of ECS requires high clinical suspicion. ECS may be the first sign of malignancy. SCLC is a common culprit of ECS

A TREATABLE MIMICKER OF METASTATIC PANCREATIC ADENOCARCINOMA

John Xie; Mazen Zaarour. Tulane University School of Medicine, New Orleans, LA. (Control ID #3184086)

LEARNING OBJECTIVE #1: Recognize the clinical features of EBV-positive DLBCL with pancreatic involvement

LEARNING OBJECTIVE #2: Differentiate prognosis of EBV-positive DLBCL with pancreatic involvement from pancreatic adenocarcinoma

CASE: A 62-year-old previously healthy man presented with a five-month history of worsening appetite, epigastric pain, and 10-lb weight loss. He had a 40-pack year smoking history. Labs revealed normal blood counts and liver enzymes, mildly elevated CA 19-9 at 49.7 (REF: <35.1 U/mL) and lactate dehydrogenase (LDH) level of 278 U/L (REF: <201 U/L), with normal CEA. Chest and abdominal CT revealed a 12 cm pancreatic mass, a 1.4 cm left upper lobe lung mass, numerous splenic lesions, two hypodense liver lesions, peritoneal carcinomatosis, and a large retroperitoneal mass. Given his clinical presentation, radiographic findings with peritoneal involvement, and elevated CA 19-9, the preliminary diagnosis was metastatic pancreatic adenocarcinoma. Surprisingly, biopsy of one of the liver lesions revealed Epstein-Barr virus (EBV)-positive diffuse large B cell lymphoma (DLBCL). Rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP) was immediately initiated, leading to an impressive clinical response with resolution of most of the patient's symptoms after just one cycle. A PET/CT after 2 cycles of treatment showed a significant decreased in size of the pancreatic and lung masses, along with resolution of the liver and spleen lesions.

IMPACT/DISCUSSION: EBV-positive DLBCL is a rare subtype of B-cell neoplasm found in immunocompetent patients usually over 50 years of age. It accounts for 8%-15% of DLBCL in the Asian population and less than 5% in the Western population. EBV-positive DLBCL is an aggressive lymphoma subtype, as roughly 80% of patients present with extra-nodal involvement, which can include the stomach, eyelid, liver, lung, female genital tract, kidney, and testis. Although EBV-positive DLBCL of the pancreas is a known entity, only one case reported with isolated pancreatic involvement was identified. Based on earlier studies, it was believed that patients with EBV-positive DLBCL had a worse clinical course and survival compared to EBV-negative cases, especially in the Asian populations. However, recent data suggests that EBV positivity does not affect survival in North American patients with DLBCL. Median overall survival was 129 vs. 143 months for the EBV-positive and negative groups, respectively. Although there is no uniformly accepted treatment for EBV-positive DLBCL, the standard treatment for DLBCL is R-CHOP and recent studies suggest a better prognosis than originally believed, especially for North American patients with EBV-positive DLBCL.

CONCLUSION: Given the limited treatment options associated with metastatic pancreatic adenocarcinoma, tissue diagnosis is critical as alternative underlying pathology such as EBV associated DLBCL have a better prognosis with an appropriate chemotherapy regimen.

A TWISTED CASE OF JAUNDICE

Hung Hoang; Tara Norris. Methodist Dallas Medical Center, Dallas, TX. (Control ID #3180005)

LEARNING OBJECTIVE #1: Diaphragmatic hernia (DH) causing obstructive jaundice in the elderly is extremely rare, but it can occur.

LEARNING OBJECTIVE #2: This condition can be managed surgically or non-surgically.

CASE: A 71-year-old woman presented to the hospital after her granddaughter noticed two days of worsening jaundice. The patient reported a one-week history of fatigue, early satiety, poor appetite, nausea, and vomiting. She also noted having tea-colored urine and a 30-pound unintentional weight loss during the previous eight months. She denied history

of trauma, recent surgery, abdominal pain, fever, or chills. Upon admission, the patient was noted to be diffusely jaundiced over her entire body. Her liver function tests were elevated, and abdominal ultrasound demonstrated a mildly dilated common bile duct at 8mm, as well as intrahepatic ductal dilation. Magnetic resonance cholangiopancreatography (MRCP) demonstrated stomach, pancreas, small bowel and most of the colon to be above the diaphragm with abnormal orientation of the extrahepatic bile ducts extending superiorly to the duodenum located in the thorax. Computed tomography (CT) of thorax, abdomen, and pelvis revealed a large diaphragmatic hernia, and it confirmed presence of pancreas, small bowel, and colon in the thorax. Surgical repair of the defect was considered, however, due to the patient's poor functional status, the risks of surgery were determined to outweigh the benefits. Biliary decompression with stent placement was performed instead. This was accomplished percutaneously, as her anatomy was not amenable to an endoscopic approach. She tolerated the procedure well, and her jaundice and transaminitis subsequently resolved. Plan was made for stent replacement as needed for recurrence of jaundice.

IMPACT/DISCUSSION: DH can be congenital or traumatic. The vast majority of congenital diaphragmatic hernias (CHD) present in infancy or childhood and occur at a rate of less than 5 per 10,000 live births. The incidence of CDH found incidentally on CT in adults is 0.17%, but the incidence of CHD leading to clinical presentation has not been reported. While several case reports of congenital DH causing obstructive jaundice can be found in the pediatric literature, only two published cases could be located describing this phenomenon in adults. One case was reported in a 19-year-old female and the other was reported in a 64-year-old female. Our patient reported no history of trauma therefore, her diaphragmatic hernia was presumed to be congenital. The treatment of choice is surgical correction of the hernia to decompress biliary obstruction while preventing bowel obstruction or ischemia and lung injuries.

CONCLUSION: Painless jaundice with early satiety and weight loss can be caused by compression of the common bile duct from a complication of a diaphragmatic hernia. Newly discovered anatomic anomalies are rare in elderly patients, but nonetheless should be considered by clinicians in the differential diagnoses when evaluating patients with jaundice.

A UNIQUE CASE OF MIXED AUTOIMMUNE WARM AND COLD HEMOLYTIC ANEMIA WITH EXTRAVASCULAR HEMOLYSIS LEADING TO CONJUGATED HYPERBILIRUBINEMIA

Shaheen Fatima; Adetoun Adeyemi; Eric Chang; Pooja Padigala; Muhammad Bilal; Balsam Elhammali; Nicolas Bakinde. Morehouse School Of Medicine, Atlanta, GA. (Control ID #3186576)

LEARNING OBJECTIVE #1: Recognize the unique features of mixed autoimmune hemolytic anemia

LEARNING OBJECTIVE #2: Assess the need of involvement of multidisciplinary team for management of mixed autoimmune hemolytic anemia

CASE: 25 year-old-female presented with fatigue, diffuse body pain, nausea/vomiting, fever for the past two days. History was significant for iron-deficiency-anemia. Labs revealed hemoglobin/hematocrit of 4.4/13.6, mean-corpuscular-volume: 107, elevated reticulocytes-count, total-bilirubin: 26.7, direct-bilirubin: 21.9, leukocyte-count: 6.3 with neutrophilic predominance, lactate-dehydrogenase: 193, haptoglobin in normal range, elevated d-dimer/fibrinogen/NR (1.6)/procalcitonin, peripheral smear showed macrocytes and toxic granulation. Coombs-auto-antibody test for both warm and cold was positive, direct-anti-globulin testing (DAT) was positive. HIV screening test, rheumatoid-factor and parvovirus-panel were negative. Hb phenotype was not consistent with sickle cell/thalassemia. Hematology was consulted and 6 units of pRBC were transfused with a poor response, she then received IVIG (3 doses), epoetin-alfa, folic acid, bortezomib and high dose steroids with improvement in blood counts and hemolysis. Gastroenterology was consulted due

to conjugated-hyperbilirubinemia and recommended abdominal imaging. CT-abdomen showed no evidence of biliary obstruction/cholecystitis, showed splenomegaly. US-abdomen was negative. CT-chest revealed mildly enlarged right axillary lymph node. Lymph node biopsy was negative for malignancy, flow cytometry had no evidence of clonal process. EBV qualitative PCR and EBV IgG were positive but IgM negative indicating likely past infection, hepatitis panel was negative, Mycoplasma IgM was negative. Positive ANA IFA of 1:80 (with negative ANA screen) which was assessed to be secondary to IV immunoglobulin. She improved throughout the hospital course, hemolysis resolved, hematocrit and hemoglobin (10.3/31.6) and was discharged with prednisone taper and hematology follow up.

IMPACT/DISCUSSION: This unique presentation of mixed-hemolytic-anemia with conjugated-hyperbilirubinemia points towards similarity of mixed hemolytic anemia to warm-autoimmune-hemolytic-anemia (wAIHA) than cold-hemolytic-anemia (cAIHA). The importance of recognizing this is directly proportional to patient's clinical outcome as treatment for wAIHA is different from cAIHA. Although intravascular hemolysis is 10-fold greater than extravascular hemolysis, the slowed response to blood transfusion, no signs of hemolysis on the peripheral smear and conjugated hyperbilirubinemia should shift the focus to extravascular hemolysis. Early involvement of hematology and gastroenterology is crucial in such cases.

CONCLUSION: Only 7-8% of all AIHAs show a DAT positive for IgG and C3d, with the coexistence of warm autoantibodies and high-titer cold agglutinins (mixed AIHA). Further investigation is needed to delineate mixed type AIHA from wAIHA in terms of pathophysiology to better understand and treat this condition effectively.

A UNIQUE CASE OF SPOROTRICHOID-LIKE SPREAD OF AN OPPORTUNISTIC INFECTIOUS ORGANISM

Jodi-Anne Wallace; Hila Miskin; Anthony Cannella; Omar Taha. University of Florida, Gainesville, FL. (Control ID #3148667)

LEARNING OBJECTIVE #1: Recognize and manage severe cutaneous *Mycobacterium chelonae* infection

CASE: A 57 year-old woman with lupus nephritis and subsequent renal transplant failure on immune suppression was admitted for right forearm cellulitis. She noticed yellow exudate near her right thumbnail that spread to erythema of her hand and antecubital, one month prior to presentation. She was evaluated by several clinicians and finally a dermatologist who prescribed clindamycin, cephalaxin and trimethoprim-sulfamethoxazole respectively. Dermatology also performed a biopsy with bacteria culture. Painful nodules began to spread up her forearm, and she presented to this hospital. She was immediately started on vancomycin. Infectious disease was consulted, who discovered she was an avid gardener and requested repeat biopsy adding AFB and fungal cultures. The first biopsy demonstrated filamentous Gram-positive organisms thought to be *Nocardia*. As a result, she was started on amikacin and trimethoprim-sulfamethoxazole. However five days later, the AFB culture of the repeat biopsy grew *M. chelonae*. Trimethoprim-sulfamethoxazole was exchanged for moxifloxacin and clarithromycin. Treatment was complicated by major side effects including QT prolongation. The regimen was adjusted with combinations of tobramycin, tigecycline, and imipenem/cilastatin. Unfortunately, control of the infection was not achieved and she expired.

IMPACT/DISCUSSION: This case adds to the few reports of severe cutaneous *M. chelonae* in an immunocompromised patient. It reinforces the importance of having opportunistic infectious organisms high on the differential when immunocompromised individuals present with chronic cellulitis.

CONCLUSION: *M. chelonae* is a rapidly growing species of nontuberculosis mycobacteria found in water and soil. Disseminated cutaneous *M. chelonae* manifests as abscesses or violaceous subcutaneous nodules. A sporotrichoid pattern in *M. chelonae* infections is not

commonly seen. Diagnosis is often difficult as it involves differentiating *Nocardia* and nontuberculous mycobacteria. However, a specific diagnosis is needed as rapidly growing mycobacterium are usually notoriously difficult to treat. Treatment of *M. chelonae* is based on susceptibility patterns and involves use of antibacterial drugs including amikacin, tobramycin, clarithromycin, or moxifloxacin. In the setting of soft tissue infections, oral antibiotic therapy with two agents is recommended for at least 4 months. Treatment for severe cutaneous infections includes parenteral therapy with two different antibiotics until there is evidence of clinical improvement (usually 2-6 weeks) followed by 2 oral agents for at least 6-12 months. In this case of *M. chelonae* infection, it took time to isolate the correct bacteria, which delayed treatment. Also, prior medication exposures encouraged resistance, limiting treatment options. Ultimately, her gardening hobby mandated an expansion of the differential diagnosis to include *Nocardia* and nontuberculous mycobacteria.

A WALK TO NOT REMEMBER

Marcelle Tuttle¹; Laura K. Snydman². ¹Tufts University School of Medicine, Somerville, MA; ²Tufts Medical Center, Boston, MA. (Control ID #3184167)

LEARNING OBJECTIVE #1: Recognize the presentation of Henoch-Schonlein Purpura and the heterogeneity of its presentation/severity.

LEARNING OBJECTIVE #2: Recognize the pitfalls of anchoring bias.

CASE: A 61-year-old man with PMH significant for pre-diabetes presented to the emergency department with one week of arthralgias, night sweats, abdominal pain and constipation. He stated that these symptoms started several days after he went for a walk in the woods of New England and he noticed "tick bites" on his ankles bilaterally. Doxycycline was initiated for presumed tick-borne infection and he was discharged home. One day later, he represented to the ED as the rash had spread up to his thighs. A biopsy was taken at that time and he was again sent home. One week later, he returned to the ED with chest pressure and continued abdominal pain/constipation. CT demonstrated marked mural thickening of the duodenum and proximal jejunum consistent with enteritis and he was transferred to a tertiary care hospital. Labs on transfer were notable for CRP 104 and a serum IgA of 381. He was started on solumedrol and Toradol for pain. Subsequently, immunofluorescence was performed on the biopsy sample and demonstrated Henoch Schonlein Purpura (HSP). He remained in the hospital for 12 days as his enteritis continued to cause him extreme pain requiring patient-controlled anesthesia. During this time he developed significant proteinuria with a protein to creatinine ratio of 8134 mg/g at its peak. At followup 4 months later he still had significant proteinuria which was treated with prednisone.

IMPACT/DISCUSSION: This case demonstrates the danger of anchoring bias. This cognitive error occurs when a clinician mistakenly latches onto a piece of information not relevant to a diagnosis. In this case, the walk in the woods and the patient's misinterpretation of his purpura as tick bites caused the clinician to assume that this was a tick-borne infection. However, his clinical picture did not fit with this diagnosis. Lyme can cause rash and arthralgias but does not usually cause abdominal pain or constipation. Rocky Mountain Spotted Fever could also be a consideration but is not generally found in New England. HSP typically presents in children less than 10 years old with palpable purpura, abdominal pain and arthritis. Renal involvement, including hematuria and proteinuria can also occur and is more commonly found in older children and adults. While most cases are self-limited, our patient required significant pain control as well as a course of steroids. The rate of recurrence of HSP is high, up to 40% in one year.

CONCLUSION: HSP is an uncommon disease in adults that presents with palpable purpura, abdominal pain and arthritis. Anchoring bias can occur when a clinician mistakenly believes a piece of information is of great importance.

A YOUNG WOMAN PRESENTING WITH PANCYTOPENIA AND ISCHEMIC STROKE

Michelle Lam. University of Washington, Seattle, WA. (Control ID #3147866)

LEARNING OBJECTIVE #1: Diagnose acute leukemia in a patient presenting with pancytopenia

LEARNING OBJECTIVE #2: Manage acute promyelocytic leukemia in setting of coagulopathy

CASE: A 33 year old woman with history of hypertension initially presented with 5 days of nausea and abdominal pain and 1 day of new-onset confusion. She takes no medications, lives with her parents, and has no history of any tobacco, alcohol or drug use. Brain MRI showed multiple right-sided cerebellar infarcts. She was found to be hypertensive to 200s/100s, lethargic and afebrile, with pancytopenia with WBC of 1.9, hemoglobin of 10.5, platelets of 44 and elevated LDH at 437. She had normal creatinine and LFTs. ESR, complement, and ANCA testing were negative. Plasma exchange was initiated due to concern for atypical HUS/TTP, however this was discontinued after no improvement in her symptoms. Initial transthoracic echocardiogram (TTE) imaging was negative for any vegetations and blood cultures were negative. She had hypofibrinogenemia (<60) despite receiving multiple units of cryoprecipitate. She was transferred to a tertiary medical center and peripheral blood smear and bone marrow biopsy showed hypercellularity consistent with acute promyelocytic leukemia (APL). She was initiated on all-trans retinoic acid (ATRA) and arsenic treatment and was given repeated cryoprecipitate and platelet transfusions. Although initially alert with word-finding difficulties, she became more somnolent with withdrawal to pain only in her right upper extremity and later became obtunded, requiring intubation for airway protection. Repeat MRI imaging showed ongoing ischemic infarcts, including basilar artery occlusion. A repeat TTE showed a large aortic valve vegetation, with negative blood cultures. Despite concern for disseminated intravascular coagulation (DIC) and bleeding, given her ongoing cerebral infarcts, a heparin drip was initiated. Nevertheless, her infarcts progressed and due to poor long-term prognosis including blindness, inability to speak and hemiplegia, she was transitioned to comfort care after discussion with her parents and later died from complications related to APL.

IMPACT/DISCUSSION: Acute promyelocytic leukemia frequently presents with pancytopenia and coagulopathy including DIC. While bleeding from a coagulopathy is the most common presentation of APL, prothrombotic states are also seen in APL, with case reports showing acute myocardial infarction and ischemic stroke. ATRA is the main treatment for APL and can be curative, though it has been implicated in potentially worsening the prothrombotic state. In this case, the risks and benefits of treating DIC and avoiding bleeding complications had to be weighed with treating her ongoing thrombotic strokes.

CONCLUSION: A peripheral blood smear should always be reviewed in patients presenting with pancytopenia. Bleeding coagulopathies and thrombotic events are common presentations of APL. ATRA is the main treatment of acute promyelocytic leukemia and can be curative, though can contribute to prothrombotic states.

A ZEBRA OF ADRENAL INSUFFICIENCY, WHAT WAS ONCE COMMON-NOW RARE

Sean J. Godfrey¹; Victoria Hudspeth²; Kelli Dunn². ¹Atrium Health, Morganton, NC; ²Atrium Health, Charlotte, NC. (Control ID #3186373)

LEARNING OBJECTIVE #1: Recognize atypical causes of persistent hypotension.

CASE: A 62 year old woman with a history of CKD, hyperlipidemia, and possible heart failure presented to the hospital with a 3 week history of worsening right knee pain. She was initially hypotensive at 68/48. Her

hospital course was complicated by renal failure, persistent hypotension, and hyponatremia. She received approximately 5 liters of fluid with no significant hemodynamic response. Initial labs showed sodium of 125 with normal range 135-145 and a creatinine of 3.63 with sodium levels hovering in the low 130's throughout the next 8 days while systolic pressure remained less than 110. Endocrinology was consulted to evaluate the ongoing hypotension and hyponatremia 5 days into admission. Infectious disease was also consulted after it was later revealed that the patient had a history of TB with a positive ppd in 2014, treated with Isoniazid but she was unable to confidently state whether she completed treatment. Other lab work was remarkable for a positive ppd test, negative HIV, and random cortisol levels of 1.3 and 1.1. Cosyntropin stimulation test was very abnormal with cortisol results of 1.3 and 1.1 at 30 and 60 minute intervals (normal >18). ACTH on day 6 of admission was greater than 2000, consistent with primary adrenal insufficiency. Abdominal CT without contrast on day 11 showed adrenal fullness with nodal calcifications consistent with post-infectious TB. Blood pressure and sodium improved on hydrocortisone 50 mg three times daily. She was discharged on hydrocortisone 20mg in the AM and 10mg in the PM, fludrocortisone 0.1mg daily and the 4 drug combo for TB; Rifampin, Isoniazid, Pyrazinamide, and Ethambutol.

IMPACT/DISCUSSION: While TB was once a common cause of primary adrenal insufficiency, it is now most often autoimmune in the developed world, but there are rarely observed infectious causes, including TB, Fungal, and CMV. The extra-adrenal manifestations typically stem from pulmonary TB. When TB invades the adrenals, imaging of the adrenal glands initially shows hypertrophy, which progresses to fibrosis and calcification in almost half the cases. This adrenal hypertrophy is often a key marker for differentiating tuberculous adrenal insufficiency from autoimmune adrenalitis, in which case adrenals are usually atrophied. This case of primary adrenal insufficiency highlights an atypical cause that is now rare in the developed world. TB causes adrenal destruction in a gradual manner, targeting the medulla and cortex secondarily as illustrated here by this HIV-negative latent TB patient.

CONCLUSION: Tuberculous adrenal insufficiency typically presents in an insidious manner. This case demonstrates the importance of a thorough history and evaluation especially in a patient with persistent hypotension. Another key point is the importance of realizing that not all primary adrenal insufficiency is autoimmune.

ABRUPT WORSENING OF DIABETES CONTROL ASSOCIATED WITH NEW DIAGNOSIS OF ENDOMETRIAL ADENOCARCINOMA, WITH RETURN TO BASELINE FOLLOWING CURATIVE SURGERY

Michael Goulet¹; Zehra Hussain². ¹Christiana Care, Newark, DE; ²Christiana Care, Wilmington, DE. (Control ID #3184521)

LEARNING OBJECTIVE #1: Recognize malignancy in the differential diagnosis of a patient with abrupt worsening of diabetes or new-onset diabetes

CASE: A 72 year old female with diabetes mellitus presented to the primary care office in January 2017 for diabetes follow up and with complaint of vaginal bleeding. Her diabetes had been well controlled for the past 12 years on metformin and basal insulin, but at this visit her A1c had increased to 8.7%. The patient endorsed occasional dietary nonadherence but denied any lifestyle nonadherence, infectious symptoms, steroid use, or new medications. She was advised to follow a strict diabetic diet and monitor her blood sugars closely. For her postmenopausal bleeding, gynecologic workup over the next 2 months revealed a diagnosis of grade 2 endometrial carcinoma. She was scheduled for hysterectomy with bilateral salpingo-oophorectomy and staging. Over this time period, she reported persistent elevated blood sugars to the 300s-400s despite several increases in her basal insulin and the addition of mealtime insulin. Her pre-operative A1c increased to >15%. The surgical team initially hoped for improved glycemic control, but decided to proceed with surgery given the risks of delay. The patient noted improved

blood sugars within days after her hysterectomy. A1c returned to 6.3% within 3 months and remained stable as her insulin was titrated down. As of January 2019 her diabetes is well controlled on metformin alone. Pathology had indicated stage 1 disease, and she remains cancer-free.

IMPACT/DISCUSSION: Our patient had a long standing history of well controlled diabetes with a clear worsening associated with a new diagnosis of endometrial cancer, and without any other known variables to explain the deterioration. Her blood sugars returned to baseline immediately following curative surgery, indicating that hyperglycemia was likely caused by her malignancy. Hyperglycemia is known to be a risk factor for the development of endometrial cancer, but to our knowledge hyperglycemia as a consequence of endometrial cancer has not been previously reported. Pancreatic malignancy is the only cancer that is known to induce insulin resistance and diabetes, and screening strategies have been suggested for older patients with new-onset diabetes. The mechanism is thought to be through hormonal mediators produced by pancreatic tumor cells. Adrenomedullin is one hormone that has been implicated in this paraneoplastic process. This hormone has also been shown to play a role in endometrial cancer, allowing for the possibility of an overlapping mechanism in endometrial cancer.

CONCLUSION: This case highlights the importance of taking a careful malignancy-focused history and physical in patients presenting with new or abruptly uncontrolled diabetes. Hyperglycemia has previously been described as an early sign of pancreatic cancer, and our case suggests it may be a sign of endometrial cancer as well.

ABSENT TESTIS IN AN IMMIGRANT PATIENT

Vishnu Manoranjan¹; David Feldstein²; Linda Baier³; Brian Lewis⁴.

¹University of Wisconsin Hospital and Clinics, Madison, WI; ²University of Wisconsin School of Medicine and Public Health, Madison, WI; ³f Medicine and Public Health, Madison, WI; ⁴University of Wisconsin, Middleton, WI. (Control ID #3186199)

LEARNING OBJECTIVE #1: Describe reasons for and possible contraindications to starting testosterone therapy in a hypogonadal male.

LEARNING OBJECTIVE #2: Recognize the effects of social uncertainty on immigrant patients.

CASE: A 32 year-old male presents to establish care. His chief complaint is insomnia. He has difficulty falling asleep and is kept awake by racing thoughts. He and his wife are from Iran and he worries about their future in the US. He also mentions that he cannot feel his right testis. He thinks it was removed in his youth, but is unaware of the details. He also reports decreased energy and mood. Physical exam is unremarkable except for a lack of palpable testis on the right; left is present; no surgical scar. He is started on sertraline for anxiety. MRI shows absent right testis without evidence of undescended testis or previous procedure and an atrophic left testis. Testosterone levels are low and semen analysis shows azoospermia. At 6-week follow-up, sleep has greatly improved. Urology performs further evaluation and recommends karyotype testing and testosterone supplementation. Patient declines further testing and therapy, citing costs and uncertainty about future residence.

IMPACT/DISCUSSION: Endocrine Society guidelines recommend testosterone therapy in primary hypogonadism to induce secondary sex characteristics and to correct symptoms such as sleep disturbance, depression, and decreased energy, which were seen in this case. Other, more suggestive symptoms include erectile dysfunction, low libido, and low-trauma fracture. Guidelines caution against testosterone use in patients who desire fertility in 6-12 months due to suppression of spermatogenesis. Caution is also advised in those with elevated hematocrit, thrombophilia, severe sleep apnea, severe lower urinary tract symptoms, uncontrolled heart failure, prostate cancer (or increased risk), or recent myocardial infarction. This case made me aware of the adverse effects of testosterone therapy, especially the negative effect on fertility, which I will now consider prior to prescribing. This case also highlights the de-stabilizing

effects of uncertainty on immigrants. Grace et al. (2018) call this the "violence of uncertainty." Immigration is an inherently high-stress event; thus, anxiety, depression, and post-traumatic stress disorder may occur. Shifting immigration policies affect whether and how immigrants seek care. Those worried about finances or resident status may be less likely to follow-up or pursue long-term treatment. This case made me aware of the psychological and socio-political factors that may impact care.

CONCLUSION: Testosterone can correct hypogonadism symptoms and induce and maintain secondary sexual characteristics, but is contraindicated in those who desire fertility in the near term. Immigrant patients are often subject to social uncertainty, which can manifest as mental health disorders and difficulty with seeking and maintaining care.

ACANTHAMOEBA ENCEPHALITIS IN HIV-INFECTED MALE PRESENTING WITH HEADACHE AND TONIC-CLONIC SEIZURES: A CASE REPORT

Abigail C. Watts; Nonglin Mel. Emory University School of Medicine, Atlanta, GA. (Control ID #3165946)

LEARNING OBJECTIVE #1: Recognize the radiographic and pathologic features of Acanthamoeba encephalitis

LEARNING OBJECTIVE #2: Formulate a differential diagnosis for space-occupying brain lesions in immunocompromised patients

CASE: A 27-year-old man with Acquired Immune Deficiency Syndrome (with a CD4+ cell count of 5 cells/mm³) presented with tonic-clonic seizures and headache. Physical exam on admission did not reveal focal neurological deficits. Laboratory studies showed a WBC of 4.6 K/mcL (12.7% eosinophils). Magnetic resonance imaging (MRI) demonstrated a right frontoparietal peripherally enhancing lesion with mild surrounding edema and associated mass effect. Cerebrospinal fluid studies demonstrated neutrophil-predominant pleocytosis (WBC 147/mcL with 50% neutrophils) with normal protein and glucose. Broad-spectrum therapy for potential bacterial, viral, and fungal infections was initiated; nonetheless, the patient developed increasing somnolence and new focal neurological deficits. Repeat MRI six days after admission demonstrated new, enlarging edematous and peripherally enhancing lesions favored to represent multifocal cerebritis. Craniotomy and open brain biopsy with resection of dura was performed ten days after admission. Pathology revealed lymphohistiocytic inflammation with amoebic necrotizing abscesses. Immunohistochemical and PCR testing confirmed Acanthamoeba infection. Despite multidrug treatment (with miltifosine, flucytosine, pentamidine, sulfadiazine, fluconazole, and azithromycin), the patient expired on hospital day 16.

IMPACT/DISCUSSION: Acanthamoeba is a pervasive protozoal species found in soil, water, air, and dust; the organism has been associated with three infectious syndromes in humans: amoebic encephalitis, disseminated granulomatous amebic disease, and keratitis (especially in contact lens users). Unlike the fulminant infection caused by *Naegleria fowleri*, Acanthamoeba causes a subacute encephalitis that progresses over days to months. Acanthamoeba likely causes central nervous system infection in immunocompromised hosts through hematogenous spread after initial pulmonary or skin inoculation and subsequent penetration of the blood-brain barrier. Investigational therapies for Acanthamoeba encephalitis include surgical resection of lesions and combination drug therapy.

CONCLUSION: Amoebic encephalitis is an exceedingly rare cause of central nervous system infection with a mortality exceeding 90%. Various protozoa have been implicated in central nervous system disease, including *Naegleria fowleri*, *Balamuthia mandrillaris*, and multiple species of Acanthamoeba. Little data exists regarding the clinical characteristics, radiographic findings, and treatment of Acanthamoeba encephalitis, as fewer than 150 cases have been reported globally since the condition was first described in the 1960s. Acanthamoeba encephalitis should be considered in immunocompromised patients presenting with central nervous system infection, as delayed recognition and treatment contribute to the condition's grave prognosis.

ACQUIRED HEMOPHILIA A DUE TO ALEMKTUZUMAB TREATMENT FOR MULTIPLE SCLEROSIS

Jesse D. Faulk¹; Dennis Sehgal¹; Jorge Diaz²; Pavan Panchavati³. ¹University of Alabama at Birmingham, Huntsville, AL; ²Clearview Cancer Institute, Huntsville, AL; ³Huntsville Hospital, Huntsville, AL. (Control ID #3185958)

LEARNING OBJECTIVE #1: Diagnose acquired hemophilia A.

LEARNING OBJECTIVE #2: Treat acquired hemophilia A.

CASE: A 66-year-old Caucasian female presented to the ED due to bruising. Her bruising began 4 days prior, beginning on her hands and feet then involving her torso. She also admitted to hematuria for 4 days but denied melanotic stools, hematemesis, hematochezia, epistaxis, or joint swelling. She denied any recent trauma or history of easy bruising or bleeding. She has a medical history significant for multiple sclerosis and was treated nine months prior with alemtuzumab. She had a prior appendectomy and cholecystectomy without any significant bleeding. She has no family history of bleeding or clotting disorders. On examination, she was afibrile and normotensive. She had diffuse bruising. Her hemoglobin was 8.1 g/dL, platelet count was 381x10³/µL, and WBC was 11.7x10³/µL. Prothrombin time (PT) was 13.1 s and partial thromboplastin time (PTT) was 90.2 s. Factor 8 activity was 3% (normal: 50-150%). A PTT mixing study was performed with PTT failing to correct. Lupus anticoagulant was not detected. Factor VIII inhibitor was detected. Computed tomography of chest, abdomen, and pelvis showed no malignancy. Antinuclear antibody was negative. She was diagnosed with acquired hemophilia A secondary to alemtuzumab therapy and started on prednisone and rituximab, which was changed to cyclophosphamide due to allergic reaction. Her PTT began to decrease, and she was discharged on prednisone and cyclophosphamide.

IMPACT/DISCUSSION: Acquired hemophilia A is an uncommon autoimmune disorder that is caused by an inhibitory autoantibody to factor VIII. Acquired hemophilia may be associated with certain medications, autoimmune disorders, or malignancy. Almost half of patients may not have an identified etiology. Alemtuzumab, a humanized monoclonal antibody targeting the surface molecule of CD52 of B and T lymphocytes, has been reported to cause autoimmune conditions, and limited case reports exist of this monoclonal antibody causing acquired hemophilia A. The usual presenting symptom is bleeding that may occur after a surgical procedure or spontaneously. Patients may present with mucocutaneous bleeding, such as epistaxis, gastrointestinal bleeding, hematuria, ecchymosis, or large hematomas. Acquired hemophilia is characterized by prolonged PTT with normal PT. A mixing test that results in uncorrected PTT differentiates acquired hemophilia from inherited factor deficiency, and a Bethesda assay diagnoses the presence of a factor VIII inhibitor. Desmopressin, factor VIII concentrates, or activated prothrombin complex concentrate can be used to control bleeding. In order to eliminate the inhibitor, immunosuppressive modalities, such as glucocorticoids, cyclophosphamide, and rituximab, may be used.

CONCLUSION: Acquired hemophilia A is a rare but important cause of mucocutaneous bleeding and must be differentiated from inherited factor deficiencies. Alemtuzumab has been reported as a cause and must be identified to avoid re-exposure.

ACUTE BACTERIAL MYOPERICARDITIS IN AN INTRAVENOUS (IV) DRUG USER.

Julian Koleszar¹; Timothy Byrnes². ¹Summa Health System/Northeast Ohio Medical University Program, Akron, OH; ²Summa Health System, Akron, OH. (Control ID #3186998)

LEARNING OBJECTIVE #1: Recognize the clinical features of acute bacterial myopericarditis.

LEARNING OBJECTIVE #2: Distinguish between pericarditis and myopericarditis.

CASE: A 42-year-old Caucasian male with a history of IV drug use, alcohol abuse, hepatitis B and C, esophageal varices, and cirrhosis presented to the ER with two days of diffuse chest pain, 10/10 in intensity, sharp, nonradiating, and constant, associated with dyspnea and fever. It worsened with inspiration and lying supine and improved with sitting upright. Physical examination revealed a temperature of 39.1°C, pulse of 121 beats/min, respiration rate of 20 breaths/min, and a blood pressure of 121/80 mmHg. Pulse oximetry on room air was 96% saturation. He appeared cachectic and chronically ill. Chest and cardiac auscultation revealed clear lungs, tachycardia with a regular rhythm, and no jugular venous distention, murmur, rub, or gallop. He had 2+ bilateral pitting edema to the knee and abdominal ascites. Complete blood count showed 19.2×10^3 WBC/uL and 109×10^3 platelets/uL. Troponin was elevated at 1.2 ng/mL. Electrocardiogram (EKG) showed diffuse ST elevations suggestive of pericarditis. CTA of the chest showed bilateral infiltrates concerning for pneumonia. Blood cultures were obtained and IV Vancomycin and IV Piperacillin/Tazobactam initiated. Transthoracic echocardiogram (TTE) revealed an ejection fraction of 65% and a moderate free-flowing pericardial effusion without evidence of tamponade. The patient underwent pericardiocentesis, 600cc of cloudy fluid was removed, and a pericardial drain placed. Blood and pericardial fluid cultures returned positive for MRSA. IV Vancomycin was continued for MRSA bacteremia and purulent myopericarditis. Pericardial cytology returned negative. The patient left against medical advice (AMA) but returned a few days later for worsening ascites and chest pain. Repeat TTE showed a small pericardial effusion. Repeat blood cultures returned negative. A six-week course of IV vancomycin was planned but the patient again left AMA.

IMPACT/DISCUSSION: A PubMed search using the terms *MRSA* and *myopericarditis* resulted in only two case reports of MRSA bacterial myopericarditis: a 41-year-old male with community-acquired pneumonia and a 48-year-old male with an initial elbow abscess. If the clinician encounters a septic patient who meets diagnostic criteria for acute pericarditis, broad spectrum antibiotic therapy should be initiated, and a TTE obtained to determine need for pericardiocentesis. MRSA bacterial myopericarditis is a rare entity, however with the rise of IV drug use within the US, its incidence is likely to increase.

CONCLUSION: Bacterial pericarditis is an infrequent finding in areas with low prevalence of tuberculosis, and purulent pericarditis is rarely diagnosed, comprising <1% of all pericarditis cases. Patients meeting diagnostic criteria for pericarditis with positive cardiac biomarkers in the absence of ventricular dysfunction are further classified as having myopericarditis.

ACUTE INFLUENZA B-RELATED ENCEPHALOPATHY

Merza Nooraldin¹; Muath Alsharif²; Mais Abdou³; Mazin Saadaldin⁴; Tareq Naguib³. ¹ttuhsc, Amarillo, TX; ²Texas Tech University Health Science Center, Amarillo, TX; ³TTUHSC, Amarillo, Amarillo, TX; ⁴NWTHS, TTUHSC, Amarillo, TX. (Control ID #3184711)

LEARNING OBJECTIVE #1: 1-Discuss diagnostic criteria and clinical presentation of influenza-related encephalopathy. 2-To lower the threshold for diagnosing Influenza B-related encephalopathy in adults in the face of higher prevalence.

CASE: A 62-year-old male with prostate cancer treated with radiation therapy was admitted for hypertensive crisis with seizures and altered mental state. Although blood pressure improved, he deteriorated and developed oral apraxia. There was no cough, nasal discharge, sore throat, headache, arthralgia, or muscle aches. The temperature was 38.9°C, blood pressure 150/80 mmHg, pulse 106 beats/min, respiratory rate 21 breaths/min, and oxygen saturation 96% on room air. The Glasgow Coma Scale (GCS) score was 13 with eye opening 4 and verbal response 4. The rest of the exam was unremarkable including normal pupillary reflexes and muscle tone of the neck. A nasopharyngeal swab was positive for influenza B rapid test, and Tamiflu was started, while spinal tap findings were all

normal, including viral panels, ruling out meningoencephalitis. Subtle punctate acute cortical infarct involving both left parietal and right occipital lobes, appeared on MRI along with old left lacunar thalamic infarct and EEG suggested encephalopathy, all consistent with influenza B-related acute encephalopathy. Due to brain damage and altered mentation, our patient was transferred to a skilled nursing facility upon discharge for rehabilitation and consideration for permanent placement.

IMPACT/DISCUSSION: Our patient was positive for Influenza B virus and met the diagnostic criteria of the Japanese research committee of influenza encephalopathy, which include severe impairment of consciousness with a sustained GCS score of 13 for more than 24 hours. The majority of cases are associated with influenza A in younger age but cases in adults are on the rise. Our case of influenza B-related encephalopathy in an older adult serves to raise awareness of this unusual condition.

CONCLUSION: Acute influenza B-related encephalopathy presents with various neurological complications but sharing common findings of seizure, fever and encephalopathy/encephalitis. The presence of influenza virus RNA in brain biopsy tissue, CSF, or even respiratory samples is diagnostic. The presence of brain lesions on MRI and influenza virus in CSF appear to be of prognostic value.

ACUTE KIDNEY INJURY: LOOKING BEYOND THE URINARY TRACT

Carine Davila; Nicholas Iverson; Irina Kryzhanovskaya; Sarah Schaeffer. University of California, San Francisco, San Francisco, CA. (Control ID #3184723)

LEARNING OBJECTIVE #1: Recognize gynecologic malignancy as a cause of obstructive uropathy in women

LEARNING OBJECTIVE #2: Identify appropriate imaging modalities to evaluate for malignancy in women with obstructive uropathy

CASE: A 62-year-old woman with no known past medical history arrived at the emergency department obtunded after being found down at home. A friend revealed she had not seen a doctor in 20 years. She lives alone and does not use substances. On exam, she is afebrile, tachycardic to 120, and hypertensive to 229/116. She was arousable but disoriented, without clonus or asterixis. Initial labs showed potassium 6.5 mEq/L, BUN 154 mg/dL, and Cr 31.2 mg/dL. A Foley catheter was placed and drained 200mL of light-yellow urine; urinalysis showed moderate blood and protein and urine toxicology was negative. Renal replacement therapy was initiated. A renal ultrasound after Foley placement showed moderate bilateral hydronephrosis without apparent cause. A non-contrast CT abdomen/pelvis was performed to assess the cause of hydronephrosis, but noted only non-enlarged retroperitoneal lymphadenopathy, moderate ascites, and a uterine myoma. Ureteral stents were placed but failed to relieve the obstruction and the patient required bilateral nephrostomy tubes several days later. On hospital day five, a pelvic ultrasound was performed and showed endometrial thickening and an 8 cm calcified solid mass, concerning for malignancy. A cervical biopsy revealed squamous cell carcinoma; PET/CT demonstrated a hypermetabolic endometrial mass, abdominal carcinomatosis, and osseous metastases. The final diagnosis was cervical malignancy with retroperitoneal adenopathy causing bilateral complete obstructive uropathy, acute anuric renal failure, and uremic encephalopathy.

IMPACT/DISCUSSION: Though obstructive uropathy represents 10% of all cases of acute kidney injury (AKI), the incidence in women is one third to one half compared to men (Pichler 2010). Historically, a renal ultrasound is the first imaging study performed, as it can identify obstruction and at times an etiology of the obstruction. Licurso (2010) argues that this is not cost-effective given the low incidence of obstruction in all cases of AKI. When obstructive uropathy occurs in women, workup should include a prompt evaluation for malignancy, as it accounts for 72% of cases (Norman 1982). Renal ultrasound and CT abdomen/pelvis, as obtained in this case, do not always effectively evaluate for gynecologic

malignancy. Pelvic ultrasound is a critical tool for evaluating female patients. Transvaginal ultrasound has been shown to be superior even to pelvic MRI for delineating cervical tumor (Alcazar 2014). Therefore, although CT is an easily-obtainable imaging modality, a transvaginal ultrasound is necessary to adequately evaluate a woman with urinary obstruction for gynecologic malignancy.

CONCLUSION: Malignancy accounts for nearly 75% of cases of obstructive uropathy in women. To better evaluate for gynecologic malignancy, a transvaginal ultrasound is more useful than CT or MRI.

ACUTE ONSET TYPE 1 DIABETES MELLITUS IN A 95-YEAR-OLD PATIENT WITH METASTATIC MELANOMA

Damond B. Ng¹; Sara-Megumi Naylor². ¹David Geffen School of Medicine at UCLA, Los Angeles, CA; ²Department of Veterans Affairs, Los Angeles, CA. (Control ID #3162607)

LEARNING OBJECTIVE #1: Demonstrate that T1DM is a rare, but critical side effect of anti-programmed cell death-1 (PD-1) antibodies. Endocrine disturbances can contribute to the morbidity of patients with malignancy.

LEARNING OBJECTIVE #2: Appreciate that primary care providers can play a role in managing the side effects and weighing the benefits and risks of immune checkpoint inhibitors.

CASE: A 95 year-old man with a history of metastatic melanoma presenting for surveillance imaging was incidentally found to have a serum glucose of 428 mg/dL. He had no past medical history of diabetes or known evidence of pancreatic metastases. His family history was notable for a daughter with type 1 diabetes mellitus (T1DM) diagnosed at a young age. For metastatic melanoma, he received 7 cycles of pembrolizumab (200mg every 3 weeks) for palliation. He reported polyuria, polydipsia, and weight loss for the last 3 months. He denied abdominal pain, nausea, and vomiting. His physical exam was pertinent for hypotension (80/40 mmHg), normal respiratory effort, normal mentation, a normal abdominal exam without tenderness, and poor skin turgor. Laboratory evaluation revealed a normal anion gap and serum osmolality. There were no ketones in his urine and serum. Further studies demonstrated a hemoglobin A1c of 9.5%, an inappropriately low serum C-peptide at 0.56 ng/mL (0.8-3.85), and an undetectable anti-GAD titer. Pembrolizumab was held and the patient was started on basal-bolus subcutaneous insulin. He successfully obtained glucose control with a follow-up hemoglobin A1c of 7.2% and normalization of his C-peptide.

IMPACT/DISCUSSION: Although pembrolizumab, a monoclonal antibody against PD-1, has improved survival in patients with metastatic melanoma, descriptions of endocrine disturbances are accumulating. Fortunately, most side effects are reversible, but early recognition and proper management are crucial.

CONCLUSION: Checkpoint inhibitor therapy has been associated with the acute onset of T1DM in approximately 0.2% of cases with a range of 1-52 weeks after initiation. This patient had the following glucose trend: 186 mg/dL at week 15, 329mg/dL at week 18, and finally 428 mg/dL at week 21. There was no investigation or intervention until week 21. Timely evaluation might have led to pembrolizumab cessation and evaluation for T1DM rather than a presentation of a hyperglycemia crisis. Per recent guidelines, serum glucose should be measured at baseline and with each treatment cycle during induction for 12 weeks, then every 3 to 6 weeks thereafter. In a series of five cases of pembrolizumab associated T1DM, patients initially presented with hyperglycemia or diabetic ketoacidosis. All required insulin at diagnosis and remained insulin-dependent for diabetic control. The patient's advanced age, Do-Not-Resuscitate status, visual impairment and poor social support made this new diagnosis challenging. He was admitted overnight for insulin therapy and endocrine consultation. The risks and benefits of pembrolizumab were discussed and the drug was discontinued.

ACUTE RENAL AND SPLENIC INFARCTIONS AS THE INITIAL MANIFESTATION OF PAROXYSMAL ATRIAL FIBRILLATION (PAF)

Liangbo (linus) L. Shen¹; Wei Qi¹; Jose C. Duarte¹; Anil Nagar^{1, 2}; Naseema B. Merchant^{1, 2}. ¹Yale University School of Medicine, New Haven, CT; ²VA Connecticut Health Care, West Haven, CT. (Control ID #3184327)

LEARNING OBJECTIVE #1: Diagnose uncommon embolic presentations of paroxysmal atrial fibrillation (PAF).

LEARNING OBJECTIVE #2: Recognize the importance of cardiac monitoring and appropriate imaging studies in patients presenting with visceral emboli.

CASE: A 73-year-old man with a history of hypertension and diverticulitis presented to the emergency department with one day history of severe left lower quadrant (LLQ) abdominal pain and nausea. He denied dizziness, chest pain, palpitations, shortness of breath, hematuria, fever or diarrhea. Vitals were notable for hypertension (187/104 mmHg). Physical exam including cardiac was normal except for tenderness in LLQ. results of WBC, creatinine, LFT's and urinalysis (1+ protein, 1 white blood cell, and 4 red blood cells) were normal. Initial EKG showed normal sinus rhythm. A non-contrast abdominal CT showed no calculi in the urinary tract. Due to concern for acute diverticulitis and intestinal ischemia, he underwent a contrast enhanced abdominal CT scan showing acute infarctions in the left kidney and spleen. Anticoagulation was initiated due to a high suspicion of cardioembolic events as an underlying etiology. Subsequently, continuous telemetry showed occurrence of PAF, confirmed by a subsequent EKG. Patient's symptoms quickly improved, and he was discharged 3 days later in normal sinus rhythm on anticoagulation.

IMPACT/DISCUSSION: In patients with PAF, brain is a common site for cardiac emboli. Embolization to other organs is low (extremities: 1.22%, mesenteric: 0.58%, pelvic artery: 0.18%, aorta: 0.14%, renal: 0.04% - Frost 2001). Splenic infarcts are rare and true incidence is unknown. AF is a common underlying etiology in patients presenting with renal infarction. Symptoms include flank or abdominal pain, nausea, vomiting, and fever. Lab abnormalities include elevated levels of LDH and WBC, hematuria and proteinuria. The common causes of splenic infarction include hematologic diseases (e.g. malignancy and sickle cell) and cardioembolic causes (Antopolksy 2009). Symptoms of splenic infarcts include left-upper-quadrant pain, fever, chills, nausea, vomiting, pleuritic chest pain, and left shoulder pain. Our patient presented with a normal cardiac exam, EKG, lab data and non-contrast abdominal CT but high clinical suspicion for a serious underlying abdominal condition prompted a contrast CT scan which confirmed the diagnosis and subsequent telemetry monitoring helped establish the diagnosis of PAF as a cause of his visceral infarctions.

CONCLUSION: Acute renal and splenic infarctions are rare, but can manifest as the first and only presentation of PAF even in the absence of arrhythmia on initial cardiac exam or EKG. Hence for patients presenting with acute renal and splenic infarction, continuous telemetry monitoring is very important to diagnose PAF. Lastly, this case also demonstrates the value of using intravenous and oral contrast in patients suspected of having visceral embolic or ischemic events in the abdomen.

ACUTE RENAL INFARCT A DELAYED OR MISSED DIAGNOSIS.

Anthi Katsouli. Loyola University Medical Center, South Barrington, IL. (Control ID #3168568)

LEARNING OBJECTIVE #1: Recognizing acute renal infarct in patients with lower abdominal or flank pain and with risk factors for thromboembolism.

CASE: A 68-year-old man with past medical history of coronary artery disease with multiple stents placement, ischemic cardiomyopathy with

ejection fraction 35% presented to the emergency department with sudden left-sided abdominal/flank pain and fever. Physical examination revealed normal vital signs, left lower quadrant and CVA tenderness, and no additional abnormalities. Laboratory investigations revealed mild leukocytosis (white blood count [WBC] $11.1 \times 10^9/\text{L}$) and a normal serum creatinine. His liver function tests were mildly elevated (AST 80, ALT 58) with normal alkaline phosphatase, total bilirubin and lipase. Urine analysis performed and was negative for infection but showed trace blood with 0-2 RBC's. Computer tomography of the abdomen and pelvis showed a wedge-shaped area of decreased enhancement in the inferior left kidney concerning for infarct. Tele monitor revealed atrial fibrillation and electrocardiogram confirmed it. Patient was started on anticoagulation with heparin drip and underwent synchronized electrical cardioversion after transesophageal echocardiogram showed no left atrial appendage thrombus. Patient was discharged with oral apixaban and amiodarone.

IMPACT/DISCUSSION: Acute renal infarction involves occlusion of the arterial supply to the kidney and most commonly occurs as the result of thromboembolism. Incidence in patients presenting to hospital is estimated between 0.004 and 0.007%. The average age at presentation is in the 6th to 7th decades, with a similar incidence among the sexes. Bilateral infarcts occur in 2% to 20% of cases. Renal infarction nearly always occurs in patients with risk factors for thromboembolism, and patients may experience additional embolic sequelae. The most common risk factor is atrial fibrillation, present in 25% to 65% of cases. Other risk factors include valvular and ischemic heart disease, cardiomyopathy, known atherosclerotic disease, and prior thromboembolism. Cases have also been described in patients with heritable and acquired hypercoagulability, connective tissue disorders, endocarditis, and trauma.

CONCLUSION: Acute renal infarction is a rare condition. Recent advances in diagnostic imaging have increased the detection of renal infarction. The non-specific presentation of acute renal infarction has led to delayed diagnosis, but with the broad availability of high-quality computed tomography imaging, it is possible to identify cases early and initiate prompt treatment. Given the small numbers of cases described to date, quality evidence regarding treatment is lacking.

ACUTE RENAL INFARCTION SECONDARY TO RENAL ARTERY DISSECTION PRESENTING AS ACUTE ABDOMINAL PAIN

Shiva Shankar Vangimalla; Zehra Dhanani; Hannie Batal; Jason Wexler. Medstar Washington Hospital Center, Washington, DC. (Control ID #3186060)

LEARNING OBJECTIVE #1: Recognize the clinical presentation of acute renal infarction (ARI) given its rarity and non-specific clinical presentation.

LEARNING OBJECTIVE #2: Distinguish between various etiologies of ARI to initiate prompt treatment.

CASE: A 62 year female with past medical history of atrial fibrillation/flutter status post ablation, complete heart block status post permanent pacemaker insertion, Stanford type A aortic dissection status post endovascular repair, hypertension presented with severe right flank pain, nausea and emesis since 1 day. Vital at admission were - blood pressure (BP) 230/106, heart rate 73 beats per minute, temperature 36.3 C. Initial lab work was notable for elevated white blood cell count (WBC) 11.5 k/uL, serum creatinine 0.64 mg/dL, lipase 93 units/L and lactic acid 1.3 mmol/L. Urine analysis revealed specific gravity 1.013, red blood cells 3, WBC <1, negative leukocyte esterase, and no bacteuria. Computed tomography angiography (CTA) of abdomen/pelvis with IV contrast was concerning for occluded right renal artery with a large infarct and contrast enhancement of only a small portion of upper pole of right kidney. She was started on nicardipine and heparin drip for blood pressure control and anticoagulation immediately. Pain was controlled with fentanyl PCA. Vascular surgery did not recommend any acute surgical intervention as

the kidney was unlikely to be salvageable due to the time of onset symptoms. Nephrology recommended continuing observation. Review of the CTA images showed occlusion of the right renal artery 2 cm from its origin and its supply from the false lumen suggestive of renal artery dissection. As her pain and renal function continued to improve over the next few days. She was transitioned to oral anti-hypertensive medications to keep her BP < 130/70. Hospital course was complicated by acute urinary retention and acute urinary tract infection secondary to her PCA use that resolved with insertion of foley catheter and antibiotic coverage. Her serum creatinine peaked at 1.80 mg/dL and improved to 0.63 mg/dL at the time of discharge. She was resumed on oral eliquis for her other anticoagulation needs. At the time of discharge, her presenting symptoms resolved and had a good renal function.

IMPACT/DISCUSSION: ARI can be missed easily as there is a lack of awareness among the physicians including the radiologists given its rarity. Prompt identification of etiology may help guide treatment. Conservative management may be reasonable in patients with two functioning kidney and unilateral disease. Optimal treatment is uncertain given limited case reports and the absence of comparative studies.

CONCLUSION: High index of clinical suspicion is needed to diagnose ARI. An initial evaluation must include CBC, serum creatinine and lactate dehydrogenase, urine analysis with culture and EKG. CT scan with contrast can help assess renal infarction. Reported treatment approaches include anticoagulation, endovascular therapy, open surgery, and observation depending on the etiology. Prognosis remains unknown.

ACUTE RETROVIRAL SYNDROME PRESENTING WITH ACUTE LIVER INJURY

Rinad Tabbalat; kavya Kelagere Mayigegowda; Shazia Samanani. Baystate Medical Center, Springfield, MA. (Control ID #3186878)

LEARNING OBJECTIVE #1: Recognize that acute antiretroviral syndrome can present with acute liver injury

CASE: A 23-year-old previously healthy male presented with 5 days of nausea, vomiting and diarrhea preceded by one day of flu-like symptoms. He denied any recent travel, exposure to sick contacts or consumption of possibly contaminated food or water. He reports being sexually active with one male partner and recent negative HIV test. On presentation he was febrile to 102.9F. Labs showed white blood cells of 3.1 k/mm³ with 38.4% neutrophils, platelet count 127 k/mm³, AST 1,075 units/L, ALT 1,012 units/L, alkaline phosphatase 71 units/L, and total bilirubin 0.3 mg/dL. Initially there was concern for a possible tick born illness or acute viral hepatitis. Workup included Northeastern tick panel, viral panel for hepatitis A, B and C, infectious mononucleosis antibody, influenza A and B, and RPR for syphilis which were all negative. Additional work up for acute liver injury included acetaminophen level, EBV and CMV serologies which were also negative. Given his high risk profile he was also tested for HIV 4th generation Ab-Ag which came back positive. Absolute CD4 count was 246 and HIV viral load was greater than 10 million, confirming a diagnosis of acute retroviral syndrome. As the patient's viral load began to decrease, so did his transaminitis and shortly after he was started on antiretroviral therapy.

IMPACT/DISCUSSION: Signs and symptoms of acute HIV infection are nonspecific, making diagnosis difficult at times. Liver function test abnormalities are not uncommon in HIV patients but these are usually secondary to hepatotoxicity in those taking antiretroviral therapy (ART) or due to co-infection with viral hepatitis. Most clinical studies with severe elevation in liver enzymes (>5X the upper limit of normal) were seen in those taking ART. A review of the literature from the last 13 years found 31 cases of autoimmune hepatitis presenting in patients with different stages of HIV. Most of these were also in the setting of viral hepatitis and only one of these patients improved without use of steroids or immunotherapy making autoimmune hepatitis much less likely in our patient.

CONCLUSION: Although this is less common, abnormalities in liver function tests and acute liver failure may be the first presentation for acute HIV infection. Given that HIV is not routinely tested in patients presenting with acute liver injury, it is important to have a high index of suspicion to prevent under detection and delays in diagnosis.

ACUTE TOXIN MEDIATED RHABDOMYOLYSIS IN SETTING OF RECENT INITIATION OF SULFAMETHOXAZOLE-TRIMETHOPRIM THERAPY FOR URINARY TRACT INFECTION

Dorjan Pantic; Michael Sperandeo; Linda Kurian. Hofstra Northwell School of Medicine, Manhasset, NY. (Control ID #3141559)

LEARNING OBJECTIVE #1: Identifying bactrim as a possible cause of rhabdomyolysis

CASE: A 41-year-old African American male with a past medical history of overactive bladder and benign prostatic hyperplasia presented to the ED with increasing proximal bilateral lower extremity muscle pain for 5 days and increasing difficulty with ambulation. The patient also complained of persistent hematuria, urgency and hesitancy for the 9 days. Prior to presentation, the patient saw his outpatient urologist and was diagnosed with a UTI for which he was prescribed TMP-SMX DS. On exam, patient was found to have lower extremity proximal muscle strength 4/5 without point tenderness. Abdominal exam showed mild left lower quadrant and suprapubic tenderness to palpation. Physical exam was otherwise unremarkable. Initial laboratory analysis in the ED showed an AST 274 U/L, ALT 102 U/L, and a CK 60665 U/L. Prior labs from his urologist showed normal AST/ALT and urine consistent with a UTI without laboratory evidence of rhabdomyolysis prior to initiation of TMP-SMX. The patient was admitted for non-traumatic acute rhabdomyolysis and UTI and had TMP-SMX discontinued. During the course of admission, the CK peaked on day 4 at 240000 U/L, AST at 1200U/L and AST 1600 U/L prior to normalizing by day 8. The symptomatic improvement preceded laboratory improvement by ~3 days. During admission the patient was evaluated for influenza, HIV and cocaine toxicity as possible other etiologies for rhabdomyolysis during his admission. These studies were negative. Epstein Barr Viral studies were consistent with a prior infection with immunity, without evidence of an acute viral process. Thyroid function tests and Glucose-6-Phosphate dehydrogenase studies were also normal.

IMPACT/DISCUSSION: Our patient is to our knowledge the fourth case of TMP-SMX induced rhabdomyolysis in a patient without HIV infection. Each of the three prior patients, as well as our most recent case were prescribed TMP-SMX for a presumed UTI. Our cases adds to the growing body of literature suggesting TMP-SMX as a cause of possible drug induced rhabdomyolysis and adds to the importance of a thorough medication review.

CONCLUSION: The etiology of the rhabdomyolysis is varied and may be the result of toxin-mediated mechanisms, metabolic derangements or may develop secondary to other conditions like seizures, trauma and prolonged immobilization. In this case, we present a patient with suspected acute toxin-mediated rhabdomyolysis in the setting of new Trimethoprim-Sulfamethoxazole (TMP-SMX) therapy for urinary tract infection (UTI). Based on the time course of TMP-SMX initiation and the clinical improvement with discontinuation along the elimination of other possible hypoxic, biologic or physical/traumatic etiologies of acute rhabdomyolysis in our patient, we concluded that TMP-SMX was likely the insulting agent. To our knowledge, this marks the fourth case report of an otherwise healthy patient diagnosed with rhabdomyolysis secondary to TMP-SMX, further studies may be needed.

ADRENALITIS AS A COMPLICATION OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION.

Omair Alam¹; Robert Patton¹; Manuel De La Rosa¹; Rahul U. Nayak². ¹Inova Fairfax Hospital, Fairfax, VA; ²Virginia Commonwealth University, Richmond, VA. (Control ID #3176777)

LEARNING OBJECTIVE #1: Recognize adrenalitis as a complication of Human Immunodeficiency virus (HIV) infection.

CASE: A 25 year old male with high risk sexual behavior presented with shortness of breath, productive cough and fevers. He was found to be in hypoxic respiratory failure with multifocal opacities on chest imaging and empirically treated for community acquired pneumonia. Upon further testing, he was found to be HIV positive with elevated viral load and significantly decreased lymphocyte T-cells. Thus, he was started on empiric treatment with bactrim and prednisone for pneumocystis jiroveci pneumonia (PJP). Five days after discharge he presented to our hospital with new onset of severe epigastric abdominal pain, nausea and vomiting. He was found to have hyponatremia and hyperkalemia on laboratory studies. Chest and abdominal imaging demonstrated diffuse ground glass opacities in both lungs consistent with PJP infection and inflammatory changes in both adrenal glands. His signs and symptoms were concerning for adrenal insufficiency secondary to adrenalitis from HIV. His abdominal symptoms improved with fluid resuscitation, prednisone (glucocorticoid) and fludrocortisone (mineralocorticoid) therapy. However, his respiratory failure progressed to acute respiratory distress syndrome and septic shock secondary to severe PJP infection requiring ventilatory support, vasopressors and extracorporeal membrane oxygenation. Despite aggressive treatment he eventually succumbed to his illness and passed away 46 days later.

IMPACT/DISCUSSION: Clinically significant adrenal insufficiency is evident when 80 to 90% of the gland is destroyed; therefore, this is not only rare but also a potentially devastating consequence of HIV infection. In general, the approach to a suspected endocrinopathy in a patient with HIV should be similar to that of an immunocompetent individual. However, due to the body's adaptive changes to HIV infection the interpretation of the diagnostic studies can be difficult. The following should be kept in mind during the work up: - Cortisol levels may be present without elevated adrenocorticotrophic hormone (ACTH) in the setting of infection related cytokine release. This may manifest as a blunted response to the ACTH stimulation test. - In a patient with elevated cortisol with Addisonian type clinical picture, consider peripheral glucocorticoid resistance due to HIV. - In a patient with HIV presenting malaise and non-specific abdominal symptoms, a broad differential should be kept in mind including adrenal insufficiency secondary to adrenalitis.

CONCLUSION: HIV endocrinopathies are well documented; however, with the ubiquity of antiretroviral therapy it is increasingly rare to see these clinical manifestations in practice. This case serves as a reminder to keep a broad differential diagnosis during an evaluation of a patient with HIV who presents with nonspecific abdominal symptoms found to have adrenal insufficiency due to adrenalitis.

ADVOCATING FOR CONTINUATION OF HEPATITIS C (HCV) TREATMENT IN THE MASSACHUSETTS (MA) CORRECTIONAL SYSTEM

Sarah S. Roderick¹; Juhee McDougal^{2, 1}; Alexandra Heinz¹. ¹Boston Medical Center, Boston, MA; ²Boston University Medical School, Boston, MA. (Control ID #3176871)

LEARNING OBJECTIVE #1: Demonstrate the need for advocacy for continuation of HCV treatment in incarcerated patients

LEARNING OBJECTIVE #2: Recognize the heterogeneity of access to treatment and continuation of HCV treatment in the correctional system

CASE: Mr. S is a 34 year-old male with a history of chronic HCV and opioid use disorder (OUD) on buprenorphine-naloxone who presented to primary care for HCV treatment. Initial work up demonstrated mild portal fibrosis on fibroscan. After medication counseling, he was started on a twelve-week course of sofosbuvir-velpatasvir. Over the next three weeks, Mr. S continued to be adherent to his regimen, and his OUD remained in remission. However, at his four- week follow up, our team was notified that he had been incarcerated. While incarcerated, Mr. S requested assistance

from our team in order to continue his HCV treatment. Our social worker spent a considerable amount of time speaking with multiple health care providers within the correctional system. At first, his providers refused to continue treatment due to the high cost and because he tested positive for non-prescribed benzodiazepines and alcohol. Our team communicated that his medication had already been paid for, could be delivered to the prison free of charge, and it was imperative to continue his regimen in order to avoid developing treatment resistance. Ultimately, our request was denied, as the prison had a firm policy on not continuing treatment in patients with active substance use. Mr. S was released from prison two months later. Surprisingly, he was found to have achieved sustained virologic response after completing only four weeks of treatment.

IMPACT/DISCUSSION: Both in MA and throughout the United States (US), there appears to be a conservative approach towards initiation/continuation of HCV treatment in the correctional system. This highlights a need for both advocacy and further education on the importance of continuing HCV treatment despite active substance use while incarcerated.

CONCLUSION: MA is one of the few states that has removed many of the barriers for initiation of HCV treatment; however, variations still remain based on the insurance payor and barriers still exist within the MA correctional system. In the US, few prisons initiate HCV treatment; some that do require patients to have at least advanced liver disease in order to start treatment. Outcomes are mixed when it comes to continuation of HCV treatment in prisons. Some providers continue treatment, but not without difficulty in terms of care coordination and the need to heavily advocate on behalf of the patient. Others may adopt an overall non-continuation approach to patients who continue to use substances, or they may altogether stop treatment due to high cost as prisons are not eligible for federal reimbursement. This case illustrates the need for further advocacy, education, and a coordinated approach towards continuation of HCV treatment for incarcerated individuals.

AEROCOCCUS URINAE: A RARE CAUSE OF MITRAL VALVE ENDOCARDITIS

Mallory Myers¹; Thanhnga Doan¹; Daniel Gergen¹; Rehaan Shaffie².

¹University of Colorado, Denver, CO; ²Denver Health Medical Center, Denver, CO. (Control ID #3175216)

LEARNING OBJECTIVE #1: Recognize *Aerococcus uriniae* as a rare cause of infective endocarditis.

CASE: A 69-year-old man with no past medical history presented to the emergency department with two weeks of falls, difficulty urinating, and gross hematuria. On exam, he was afebrile and hemodynamically stable with a 3/6 systolic murmur, intention tremor, and shuffling gait. Labs revealed a white blood cell count of 19.4, a beta-natriuretic peptide of 2,254, and 3+ blood in his urine. Urine and blood cultures grew 10,000-100,000 colonies per mL of *Aerococcus uriniae*. Head CT and MRI showed evidence of subarachnoid hemorrhages. Treatment began with two days of intravenous vancomycin but was switched to penicillin based on susceptibility studies in the literature. Blood cultures cleared on day three of treatment. An echocardiogram revealed a large mobile mass on the atrial side of the posterior leaflet of the mitral valve with mild to moderate regurgitation. During a right heart catheterization, the patient went into atrial fibrillation and several hours later had a stroke. MRI showed new multifocal infarcts that were likely embolic. Given the risk of additional embolic events, he was transferred to a cardiothoracic surgery center where he underwent a successful mitral valve replacement.

IMPACT/DISCUSSION: *Aerococcus uriniae* is a gram-positive, catalase-negative coccus that produces alpha-hemolysis on blood agar. Though thought to have low pathogenicity, it is implicated in cases of urinary tract infections (UTIs), infective endocarditis (IE), and sepsis. These manifestations are rare, with an estimated UTI incidence of 54 per 1 million per year and a bacteremia incidence of 3 per 1 million per year. Risk factors

for *A. uriniae* infection include old age, male gender, and predisposing conditions such as diabetes mellitus, ischemic heart disease, urologic obstruction, and catheterization. This case illustrates *A. uriniae* as a cause of IE with dangerous consequences. *A. uriniae* possesses two important virulence factors for developing IE: biofilm formation and platelet aggregation. The aortic valve is most commonly affected, though the mitral and tricuspid valves can also be affected. Invasive *A. uriniae* infections are associated with high morbidity and mortality. In a review of 29 *A. uriniae* cases, 14 patients died within one week of hospital admission, 12 had arterial embolization events, 6 had septicemia, and 10 underwent mitral or aortic valve replacement. Therefore, prompt evaluation and treatment of patients found to have *A. uriniae* bacteremia is crucial. The recommended treatment for *A. uriniae* infection is penicillin or ceftriaxone. Adding an aminoglycoside has proven synergistic in numerous studies but should be weighed against the increased risk of adverse events.

CONCLUSION: *A. uriniae* is a rare cause of infective endocarditis, especially in elderly men with predisposing health factors. In patients with *A. uriniae* bacteremia, we recommend prompt evaluation for signs of infective endocarditis and arterial embolization.

ALTERED MENTAL STATUS: SOMETIMES IT'S MORE THAN JUST THE DRUGS

syed A. abbas; rizwan zafar; Karishma Kitchloo. Montefiore Medical center, Bronx, NY. (Control ID #3186041)

LEARNING OBJECTIVE #1: Recognize catatonia as a differential for patient presenting with altered mental status (AMS); early recognition and treatment may significantly reduce inpatient length of stay.

LEARNING OBJECTIVE #2: Neuroleptics used to manage hyperactive delirium may precipitate catatonia.

CASE: A 71-year-old man from nursing home (NH) with history of Alzheimer's dementia presented with AMS. He was recently admitted for aggressive behavior and was started on valproic acid and quetiapine. Upon his return to NH, he was found to be progressively more lethargic, bed bound, and mute. At baseline, he independently communicated and ambulated. On examination, his vital signs were stable, afebrile, lying flat in bed with arms crossed over the chest, unresponsive to verbal stimuli, minimally responsive to painful stimuli, with increased tone in all limbs. All baseline laboratory tests were negative including ammonia and valproic acid levels. Neuroimaging including CT head without contrast and MRI brain without contrast were done, both of which were negative for acute intracranial disease. His condition did not improve upon cessation of all neuroleptic and sedating agents. Electroencephalography was normal. Patient was given a lorazepam challenge, and thirty minutes later he was awake, sitting in bed, talking, and drinking water. He was started on oral lorazepam and discharged to NH with significant improvement.

IMPACT/DISCUSSION: In an acute medical setting, catatonia is seldom considered as a differential diagnosis for AMS, although prevalence ranges from 1.6 - 6.3%. Due to its remarkably similar presentation to delirium, it is often misdiagnosed and inappropriately treated. Neuroleptics used to treat delirium may precipitate catatonia, prolonging the episode of AMS, and thus lengthening hospital stay. Catatonia is a clinical syndrome characterized by psychomotor symptoms including stupor, mutism, waxing flexibility, and posturing. Historically associated with psychiatric illness, catatonia is now recognized as a systemic medical syndrome, associated with medical, neurological, and psychiatric disorders. The exact pathophysiology remains unclear; studies suggest abnormal activity at the gamma-aminobutyric acid, glutamate and dopamine receptors. Medical catatonia warrants an expedient medical workup, and if unrecognized it may progress to potentially fatal syndrome of malignant catatonia. Lorazepam is the drug of choice and, in resistant cases electroconvulsive therapy is the treatment of choice. Neuroleptics should be used with caution. Remarkable phenotypic overlap between delirium and catatonia warrants further research to establish clear diagnostic and

treatment guidelines to help clinicians treating medically and psychiatrically complex patients with catatonia.

CONCLUSION: Catatonia and delirium can often similarly present; the importance of a broad differential for altered mental status refractory to conventional treatment remains vital in appropriately managing patient care.

ALTERED MENTAL STATUS: THE PARTY IS OVER

Thomas John; Marjorie E. Bateman. Tulane University School of Medicine, Mandeville, LA. (Control ID #3184074)

LEARNING OBJECTIVE #1: Recognize clinical presentation of sedative-hypnotic withdrawal

LEARNING OBJECTIVE #2: Identify barriers in uncovering substance abuse

CASE: A 32-year-old man presented after a 30 second tonic-clonic seizure. He was somnolent with normal vitals and no obvious neurologic deficits. The patient's family and friends provided his initial history. He had no recent infectious symptoms and was behaving normally until the seizure. Past medical history included narcolepsy and HIV for which he was on antiretroviral therapy. A recent CD4 count was 513. He had been drinking more alcohol than usual over the past several days but did not use illicit drugs. CSF showed elevated protein and WBC count with negative gram stain and culture. Urine drug screen was negative. CT and MRI brain were unremarkable. As the patient's mental status improved, he developed tachycardia and hypertension. On private interview, he reported taking gamma-hydroxybutyrate (GHB) daily for his narcolepsy and had been trying to wean himself off of it. He was treated with benzodiazepines for GHB withdrawal. After several days, he decided to leave against medical advice. He was counseled to follow up with a neurologist and discharged with diazepam and levetiracetam.

IMPACT/DISCUSSION: This patient's risk factors for substance abuse included HIV positive status, male gender, and young age.¹ As GHB is the active ingredient in sodium oxybate, those who develop dependence also often have sleeping conditions such as narcolepsy. This patient's presentation of seizures, tachycardia, and hypertension is classic for sedative-hypnotic withdrawal.¹ There are few cases of GHB withdrawal reported in the United States, where GHB is a Schedule I drug. Standard toxicology screens do not detect GHB, making abuse difficult to diagnose.¹ This patient's GHB dependence was diagnosed after the patient revealed he has abused the drug to treat his narcolepsy. Fewer than half of patients with HIV have discussed their substance use with their providers.² A recent study revealed that current illicit drug use reduced patient comfort in discussing substance use. Patients with high self-efficacy had higher comfort in discussing substance use.² Providers should ask patients about substance use and help them to develop the knowledge and skills for self-efficacy. Such skills may have enabled our patient to discuss his GHB dependence with a provider prior to presentation, potentially preventing his seizure.

CONCLUSION: Young age, male gender, and diagnosis of HIV have been associated with increased risk of substance abuse. GHB abuse results in high morbidity and mortality and cannot be diagnosed by urine drug screen. It is important to empower patients to make them comfortable with discussions about illicit substance use References: 1. Busardo FP, Jones AW. GHB Pharmacology and Toxicology. *Curr Neuropharmacol*. 2015; 13(1): 47-70. 2. Ray MK et al. Patient and Provider Comfort Discussing Substance Use. *Fam Med*. 2013; 45(2): 109-117.

AMIODARONE: AN UNUSUAL CAUSE OF HEMOLYTIC ANEMIA

Joel Thomas; Maniraj Neupane; Anita B. Leon-Jhong. UPMC, Pittsburgh, PA. (Control ID #3163408)

LEARNING OBJECTIVE #1: Recognize that amiodarone is a rare cause of drug-induced hemolytic anemia.

LEARNING OBJECTIVE #2: Describe findings of hemolytic anemia on peripheral smear.

CASE: Ms. Z is a 75 year old woman with mechanical mitral valve replacement on warfarin, atrial fibrillation on amiodarone, and achalasia who was admitted to the medicine service for esophageal dilation and peri-procedural heparin bridging. After the procedure her hemoglobin dropped from 11.8 to 6.9 d/L over 11 days. Blood loss was initially attributed to a PICC-related upper extremity hematoma, but hemoglobin continued to fall even after the hematoma had stabilized. CT abdomen/pelvis was negative for retroperitoneal bleed and stool hemoccult was negative. Hemolytic work-up was pursued and demonstrated elevated LDH, undetectable haptoglobin, and peripheral blood smear with spherocytosis and reticulocytes. Her Coombs test was negative. Her medication list was reviewed and amiodarone was identified as the only agent with reported cases of hemolysis. Amiodarone was discontinued and she received 2 units of packed red blood cells for Hb. 6.9 d/L. She was discharged to rehabilitation in stable condition and her hemoglobin stabilized around 10 d/L over the next month.

IMPACT/DISCUSSION: Laboratory results suggestive of hemolysis include increased serum LDH and decreased haptoglobin levels. A peripheral blood smear should be obtained to confirm the diagnosis and identify possible etiologies. Reticulocytes are present in response to either hemolysis or acute blood loss. Heinz bodies and bite cells are suggestive of G6PD deficiency, and spherocytes are seen in hereditary spherocytosis or autoimmune hemolytic anemia. Other causes of hemolysis include sickle cell anemia, acute lead poisoning (basophilic stippling), diffuse intravascular coagulopathy (schistocytes). Drugs which are commonly associated with autoimmune hemolytic anemia include cephalosporins, penicillins, NSAIDs, levodopa, nitrofurantoin, dapsone, and quinine/quinidine. In this patient, the negative Coombs test in conjunction with the spherocytes and LDH + haptoglobin suggestive of hemolysis was a peculiar finding, as the vast majority of drug-induced hemolysis is Coombs-positive. Postulated mechanisms for Coombs-negative drug-induced hemolysis include antibody-free hemolysis by natural killer cells, low-affinity antibodies, and IgA-mediated hemolysis. Fortunately, the treatment of drug-induced anemia is straightforward: discontinuation of the drug and packed red blood cell transfusion as necessary.

CONCLUSION: Impact: This case broadens the differential for an unexplained drop in hemoglobin. The patient had red herrings of hematoma and a recent invasive procedure on anticoagulation. However, the undetectable haptoglobin and spherocytes suggested drug-induced hemolysis, and amiodarone was identified as the likely culprit.

AN ATYPICAL CASE OF MILLER-FISHER SYNDROME PRESENTING WITH SEVERE DYSPHAGIA AND WEIGHT LOSS

Kishan Patel¹; Arjun Dhawan¹; Eliezer Z. Nussbaum¹; Jason Sico^{2, 3};

Naseema B. Merchant^{1, 3}. ¹Yale School of Medicine, Middlefield, CT;

²Yale School of Medicine, New Haven, CT; ³VA Connecticut Health Care, West Haven, CT. (Control ID #3183461)

LEARNING OBJECTIVE #1: Diagnose atypical presentation of Miller-Fisher Syndrome (MFS)

LEARNING OBJECTIVE #2: Recognize dysphagia as an initial presentation of MFS

CASE: A 71-year-old male with smoking history was sent to the emergency department (ED) from the speech clinic after a failed outpatient swallow evaluation performed due to a 3-week history of dysphagia, soft voice and a ~30lb weight loss. Initial physical exam was notable for hypophonia but follow up exam over the next 24-48 hours showed, dysarthria, diplopia, bilateral horizontal ophthalmoparesis, unilateral ptosis, bilateral weakness with hip flexion, ataxia and hyporeflexia, with normal upper extremity strength. CT head was normal and MRI brain showed periventricular and subcortical white matter T2 hyperintensity. Nerve conduction study of the facial nerve and lower extremities showed

axonal sensorimotor polyneuropathy. Endoscopic speech evaluation also confirmed the severe dysphagia. CSF was notable for albuminocytologic dissociation (protein 49.9mg/dL, 2 nucleated cells), and serum anti-GQ1b antibodies were elevated (titer 1:200). The triad of ophthalmoplegia, areflexia, ataxia and CSF findings led to the diagnosis of the Miller-Fisher syndrome. The patient was treated with intravenous immunoglobulin (0.4 g/kg) for 5 days, 3 weeks of enteral tube feeds and at his clinic visit 6 weeks post discharge, he was eating regular diet and all his symptoms had resolved.

IMPACT/DISCUSSION: Miller-Fisher Syndrome (MFS) is rare, estimated to occur in 1-7% of patients with GBS in the western hemisphere. Dysphagia to both solids and liquids is an uncommon presentation for MFS, and is more typically associated with botulism, myasthenia gravis, multiple sclerosis, and brainstem stroke. Estimates from prior studies suggest that only 2% of patients with MFS present with dysphagia as their primary complaint. Although other reports have identified dysphagia as a symptom of MFS, to our knowledge, this is the first report in the adult literature that demonstrates severe dysphagia with significant weight loss as the presenting complaint. Although the etiology of dysphagia in MFS reported in the literature is not clear, studies have shown positive immunostaining of human glossopharyngeal and vagal nerves with anti-GQ1b IgG, suggesting that autoimmune neuropathy of these cranial nerves may play a role. Given the results of the FEES and nerve conduction studies, our patient likely had axonal damage to the vagus nerve, resulting in dysphagia. This case illustrates MFS can initially present with a predominant dysphagia. Secondly, other typical neurologic findings of MFS can be subtle and evolve over time.

CONCLUSION: Dysphagia can be the initial manifestation of MFS in some patients without any obvious deficits in the neurologic exam or neuro-imaging. Such patients should receive a thorough initial and follow up neurological exams, with particular attention to extraocular movements, reflexes, and gait, to rule out the possibility of MFS.

AN ATYPICAL PRESENTATION OF ATYPICAL PNEUMONIA: LEGIONELLA CAUSING GUILAIN-BARRE SYNDROME

Abigail Entz; Sarah Gorgis; Junior Uduman. Henry Ford Hospital, Detroit, MI. (Control ID #3186239)

LEARNING OBJECTIVE #1: Recognize an atypical presentation of Legionella pneumonia

LEARNING OBJECTIVE #2: Identify the association between Guillain-Barre variants and infectious syndromes

CASE: A 29 year-old-female with history of Systemic Lupus Erythematosus on plaquenil presented with two weeks of nausea, emesis, and cough. During that time she developed progressive numbness in bilateral lower extremities and began to experience falls at home. On presentation she was afebrile but hypoxic requiring intubation. She had no leukocytosis but did present with a moderate hyponatremia to 127. Chest x-ray showed patchy infiltrates and urine legionella antigen was positive. She was started on treatment with moxifloxacin. Her weakness progressed to involve all extremities and respiratory muscles with decreased reflexes. A lumbar puncture was unremarkable with WBC 0, RBC 3 and protein 45 mg/dL. Electromyography (EMG) on day nine of hospitalization showed severe sensorimotor axonal polyneuropathy. She was treated with five days of intravenous immunoglobulin (IVIg) and seven sessions of plasmapheresis with limited improvement in weakness. The patient eventually required tracheostomy due to persistent weakness. We present an atypical case of legionella pneumonia causing Guillain-Barre Syndrome.

IMPACT/DISCUSSION: Legionella is an important cause of community acquired pneumonia, often with severe symptoms and a mortality rate up to 10%. Patients with legionella pneumonia can present with extrapulmonary manifestations including emesis, diarrhea, chest pain, scant hemoptysis, and high fever. Mild neurologic symptoms including headache and encephalopathy are sometimes seen. There are few case reports of Guillain Barre

variants associated with legionella pneumonia, though over two-thirds of patients with GBS have a proceeding respiratory or gastrointestinal illness. The weakness associated with GBS is typically progressive, symmetrical, and ascending- with maximal weakness occurring within two-four weeks from symptom onset. Though up to one-third of patients may require mechanical ventilation, nearly 80 percent make a near-complete recovery. Both IVIg and plasmapheresis have demonstrated in randomized controlled trials to shorten time to neurologic recovery in GBS, though the recovery phase can take several months and can require intensive rehabilitation.

CONCLUSION: Though weakness in critically ill patients is often attributed to critical illness myopathy, careful attention should be paid to timing, intensity, and progression of neurologic symptoms. Guillain-Barre syndrome has a known association with infections therefore clinical suspicion should remain high in patients with the combination of infection and rapidly progressive weakness.

AN ATYPICAL PRESENTATION OF METASTATIC TESTICULAR CHORIOCARCINOMA

Mrigank S. Gupta; Marium Khan. Medical College of Wisconsin, Wauwatosa, WI. (Control ID #3186015)

LEARNING OBJECTIVE #1: Recognizing a unique presentation of choriocarcinoma in young males.

CASE: A 29 year-old male with a past history of gastroesophageal reflux and epididymitis presented to the emergency department with a two day history of a band like abdominal pain. Pain was associated with retching emesis that was yellow gastric mucous in nature progressing to blood tinged. The patient denied any hematochezia, melena, or any recent weight loss but endorsed constipation. Home medications included ibuprofen and pantoprazole. Vital signs included temperature 98.5F, heart rate 105 beats per minute, blood pressure 131/72 mm Hg, respiratory rate 20 breaths per minute and oxygen saturation 95% on room air. Physical examination was significant for a healthy appearing young male with café au lait lesions on his back. Abdomen was tender to palpation in lower quadrants, firm, normal bowel sounds with no rebound tenderness. The remaining exam was non-focal. Labs included white blood cell count 14.8e103 uL, Hgb 13.0 g/dL, platelet 273e103uL, lipase 20 units/L, INR of 1.1 and basic chemistry within normal limits. Computed tomography chest and abdomen revealed a large central abdominal mass surrounding the inferior mesenteric artery with unclear origin, multiple lesions consistent with metastatic disease. The mass compressed the distal inferior vena cava, abdominal aorta, common iliac artery, and the right ureter causing right hydronephrosis. Recommendation from radiation oncology included obtaining a testicular ultrasound which revealed a punctate echogenic foci of the right testicle. Interestingly, the patient had a testicular ultrasound six months prior which showed a similar echogenic region on his right testicle which was lost to follow up. Tumor markers significant for Beta-hCG (human chorionic gonadotropin) 364,215 mIU/L and AFP (alpha fetoprotein) 15 ng/ml. Liver biopsy illustrated syncytiotrophoblast and cytotrophoblasts, confirming stage 3 nonseminomatous germ cell tumor. A right ureteral stent was placed to relieve the obstruction and the patient was emergently started on VIP chemotherapy (etoposide, ifosfamide, and cisplatin).

IMPACT/DISCUSSION: Choriocarcinoma is a nonseminomatous germ cell tumor (NSGCT). It is seen in caucasian males in a bimodal distribution, ages 15 to 25 and great than 60 years of age. Choriocarcinoma produces large amounts of hCG and greater than 50,000 mIU/L is associated with a poor diagnosis. In adults, choriocarcinoma most frequently spread hematogenously to the lung and lymph nodes. In advanced cases, it can spread to liver, brain, and skin. Choriocarcinoma responds well to chemotherapy and should be started as soon as the diagnosis is made.

CONCLUSION: Early identification of testicular choriocarcinoma and initiation of chemotherapy is important in survival. Imaging modalities should be utilized if suspicion for malignancy is high or the patient's presentation is atypical.

AN ATYPICAL PRESENTATION OF MRSA PNEUMONIA

Akanksha Vaidya. Emory University, Atlanta, GA. (Control ID #3185817)

LEARNING OBJECTIVE #1: Review the typical presentation of MRSA pneumonia

LEARNING OBJECTIVE #2: Diagnose MRSA pneumonia in patients with atypical presentations

CASE: A 61-year-old woman with a history significant for asthma, possible sarcoidosis with chronic pulmonary nodules and hilar lymphadenopathy, and recent MRSA folliculitis, presented to the hospital with dyspnea. Patient reported fevers, chills, and rhinorrhea two weeks prior to presentation. The fevers and chills resolved, but she continued to have a cough productive of clear sputum and started having dyspnea on exertion that started four days prior to presentation. On hospital admission, she was afebrile, had a normal blood pressure, and had an oxygen saturation of 92% on room air. Her physical exam was notable for diffuse wheezing throughout bilateral lung fields. A chest X ray showed scattered micronodular opacities that were unchanged from a prior X ray two years ago. She was started on treatment for an asthma exacerbation with steroids, azithromycin, and bronchodilators. Her symptoms failed to improve after 7 days of treatment, so a CT scan of the chest was ordered. The CT scan showed small cavitary changes in the right lower lobe, suggestive of a necrotizing bronchopneumonia. She underwent CT guided biopsy of the cavitation and was positive for MRSA that was resistant to clindamycin. She was treated for MRSA pneumonia with a 14 day course of doxycycline with improvement in her symptoms.

IMPACT/DISCUSSION: Community acquired MRSA pneumonia typically presents as a severe pneumonia and has a high mortality rate. Compared to hospital acquired MRSA, community acquired MRSA is more likely to produce the Panton-Valentine leukocidin toxin that forms cavitary lung lesions. Patients typically present with severe hypoxia, severe dyspnea, fever, and hemoptysis. Identifying patients with MRSA pneumonia is crucial in order to start timely antibiotic therapy. The patient in this case did not have severe symptoms that are usually seen in MRSA pneumonia cases. However, she did have some risk factors for MRSA pneumonia. Patients with MRSA pneumonia will typically have a preceding flu-like illness. Patients with a history of MRSA infection or colonization are also at risk for MRSA pneumonia. The patient presented in this case had both of these common risk factors. Recognizing these risk factors for MRSA pneumonia can help identify patients with atypical presentations of the disease and ensure that the appropriate antibiotic therapy is started for the patients.

CONCLUSION: This case illustrates an atypical presentation of community acquired MRSA pneumonia. While MRSA pneumonia usually has severe symptoms, the patient in this case had mild symptoms, which made it difficult to identify the disease. It is important to recognize risk factors for MRSA pneumonia to identify patients with atypical presentations of the disease.

AN EMBOLIC ETIOLOGY OF NSTE-ACS

Kristie Yang; Eli Wilber. Emory University, Atlanta, GA. (Control ID #3184559)

LEARNING OBJECTIVE #1: Recognize features of NSTE-ACS secondary to infective endocarditis.

CASE: A 58 year-old man presented with one day of exertional chest pain that began while moving a refrigerator. He described the mid-sternal pain as "twinges" radiating to the left arm and leg not alleviated by rest. Associated symptoms included shortness of breath, diaphoresis, and numbness in his left fingers. One week prior he had similar pain that resolved with rest. He had not seen a healthcare provider in 30 years, had no known medical problems, and reported no family history of heart disease. He was a 30 pack-

year smoker and had poor dentition. Vitals were T 36.4, HR 79, BP 136/78, RR 18, SpO₂ 100% on room air. He had a grade IV/VI blowing systolic apical murmur with radiation to the axilla; there were no S3 or S4 heart sounds, no jugular venous distension. His lungs were clear to auscultation; there was no lower extremity swelling. Admission labs showed troponin of 12.5 and BNP of 1080. EKG had no ST-segment or T wave abnormalities. Left heart catheterization revealed an occluded small left posterior descending coronary artery, thought to be embolic in nature, and otherwise normal coronary arteries. Transthoracic echocardiography showed mitral regurgitation and a mobile mass on the mitral valve, which was confirmed by transesophageal echocardiography. Two sets of blood cultures grew gram positive cocci in chains and the patient was started on vancomycin and ceftriaxone. The cultures speciated to Streptococcus salivarius and antibiotic regimen was narrowed to ceftriaxone. His remaining teeth were removed and he was discharged to complete two weeks of antibiotics prior to evaluation for mitral valve replacement.

IMPACT/DISCUSSION: Mechanisms of non-ST segment elevation acute coronary syndrome (NSTE-ACS) in patients without coronary artery disease include vasospasm, myocarditis, vasculitis, and embolic disease. This patient had mitral regurgitation and poor dentition, but lacked cutaneous manifestations of infective endocarditis (IE). He developed a fever at the same time that echocardiography suggested a valvular vegetation, which in conjunction with positive blood cultures for a typical organism made this a definite case of IE by the modified Duke criteria. Embolic events occur in 45% of patients with IE and most commonly affect the brain and spleen, not coronary arteries. New murmur or worsened preexisting murmur is reported in 48% and 20% of IE cases, respectively. In this case, an abnormal exam finding in a NSTE-ACS patient with unexpected angiographic results prompted additional workup leading to the correct diagnosis. While an unusual presentation for both NSTE-ACS and IE, this case reinforces a foundational principle of medicine that a stepwise approach to history and exam findings can lead to successful diagnosis.

CONCLUSION: Infective endocarditis commonly presents as either an embolic stroke or heart failure, however, rarely emboli to coronary arteries can lead to NSTE-ACS.

AN IDIOSYNCRATIC CASE OF AMIODARONE-RELATED DRUG-INDUCED LIVER INJURY

Michael Seidman; Christopher Bruti. Rush University Medical Center, Chicago, IL. (Control ID #3186409)

LEARNING OBJECTIVE #1: Evaluate an unusual presentation of amiodarone-related Drug Induced Liver Injury (DILI)

LEARNING OBJECTIVE #2: Recognize clinical and historical factors contributing to the diagnosis of idiosyncratic DILI in medically complex patients

CASE: A 61-year-old man with known atrial fibrillation, diastolic heart failure, and stage III CKD presented with excessive bleeding following minor trauma to his toe. His medications included warfarin, diltiazem, metoprolol, and amiodarone, which was started 8 weeks prior. In addition to his minor wound, exam was notable for marked jaundice. He denied history of heavy alcohol use, hepatitis, IV drug use, recent travel, sick contacts, and was not sexually active. He felt otherwise well, noting improvement in his heart failure symptoms in recent months. In addition to supratherapeutic INR attributed to amiodarone-warfarin interaction, labs were notable for cholestatic liver enzyme derangement and elevated bilirubin. Warfarin and amiodarone were discontinued and he was admitted for work-up. A thorough infectious and immunologic workup was negative, and Imaging and MRCP were unrevealing. Given unclear etiology a liver biopsy was obtained, demonstrating cholestatic injury without steatosis, Mallory bodies, or lamellar inclusions. Inflammatory changes were consistent with a variety of etiologies including cardiac, sepsis and DILI. Hepatic labs continued to worsen and in the 2nd week of

admission, the patient's renal function deteriorated with acute tubular necrosis, progressing to anuric ESRD requiring hemodialysis. The patient was evaluated for liver transplantation but declined given concurrent multiorgan failure. Over subsequent weeks the patient's liver function gradually improved and he was ultimately discharged.

IMPACT/DISCUSSION: While congestive hepatopathy was initially suspected, this patient's concurrent improvement in CV symptoms made cardiac etiology less likely as a primary mechanism. Amiodarone is a common antiarrhythmic, prescribed over 2.9 million times in the US in 2016. Amiodarone has a known propensity for hepatotoxicity, with 1% of patients developing clinically-evident liver disease annually. Amiodarone-related hepatotoxicity typically manifests as hepatocellular-pattern injury, with biopsy demonstrating steatosis with Mallory bodies and lamellar inclusions. In this case, we characterize a potential idiosyncratic presentation of amiodarone-related DILI not yet represented in the literature. Diagnosis in this case was reached only through careful history-taking and negative work-up of alternatives.

CONCLUSION: Idiosyncratic drug toxicities may be subtle and difficult to differentiate in medically complex patients. Clinicians must be vigilant in their diagnostic work-up and maintain a high degree of suspicion for idiosyncratic DILI. Clinical understanding of adverse drug reactions is constantly evolving; only through proper diagnosis, characterization, and reporting of such injuries can we increase medical knowledge of unusual reactions to common medications.

AN IMMUNOHEMOLYTIC PRESENTATION OF PERNICIOUS ANEMIA.

Steven Omansky¹; Patricia Dharapak². ¹Mount Sinai Beth Israel Hospital, New York, NY; ²Mount Sinai Beth Israel, New York, NY. (Control ID #3162810)

LEARNING OBJECTIVE #1: To understand the potentially overlapping etiologies for hemolysis in autoimmune pernicious anemia.

CASE: A 33 year-old US born woman with iron deficiency anemia presented after one episode of pre-syncope. She reported 3 weeks of progressive fatigue, shortness of breath, and pain in the chest, back, and hips. She denied abdominal pain, menstrual abnormalities, sick contacts, recent trauma, and blood disorders or malignancy in her family. She did not take any medications or herbal supplements and reported tolerating a normal, unrestricted diet. Her exam was remarkable for tachycardia and mucosal pallor at the conjunctiva and soft palate. Labwork revealed a hemoglobin of 4.5 g/dL, macrocytosis to 114 fL with an RDW of 30.6%, and platelet count of 108,000 per μ L. Her RBC count was 1.11 M/ μ L with a reticulocyte production index of 0.9%. Packed red blood cells were transfused with an appropriate response. Additional work-up was significant for a markedly elevated LDH (7035 U/L) and reduced haptoglobin (<8 mg/dL). A peripheral smear showed schistocytes and anisocytosis, and a direct Coombs test was positive. Pulse dosed steroids were started for suspected autoimmune hemolytic anemia (AIHA). A serum folate level was normal, but a cobalamin level was undetectable. Subsequent methylmalonic acid and homocysteine levels were elevated, so daily intramuscular methylcobalamin was initiated. At the time of discharge, her hemoglobin had improved to 9.1 g/dL and her presenting symptoms had resolved. Serum anti-intrinsic factor and anti-parietal cell antibody assays later returned positive and confirmed a diagnosis of autoimmune pernicious anemia (PA).

IMPACT/DISCUSSION: We present a case of combined AIHA and PA resulting in severe, symptomatic anemia. The prevalence of cobalamin deficiency is <3% in adults 20–39 years old with about 40% attributed to PA, but the incidence of PA with concurrent AIHA is unknown. A previous study of 865 patients with a positive direct Coombs test found PA in 3 lone subjects, and only 23 other case reports of dual-diagnosis have been published since 1951. Some of these reports found transiently positive Coombs tests that resolved after cobalamin supplementation.

Conversely, PA can lead to hemolysis in the absence of AIHA less than 2% of the time due to rapid and ineffective erythropoiesis. This can be detected by the reticulocyte production index; if found low, as in our case, there is evidence of lysis within the bone marrow. Although rare, these examples highlight the importance of investigating multiple etiologies of hemolytic anemia, else risking incomplete treatment of the patient.

CONCLUSION: Cobalamin deficiency caused by autoimmunity often leads to PA and can expeditiously improve with steroids and cobalamin supplementation. PA is often associated with other autoimmune conditions, although concurrent presentation with AIHA is rare. Investigating all potential etiologies for hemolytic anemia minimizes the risk for incomplete treatment and relapse.

AN INSIDIOUS ENCEPHALOPATHY: A CASE OF DISSEMINATED COCCIDIOMYCOSIS

Xin Zhang; Kyle McKenzie. Mayo Clinic, Rochester, MN. (Control ID #3181400)

LEARNING OBJECTIVE #1: Recognize signs and symptoms of coccidioidal meningitis

LEARNING OBJECTIVE #2: Manage treatment of coccidioidal meningitis

CASE: A 74 year old non-immunosuppressed, male farmer from Minnesota was hospitalized with confusion. 6 months ago, he presented to the emergency department for 1 month of non-productive cough and intermittent fevers. Coccidioides antibody testing was obtained due to frequent travel to Arizona, but he did not receive news that it was positive. Over the next few months, he developed progressive dizziness, lethargy and confusion. MRI brain showed extensive basilar meningitis. Opening pressure was normal on lumbar puncture and CSF analysis was consistent with chronic meningitis. He was diagnosed with Coccidioidal meningitis after CSF Coccidioides PCR and anti-Coccidioides antibody returned positive. Evaluation for immunosuppressive conditions was negative. He was discharged on fluconazole. Two months later, he was hospitalized due to seizures. Repeat MRI demonstrated vasculitis associated with meningoencephalitis and an acute lacunar infarct. CSF specimen was obtained and showed no evidence of persistent meningitis. He was started on levetiracetam and dexamethasone for CNS vasculitis secondary to disseminated coccidioides. Despite the above treatment, he continued to have seizures, persistent encephalopathy, and progressive functional decline. He ultimately decided to pursue comfort cares and passed away 4 months after original diagnosis.

IMPACT/DISCUSSION: Coccidioidal meningitis is a rare presentation of disseminated coccidiomycosis. It is associated with a high mortality rate of 95% within 2 years for untreated patients. The most common sign is persistent headache, but nonspecific symptoms and subacute presentation makes diagnosis difficult. Diagnosis can be made definitively by identifying Coccidioides in the CSF or presumptively by finding anti-Coccidioides antibodies in the CSF. CNS findings include hydrocephalus, basilar meningitis and vasculitic cerebral infarction. The cerebral vasculitic infarctions occur in setting of inflammation of small and medium sized cerebral arteries and clinically affect 10% of patients. The IDSA recommends oral fluconazole 400-1200 mg as initial treatment for coccidioidal meningitis. If treatment failure occurs, clinician can increase fluconazole dose, change azole, or use intrathecal amphotericin B. Of note, lifelong azole therapy is recommended to prevent recurrence. Corticosteroid has been shown to reduce recurrence of vasculitic cerebral infarctions in a retrospective study, but its use is controversial.

CONCLUSION: 1. Coccidioidal meningitis can present with hydrocephalus, basilar meningitis and vasculitic cerebral infarction. 2. Patients should remain on lifelong azole therapy. 3. In patients with cerebral infarctions, corticosteroid can be considered to prevent recurrent vasculitic infarctions.

AN INTERESTING PRESENTATION OF "HEART FAILURE"

Priyanka Ballal; Albin Oh. Boston Medical Center, Boston, MA. (Control ID #3183312)

LEARNING OBJECTIVE #1: Recognize a formidable diagnosis masquerading as acute decompensated heart failure.

CASE: A 61-year-old-female with a history of diastolic heart failure and atrial fibrillation presented to the emergency room with progressively worsening lower extremity edema, shortness of breath and orthopnea as well as a 15 kg weight gain over the last eight weeks. She noted the above symptoms despite faithfully taking her home diuretic as prescribed and adhering to a salt restricted diet. Her heart failure had been previously well controlled, with no hospital admissions for decompensation. Physical exam was consistent with volume overload as evidenced by jugular venous distention to 14 cm, crackles over bilateral lung bases, marked abdominal distention, and pitting peripheral edema extending to mid-thigh bilaterally. Importantly, she was noted to have a large abdominal mass with ill-defined borders, palpable in all quadrants. A CT abdomen and pelvis was then obtained which revealed a large complex cystic structure measuring 15 x 28 cm encompassing most of the abdomen and pelvis, compressing the inferior vena cava and abutting the inferior margin of the liver. Origin of the mass was unclear. This was followed by a dedicated MRI pelvis with contrast which did not visualize the left ovary, making the mass concerning for an ovarian primary. The patient was admitted to the medicine service, with general surgery and gynecology-oncology services consulted for operative management. On hospital day 2, the patient developed liver dysfunction with direct hyperbilirubinemia, elevated transaminases and alkaline phosphatase, concerning for congestive hepatopathy. After pre-operative cardiology clearance, she underwent exploratory laparotomy with left salpingo-oophorectomy, excision of the pelvic mass with omental dissection and lysis of adhesions. Patient tolerated the surgery with no major complications. Post operatively, however, she developed volume overload, thought to be due to peri-operative fluid resuscitation. She was diuresed with furosemide boluses over 4-5 days till she attained euolumia. Her liver dysfunction completely resolved after surgery. The pathology report revealed benign mucinous cystadenoma with no evidence of malignancy in the omentum. Patient was discharged with physical rehabilitation services and is currently doing well.

IMPACT/DISCUSSION: This case illustrates the varied clinical presentation of an adnexal mass and the importance of a detailed physical examination, even when the diagnosis may seem apparent with just a thorough history. It is important to note that ovarian tumors do not present with menstrual symptoms, with the exception of sec cord tumors, and are often asymptomatic until their sheer size causes pressure related symptoms, like described in our case. Prognosis of benign ovarian tumors after operative management is excellent.

CONCLUSION: Timely diagnosis and operative management is key to avoid adverse outcomes in benign ovarian tumors.

AN OFFAL ABSCESS: NON-ENDOCARDITIS ERYSIPELOTHRIX BACTEREMIA AND ABSCESS FORMATION

Kathryn Snyder¹; Jennifer Keen²; LeeAnn M. Cox². ¹Indiana University School of Medicine, Carmel, IN; ²Indiana University School of Medicine, Indianapolis, IN. (Control ID #3182931)

LEARNING OBJECTIVE #1: Recognize patient characteristics that increase the risks for systemic infection with the zoonotic organism *Erysipelothrrix*.

LEARNING OBJECTIVE #2: Recognize that while initial non-operative management of epidural abscesses may be reasonable, close monitoring with early re-imaging for changing numbness, weakness or pain is necessary.

CASE: A 60 year old male with history of multiple myeloma (MM), alcohol abuse, and treated Hepatitis C was admitted to the hospital for unintentional acetaminophen overdose secondary to attempts at relieving three days of severe right-sided lower back pain. The pain became progressively worse over the prior three days with radiation down his right leg and an associated perception of "weakness" in his lower extremities. He denied fevers or any trauma/injury. He presented to the ED due to increased pain despite attempts to self-treat with large doses of acetaminophen, ibuprofen, and significant amounts of alcohol. Incidentally, he noted that about one week prior to his admission he had a generalized "purplish" rash that spontaneously resolved. On admission he was initially afebrile and without leukocytosis. His physical exam did not demonstrate any sensory deficits or overt asymmetrical weakness, though the exam was limited by his pain and intoxication. While his MM had been monitored and stable for a long time, his back pain was concerning and an MRI was obtained. Concurrently, he developed fevers, and blood cultures were drawn with initiation of broad spectrum antibiotics. The MRI was notable for a paravertebral and epidural abscess with osteomyelitis. Cultures from blood and the abscesses were initially reported as "diphtheroids" but later identified as *Erhusiopathiae*. The infection progressed despite initial drainage thus urgent L3-5 laminectomy with debridement was completed. A transesophageal echo demonstrated no endocarditis, and the patient was treated with continuous IV Penicillin for eight weeks. Patient later shared he was a chef with frequent work-related hand injuries. He recalled a "cellulitis" of his left hand after making "head cheese" from a raw pig head a month prior to admission. This had been treated outpatient with a course of clindamycin and apparent clinical resolution. His bacteremia and abscesses were likely related to butchering the pig head.

IMPACT/DISCUSSION: This case demonstrates a rare presentation of *Erysipelothrrix* infection manifesting as bacteremia with paravertebral and epidural abscesses, but lacking endocarditis. It additionally emphasizes the importance of appropriate surgical management and consideration of occupational exposures in the patient history.

CONCLUSION: *Erysipelothrrix* is a rare, invasive pathogen in humans. It remains an important consideration in patients with relevant exposure history. A detailed, chronologic history is important to identify potential exposures. Non-operative management for epidural abscess is reasonable, but close monitoring and early re-evaluation is necessary.

AN UNCOMMON CASE OF COMPLETE HEART BLOCK

Anisha Contractor¹; Deirdre Lewis²; Jason Phillipi². ¹UMMS-Baystate Medical Center, Easthampton, MA; ²Baystate Medical Center, Northampton, MA. (Control ID #3185684)

LEARNING OBJECTIVE #1: Recognize non-specific presentations of sarcoidosis.

LEARNING OBJECTIVE #2: Distinguish isolated cardiac sarcoidosis from systemic disease.

CASE: A 59-year-old African American male with past medical history of recurrent palpitations and hypertension on nadolol presented to the hospital with syncope, bradycardia, and new onset complete heart block. Laboratory data significant for pro-BNP elevation to 1254 pg/mL, and rising ACE and ionized calcium levels to 75 U/L and 1.39 mM respectively. Lyme C6 antibody negative. The patient failed emergent stabilization and required a permanent pacemaker. Electrophysiological and radiological evidence present prior to patient's presentation guided medical decision making to obtain cardiac PET. This study confirmed active sarcoid involvement of the distal aspect of the anterior wall of the heart, intraventricular septum, and inferior aspect of the right ventricle.

IMPACT/DISCUSSION: Sarcoidosis is an autoimmune disease characterized by non-caseating granuloma formation within multiple tissues, commonly affecting the lymphoreticular system, lungs, eyes and skin. Peak incidence of systemic disease among adults occurs between 20 and 39, with female predominance. Though uncommon, sarcoidosis can

present in patients over 60 with a similar gender predilection. Ethnic prevalence is higher among African American, Scandinavian and Japanese populations. Sarcoidosis can encompass diverse clinical presentations and as such lend itself to delayed diagnosis. Furthermore, there is no established diagnostic criterion; diagnosis relies on clinical and radiological evidence, pathology consistent with noncaseating granulomas, and exclusion of disorders with similar presentation and histopathology. Among patients diagnosed with sarcoidosis 5% will clinically manifest cardiac sarcoidosis (CS). The extent of left ventricular dysfunction is the most important predictor of prognosis among patients with clinically manifest CS, guiding treatment with steroids or assisted devices. CS may be further defined as systemic or confined to the heart, known as: isolated cardiac sarcoidosis (ICS). The rate of ICS is about 25% among cases of CS. Diagnosis of ICS involves excluding extra-cardiac involvement combined with cardiac MRI and PET. It is important to identify because patients with ICS have worse left ventricular systolic function at presentation compared to patients with systemic sarcoidosis and CS. Prognosis for patients with ICS is poor as patients are prone to ventricular arrhythmias and less event-free survival.

CONCLUSION: Sarcoidosis can be difficult to diagnose due to variable presentation. Early recognition of isolated cardiac sarcoidosis and extra-cardiac disease is crucial for prevention of critical complications.

AN UNCOMMON CAUSE OF TERTIARY ADRENAL INSUFFICIENCY

Zachary Reese; Shoshana J. Herzig; Gila Kriegel. Beth Israel Deaconess Medical Center, Brookline, MA. (Control ID #3177781)

LEARNING OBJECTIVE #1: Understand the physiology and causes of tertiary adrenal insufficiency

LEARNING OBJECTIVE #2: Recognize common symptoms of carcinoid syndrome of neuroendocrine tumors

CASE: A 60-year-old female with history of hypertension presented with asymptomatic hypotension of 70/50. She noted a 10-pound weight loss in the preceding 6 months, and worsening diarrhea. Medications included lisinopril daily. She had a 60-pack year smoking history, and quit 6 months prior to admission. Family history was notable for metastatic melanoma in her mother. While inpatient, she was found to have orthostatic hypotension. A morning cortisol level was low at 1.7 ug/dL (nL 2-20 ug/dL), and responded appropriately to cosyntropin stimulation test (20.2 ug/dL, 60 minutes after cosyntropin administration). Serum ACTH was low-normal at 6 pg/mL (nL 6-50 pg/mL). A CT scan of the torso revealed hilar lymphadenopathy, bilateral lung masses, and retroperitoneal lymphadenopathy, all concerning for malignancy. MRI brain showed masses in the hypothalamus and parieto-occipital lobe. Biopsy of the hilar lymphadenopathy revealed well-differentiated neuroendocrine tumor. She was discharged on hydrocortisone. For treatment of her neuroendocrine tumor, she underwent radiation to the brain metastases, and was started on octreotide and everolimus. In follow-up, her orthostatic hypotension had resolved.

IMPACT/DISCUSSION: This case highlights an uncommon cause of tertiary adrenal insufficiency. Tertiary adrenal insufficiency arises when there is interference with secretion of corticotropin-releasing hormone (CRH) from the hypothalamus, leading to lower ACTH from the pituitary gland, and a decrease in cortisol release from the adrenal gland. Tertiary adrenal insufficiency is most commonly caused by abrupt cessation of chronic steroid administration, but can also be caused by invasion of the hypothalamus, as seen in this case. Treatment is aimed at treating the underlying cause, and administering glucocorticoids. Neuroendocrine tumors (NETs) are neoplasms arising from epithelial cells of the gastrointestinal and/or bronchopulmonary tract. NETs release serotonin, histamine, and prostaglandins into the circulation. These can cause a constellation of symptoms, called carcinoid syndrome, which most commonly manifest as cutaneous flushing (85%), and diarrhea (80%). Carcinoid syndrome is commonly seen in metastatic neuroendocrine disease. While

well-differentiated NETs typically metastasize to the liver, lymph nodes, and bones, they metastasize to the brain only 10% of the time. Treatment of metastatic NETs includes somatostatin analogues (e.g. octreotide) and mTOR inhibitors (e.g. everolimus), in addition to stereotactic radiation to brain metastases.

CONCLUSION: Metastatic disease to the hypothalamus can cause tertiary adrenal insufficiency, which is treated with steroids and treatment of the underlying malignancy. Cutaneous flushing and diarrhea are the most common symptoms of carcinoid syndrome, arising most commonly with metastatic neuroendocrine tumor.

AN UNCOMMON CULPRIT OF NECK PAIN

Islande Joseph¹; Nida Waheed²; Keely Fischbach¹. ¹University of Florida, Gainesville, FL; ²University of Florida, Gainesville, FL. (Control ID #3183332)

LEARNING OBJECTIVE #1: Identify the clinical features and risk factors for Salmonella Osteomyelitis (OM)

LEARNING OBJECTIVE #2: Diagnose and manage Salmonella OM

CASE: A 59 year-old female with a medical history of scoliosis, depression, and ADHD presented to her PCP for bilateral neck pain after cleaning her home ceiling fan. Due to persistent neck pain and new numbness, tingling, and dull pain in her right index finger, an MRI was ordered and showed abnormalities in C3, C4, C6, and C7 concerning for OM. She was transferred to our tertiary care center for a neurosurgical evaluation of C-spine OM. She denied any prior spinal trauma, IV drug use, diarrhea/foodborne illnesses, other weakness or numbness as well as changes in gait, bowel, or bladder function. Repeat cervical spine imaging showed C5-C7 with phlegmon involving the epidural space, narrowing the spinal canal and extending to her paravertebral soft tissue. Physical exam did not reveal point tenderness along her cervical spine, but she was placed in a c-collar per neurosurgery recommendations and routine neurological checks demonstrated no neurological deficit. Patient's labs revealed WBC and CRP values within normal limits, but her ESR was elevated at 48. Infectious disease was consulted and she was started on vancomycin and cefepime after interventional radiology performed a CT guided cervical disc aspiration. Aspiration biopsy culture was positive for pan-sensitive salmonella. TTE and abdominal ultrasound did not demonstrate concern for endocarditis or aortic aneurysm, respectively. Her antibiotics were de-escalated to ceftriaxone 2gm daily. She was discharged with continued administration of ceftriaxone for 6-8 weeks with weekly CBC with diff, creatinine, AST, ALT, ESR and hs-CRP as well as outpatient follow up with neurosurgery and infectious disease.

IMPACT/DISCUSSION: Salmonella OM is rare especially in an otherwise healthy individual. Salmonella is the causative organism in 0.45% of OM cases and salmonella OM itself accounts for as few as 0.8% of all salmonella infections. Salmonella typically effects the diaphysis of long bones, predominantly the femur and humerus. Histopathology of OM reveals necrotic bone with extensive resorption adjacent to an inflammatory exudate. It is predominantly seen in patients with hemoglobinopathies, including sickle cell disease or thalassemia. Due to the rarity of Salmonella OM, there are standardized antibacterial therapy regimes or surgical procedures. But chloramphenicol, third generation cephalosporins and fluoroquinolone are commonly used antimicrobials. Salmonella OM can be chronic, relapsing and difficult to treat.

CONCLUSION: Salmonella OM is rare. Further studies are needed to solidify treatment modalities. Early diagnosis and multidisciplinary management are necessary.

AN UNCOMMON PRESENTATION OF SPLENIC MARGINAL ZONE LYMPHOMA AS SPLENIC INFARCTIO

David Daniel²; Ribka Ayana¹. ¹Washington DC VA Medical Center, Washington DC, DC; ²George Washington University Hospital, Washington, DC. (Control ID #3186075)

LEARNING OBJECTIVE #1: Articulate the differential diagnoses for splenic infarction

LEARNING OBJECTIVE #2: Recognize the typical clinical presentation and indication for treatment of splenic marginal zone lymphoma

CASE: A 66-year-old man presented with an eleven-day history of severe, left upper quadrant abdominal pain. The pain was constant, non-radiating, exacerbated by inspiration and alleviated by NSAID use. His examination was notable for a non-tender abdomen and splenomegaly. Laboratory studies revealed mild leukocytosis (12.8), thrombocytopenia (72) and marginally elevated LDH. CT of abdomen and pelvis with intravenous contrast revealed enlarged spleen with an 8 x 5cm well defined hypodensity in the lower pole of the spleen consistent with splenic infarction. Vascular team recommended initiating heparin drip and obtaining abdominal CTA, which revealed patent splenic artery and vein. A transthoracic echocardiogram was also performed and was normal. Additional work up; including infectious (HIV Ab, t-spot, hepatitis panel), antiphospholipid panel, CT of chest, tumor markers (PSA, CA-19-9, CEA) was unrevealing. On day three of hospitalization, patient underwent a bone marrow biopsy, which revealed findings consistent with mature B-cell lymphoma, clinically consistent with splenic marginal zone lymphoma. Because the malignancy was symptomatic, patient was started on rituximab.

IMPACT/DISCUSSION: Splenic marginal zone lymphoma (SMZL) typically presents asymptotically with splenomegaly, lymphocytosis, and cytopenia (anemia and thrombocytopenia). Rarely does SMZL present as a splenic infarction. This case represents one of the few reported cases in the literature. The differential diagnosis for splenic infarction includes hypercoagulable state, embolic disease, myeloproliferative disease, sickle cell disease, infectious mononucleosis, splenic trauma, or any condition that causes marked splenomegaly. SMZL is an uncommon indolent subtype of non-Hodgkin's lymphoma, making up less than 1% of all NHLs, which is characterized by infiltration of pre-existing lymphoid follicles and marginal zone differentiation in the spleen. Diagnosis is made based upon pathological findings by lymphocyte morphology, immunophenotype, cytogenetic analysis, and bone marrow histology. Not all patients with SMZL require immediate treatment because of its indolent nature. Treatment is only recommended in patients with symptoms related to splenomegaly such as abdominal discomfort or early satiety and patients with cytopenia because of bone marrow involvement. First line treatment for SMZL primarily involves rituximab monotherapy. Splenectomy is typically only considered in patients with severe localized abdominal symptoms due to splenomegaly as well as cytopenia due to splenic sequestration.

CONCLUSION: Splenic infarction is an atypical presentation of SMZL. It is important to consider SMZL in patients with splenic infarction, splenomegaly and lymphocytosis. Rituximab monotherapy is the primary treatment in patients with symptomatic SMZL.

AN UNEXPECTED CASE OF WERNICKE'S ENCEPHALOPATHY IN THE ABSENCE OF ALCOHOL USE

Nancy Desai; Vassiliki Pravodelov; Won Lee. Boston Medical Center, Boston, MA. (Control ID #3152943)

LEARNING OBJECTIVE #1: Appreciate the possible causes of Wernicke's Encephalopathy (WE) in a patient without alcohol use

LEARNING OBJECTIVE #2: Understand the diagnostic criteria associated with WE

CASE: A 68-year-old woman with hypertension, major depressive disorder and recent homelessness presented to the hospital with nausea, vomiting and weight loss for 2 months. Her symptoms were thought to be psychosomatic given her underlying psychiatric disease and an unremarkable prior work up. During her hospitalization, the patient became confused, unable to recall why she was in the hospital and confabulating. She denied prior substance use including alcohol. Exam was significant for a right beating nystagmus with slowed eye movements and a slow gait.

No ataxia was appreciated. Notably, she had an undetectable thiamine level (<7 nmol/L). Imaging was significant for symmetric FLAIR hyperintense signal abnormality in the bilateral thalamus and central midbrain, suggestive of a toxic-metabolic process such as WE. She was started on intravenous thiamine supplementation and then transitioned to oral supplementation. A feeding tube was placed for nutritional support given her altered mental status, and the patient was discharged. The patient returned home after spending two weeks at a rehabilitation facility where her gastrointestinal symptoms as well as her cognitive, functional and nutritional status improved.

IMPACT/DISCUSSION: WE is a neurologic emergency secondary to thiamine deficiency requiring prompt treatment with thiamine repletion. It is commonly associated with alcohol use disorder; however, a number of other etiologies can result in acute thiamine deficiency including gastrointestinal disorders or surgeries, hemodialysis, malignancy, infection or prolonged nutritional deficiencies. WE is a clinical diagnosis classically associated with a triad of mental status changes, ataxia, and oculomotor dysfunction. As with our patient, this triad is not always present, and one can alternatively use Caine's criteria which has been shown to be more sensitive in identifying at risk patients. Caine's criteria require two of the following: dietary deficiencies, oculomotor abnormalities, cerebellar dysfunction and either an altered mental state or mild memory impairment. While plasma thiamine levels were low in this particular patient, they do not generally correlate with a diagnosis of WE. In terms of imaging, MRI is a more sensitive modality than CT and MRI findings typically include increased symmetrical T2 and FLAIR signals in the bilateral medial thalamus, the mammillary bodies, tectal plate, periaqueductal area or around the third ventricle. There are no established guidelines in the United States regarding thiamine repletion, but it is recommended that immediate IV thiamine be given when WE is suspected.

CONCLUSION: Consider WE in a patient without history of alcohol use before attributing mental status changes to a chronic or irreversible cause. Clinical history and exam are key in identifying patients at risk for this disease.

AN UNEXPECTED CAUSE OF CHEST PAIN

Austin Rezigh; Nicholas Breitnauer. University of Colorado at Denver - Anschutz Medical Campus, Aurora, CO. (Control ID #3185874)

LEARNING OBJECTIVE #1: Recognize the features of chronic cavitary pulmonary aspergillosis

CASE: A 43-year-old woman presented to a tertiary care center with dyspnea and acute worsening of chronic, left-sided, pleuritic chest pain. There was no preceding trauma, recent travel, or sick contacts. She did report fatigue and a productive cough but denied fever, chills, or weight loss. She had no past medical or surgical history and was on no medications. She was uncertain of her family history. She was a lifetime non-smoker and denied alcohol and drug use. Socially, she was born in Somalia and had moved to the US ~1 year prior to presentation after spending 11 years in an Ethiopian refugee camp. Evaluation for tuberculosis, just prior to immigration, was negative. On arrival, vital signs were unremarkable. Physical exam was notable only for decreased left-sided breath sounds. Initial laboratory work-up with CBC, BMP, D-dimer, and troponin were all within normal limits. EKG revealed normal sinus rhythm without ST segment changes. A chest radiograph showed absent lung markings on the left with a small layering effusion. Contrast-enhanced computed tomography revealed right upper lobe bronchiectasis and near complete destruction of the left lung parenchyma with replacement by a large cavity. The Pulmonary and Infectious Disease services were consulted, following which the patient underwent bronchoalveolar lavage (BAL). While AFB cultures from the BAL returned negative, fungal culture returned positive for *Aspergillus fumigatus*. A corresponding serum *Aspergillus fumigatus* IgG level returned markedly elevated at >100 U/mL. Together, these findings were consistent with a diagnosis of chronic cavitary pulmonary aspergillosis (CCPA). The patient had a brief

and uncomplicated hospital course. She was discharged on voriconazole 200mg BID with plans for a prolonged course. At last follow-up 3 months post-discharge, she was doing well.

IMPACT/DISCUSSION: CCPA, the most common form of chronic pulmonary aspergillosis, is characterized by: 1. Serologic and/or culture evidence of Aspergillus, 2. One or more pulmonary cavities, and 3. At least three months of pulmonary and/or systemic symptoms - most commonly weight loss, cough (usually productive), shortness of breath, and hemoptysis. While generally occurring in immunocompetent patients, most have underlying lung disease - most commonly COPD or prior +/- concurrent history TB/NTM infection. Important considerations in the differential diagnosis for CCPA include other cavitating infections, malignancy, granulomatosis with polyangiitis, and pulmonary embolic phenomena.

CONCLUSION: Chronic cavitary pulmonary aspergillosis, the most common form of chronic pulmonary aspergillosis, should be considered in patients with respiratory +/- constitutional symptoms and cavitary changes on lung imaging. The principal test to support this diagnosis is a positive Aspergillus IgG from the serum.

AN UNEXPECTED PREGNANCY RESULT THAT LED TO THE DIAGNOSIS OF GASTRIC CANCER

Jordonna Brown¹; Odeth Barrett-Campbell¹; Carol A. Luhrs². ¹SUNY Downstate Medical Center, Brooklyn, NY; ²Downstate Medical Center, Brooklyn, NY. (Control ID #3185892)

LEARNING OBJECTIVE #1: To diagnose gastric cancer in a non-pregnant woman with elevated hCG

LEARNING OBJECTIVE #2: To recognize elevated hCG as an important prognostic factor in gastric cancer

CASE: A 47-year-old woman with a history of uterine fibroids presented with 2 weeks of vague intermittent abdominal pain, nausea and vomiting. She denied weight loss, early satiety or alteration in bowel habits and her last menstrual period was one week prior to presentation. Her physical examination revealed normal vital signs and generalized abdominal tenderness without rebound or guarding. Labs were significant for hemoglobin 7.7 (12-15g/dL), MCV 80.4 (80-96 fL/red cell), Iron 14 (40-155ug/dL), TIBC 265 (240- 450 ug/dL), ferritin 9.9 (12-150ng/dL), alkaline phosphatase 476 (40-100 U/L), positive urine hCG with serum hCG of 75.0 (0-5mIU/ml). Transabdominal ultrasound showed an intramural uterine density and no evidence of an intrauterine pregnancy. CT abdomen-pelvis revealed ascites, multiple retroperitoneal, intraabdominal and pelvic lymphadenopathy, suspicious for metastatic disease or lymphoma and an ill-defined heterogenous density along the uterine fundus. A left para-aortic lymph node biopsy showed poorly differentiated metastatic adenocarcinoma with signet cell features suggestive of a gastric primary. Subsequent esophagogastroduodenoscopy and biopsy, confirmed poorly differentiated gastric adenocarcinoma. She received Cisplatin and 5-Fluorouracil with transient improvement in her HCG but unfortunately, she developed pleural effusions, profound thrombocytopenia, and pulmonary hemorrhage then succumbed to her illness within 3 months of diagnosis.

IMPACT/DISCUSSION: Gastric cancer is one of the leading causes of cancer mortality in the world and most patients present with advanced or widely metastatic disease. There are currently no specific tumor markers that have adequate sensitivity or specificity for diagnosis or follow-up of gastric cancer. However, serum levels of CEA, CA 125, CA 19-9, CA 72-4 and even less commonly hCG may be elevated in patients with gastric cancer and are associated with a poorer prognosis, though the use of these markers has not been standardized for clinical practice. The hormone hCG is used to monitor pregnancy and is a sensitive and specific marker for trophoblastic tumors of placental and germ cell origin. Outside of these contexts elevated levels of hCG are usually associated with malignancies such as breast cancer, leiomyosarcoma, pancreatic cancer, lymphoma, leukemia and gastric cancer. The role of hCG in the progression of gastric

cancer remains unclear but its presence is usually consistent with a more poorly differentiated tumor and associated worse prognosis.

CONCLUSION: In the absence of pregnancy, elevated hCG is an ominous sign for malignancies that are not limited to trophoblastic tumors and include gastric cancer. The presence of hCG in gastric cancer signifies aggressive malignancy with significant prognostic implications.

AN UNEXPLAINED CASE OF BILATERAL OPTIC NEURITIS

Katie O'Brien¹; Joshua Price¹; Deirdre Lewis². ¹UMMS Baystate, Springfield, MA; ²Baystate Medical Center, Northampton, MA. (Control ID #3184943)

LEARNING OBJECTIVE #1: Generate a differential diagnosis for bilateral optic neuritis

LEARNING OBJECTIVE #2: Recognize clinical features that suggest a diagnosis of CRION

CASE: A 19 year old previously healthy female presented to her optometrist's office with 2 weeks of progressive blurry vision. Her exam revealed elevated intraocular pressure and she was treated for glaucoma. Follow up 4 days later revealed improved pressures but deteriorating vision with complete loss of light perception and vision in her right eye. She was referred to the ED where CT and CTA of her brain were normal and she was admitted for further workup. The night of admission her left eye vision deteriorated resulting in complete bilateral vision loss with afferent pupillary defect on exam. Emergent LP revealed no evidence of multiple sclerosis (MS) or acute infection. MRI of her brain and spinal cord were significant only for asymmetric thickening and enhancement of the right optic nerve consistent with optic neuritis. There was no evidence of demyelinating disease. An autoimmune panel for neuromyelitis optica (NMO) antibodies was unrevealing. She had an otherwise normal neuro exam and was diagnosed with bilateral optic neuritis of unclear etiology. She improved slowly with 5 days of IV solumedrol. Two weeks after discharge she was seen by ophthalmology for recurrent left eye vision loss, diagnosed with left-sided optic neuritis, and treated with a second course of IV solumedrol. Six months later her vision had improved and her MRI was normal. Given her recurrent course and bilateral disease a diagnosis of Chronic Relapsing Inflammatory Optic Neuropathy (CRION) has been tentatively made.

IMPACT/DISCUSSION: The differential for bilateral optic neuritis is broad and includes inflammatory diseases such as MS and NMO. Less frequently it is seen in granulomatous diseases like sarcoidosis, infectious or post-infectious diseases, vasculitis, or can be idiopathic. In the setting of bilateral, recurrent optic neuritis without evidence of MS, NMO, or other autoimmune disease, a diagnosis of CRION should be considered. First described in 2003, CRION shares similar findings with NMO and MS. The current diagnostic criteria include objective evidence of loss of visual function, absence of autoantibodies associated with NMO, contrast enhancement of the optic nerve on MRI, and a disease course typically characterized as responsive to steroid treatment but with tendency for steroid-dependent relapse with at least one relapse required for diagnosis. Compared to cases linked to MS, optic neuritis in CRION patients has a worse prognosis and can lead to permanent changes in retinal nerve layers that cause blindness. These long-term sequelae typically require treatment with long term immunosuppression different from those with MS which is why the diagnosis is so important.

CONCLUSION: CRION is a rare cause of bilateral optic neuritis that is distinct from MS and NMO and is associated with a poor prognosis without treatment.

AN UNFORTUNATE CASE OF NONUREMIC CALCIPHYLAXIS

Rawan Hammoudeh; Aeman Hana; Sarah A. Gorgis; Joshua D. Collins. Henry Ford Hospital, Detroit, MI. (Control ID #3185741)

LEARNING OBJECTIVE #1: Recognize and distinguish calciphylaxis from other forms of ulcerating vasculitides in nonuremic patients.

CASE: A 74-year-old female smoker with a history of diabetes and peripheral artery disease (PAD) presents with painful persistent ulcers on her left arm and bilateral legs. She had a similar presentation one year ago and was diagnosed with thromboangiitis obliterans (Buerger's disease) after a biopsy of the leg ulcer showed inflammatory intraluminal thrombus. At that time, the patient was treated with antibiotics and counseled on smoking cessation. She successfully quit smoking, however skin ulcers continued to progress, which is unusual in Buerger's disease. She returned one year later with painful necrotic skin lesions involving the proximal legs, feet, and arms. Extensive rheumatological, hematological, endocrinological, vascular and genetic testing were all negative. A repeat punch biopsy was performed and revealed calcification and thrombosis of arterioles in the dermis and subcutaneous adipose tissue. Given extensive necrosis, she required bilateral transmetacarpal amputations.

IMPACT/DISCUSSION: We present a rare case of extensive nonuremic calciphylaxis in a patient with normal renal function. Calciphylaxis is an ischemic skin disorder recognized in patients with end-stage renal disease (ESRD). Our patient's history of heavy smoking, diabetes, and PAD gave suspicion to Buerger's disease, diabetic foot ulcerations, or ischemic ulcerations. It is essential to make the proper diagnosis, as treatment varies. The ulcers in Buerger's disease normally involve the distal legs and feet, whereas those in calciphylaxis involve the proximal extremities. Histologically, Buerger's disease has an intraluminal thrombus with relative sparing of the vessel wall and internal elastic lamina. This contrasts with calciphylaxis, which has thrombotic occlusion with dermal arteriolar calcification and subintimal fibrosis. Although rare, a systematic review revealed 36 reported cases of nonuremic calciphylaxis. The exact incidence of the disease is unknown. The only available treatment for calciphylaxis is sodium thiosulfate, but this is ineffective in patients with normal kidney function because it gets cleared by the kidneys too quickly to have any effect.

CONCLUSION: Calciphylaxis is a potentially lethal disorder that carries high morbidity and mortality if not recognized early. Although it is most commonly seen in patients with ESRD, clinical suspicion in non-uremic patients with the appropriate lesion distribution and histological findings is essential to early treatment. Further clinical research is needed to better understand non-renal etiologies and treatment.

AN UNLIKELY CULPRIT: RENAL CELL CARCINOMA MASKED AS ACUTE ABDOMINAL PAIN

Ara Vartanyan; Rachna Rawal. Saint Louis University, St. Louis, MO. (Control ID #3185730)

LEARNING OBJECTIVE #1: Recognize the importance of considering renal cell carcinoma (RCC) as a differential diagnosis in younger patients presenting with acute abdominal pain.

LEARNING OBJECTIVE #2: Identify risk factors associated with RCC.

CASE: A 37-year old male with a history of hypertension presented for acute left sided flank pain while watching television. Additional symptoms included nausea, vomiting, and diaphoresis. He noticed dark-colored urine about 3 weeks ago followed by passing of blood clots in the urine for 2 weeks. He had no dysuria. He reported an intentional 40 lbs weight loss over 5 months through lifestyle changes. On exam, the patient was hypertensive at 201/121, tachycardic at 103 BPM, obese (BMI 33.23), uncomfortable appearing, and exhibited moderate left lower quadrant and left flank tenderness. Labs were notable for an anemia of 9.8 from a baseline of 12.2 two months prior, with MCV 69.5, albumin 2.9, Hemoglobin A1c 11.2%. There was no leukocytosis or increase in creatinine/BUN. Urinalysis was significant for trace blood, 1+ protein, and 3+ glucose. Due to worsening abdominal discomfort, a CT abdomen & pelvis with contrast was performed, which revealed a 3.7 cm mass-like lesion in

the upper pole of the left kidney. MRI abdomen revealed a 9 cm, non-homogenously enhancing mass of the left kidney with direct extension into the left renal vein and inferior vena cava, left perinephric hemorrhage, and enlarged left para-aortic lymph nodes. These findings were concerning for RCC. A left open radical nephrectomy with IVC thrombectomy was performed. Pathology of the tissue revealed clear cell RCC, grade 3, without lymph node involvement. Surveillance imaging showed recurrent vena cava tumor thrombus and the patient was started on nivolumab/ipilimumab immunotherapy, which has resulted in decrease of thrombus size.

IMPACT/DISCUSSION: This case demonstrates the importance of considering RCC in younger patients and serves as a reminder to be cognizant of premature closure as physicians. This patient presented with acute flank pain, which is usually associated with acute processes rather than an insidious one such as RCC. His weight loss was a strong indicator of malignancy, but was confounded by his poorly controlled diabetes and reported history of intentional weight loss. Other risk factors for RCC included obesity and hypertension. Additionally, his work in a body shop may have exposed him to trichloroethylene, a chemical in grease removers that has been associated with RCC. Approximately 5% of patients with asymptomatic microscopic hematuria are found to have a urinary tract malignancy. By investigating further we treated this patient's cancer that could have ultimately caused more harm.

CONCLUSION: There are approximately 65,000 new cases of and 15,000 deaths from RCC, the most common form of kidney cancer, in the United States each year. Though RCC occurs predominantly in the sixth to eighth decades of life, signs such as weight loss, flank pain, and hematuria should raise red flags concerning for RCC.

AN UNSUAL CASE OF SYNCOPE: INEXPLICABLE COR PULMONALE IN A 30-YEAR-OLD-MALE

Ira Khanna¹; Eric Bondarsky²; Sharmila Ghosh¹; Christopher Taurani¹; Daniel Steinberg¹. ¹Mount Sinai Beth Israel, New York, NY; ²NYU, New York, NY. (Control ID #3176468)

LEARNING OBJECTIVE #1: Recognize clinical and diagnostic features of Pulmonary Tumor Thrombotic Microangiopathy

CASE: A 30-year-old male presented with 3 weeks of cough with hemoptysis, recent episode of syncope and decreased exercise tolerance for 6 months. Vitals in the ED: BP 134/84, HR 108, RR 18, Temp 98.1, SpO2 95%. Physical exam was normal. EKG showed TWI in v1-v4, bedside echo showed a dilated RV, labs showed troponin 0.704, BNP 363.7, D-dimer >20, LDH 328, ESR 108, CRP 83.9. CXR was unremarkable and pulmonary CTA-Dopplers were negative for PE/DVT but showed alveolitis and centrilobular nodules. Infectious and autoimmune workup was negative. TTE showed PASP 83 and RV dilation; V/Q scan showed low probability for PE. He had 3 more episodes of syncope with worsening dyspnea and a rising troponin. He was then transferred to the ICU, started on heparin drip for possible PE versus an NSTEMI and started on HFNC for hypoxic respiratory failure. RHC was suggestive of isolated RV failure. He was subsequently started on Dobutamine, Epoprostenol and inhaled NO. However, he went into PEA arrest and passed away despite resuscitative efforts. His autopsy found acute circulatory and respiratory failure secondary to Pulmonary tumor thrombotic microangiopathy (PTTM), RV hypertrophy and failure, and poorly differentiated gastric adenocarcinoma with metastases to mediastinal, perigastric and para-aortic lymph nodes.

IMPACT/DISCUSSION: Pulmonary tumor thrombotic microangiopathy is a rare but devastating complication in advanced metastatic cancers wherein tumor cells embolize into pulmonary arteries and induce activation of the coagulation cascade with intimal proliferation within small pulmonary arteries. Herbay et al first described a 3.3% prevalence of PTTM in 630 cancer autopsies with gastric adenocarcinoma being most commonly associated. It usually presents as acute or subacute dyspnea with hypoxia and

rapidly progressive Pulmonary Artery Hypertension (PAH) leading to cor pulmonale. Bloodwork may show non specific elevations of D-Dimer and LDH. Imaging is mostly negative, although CT may show dilated pulmonary arteries, V/Q scan may reveal peripheral perfusion defects and FDG PET may show uptake in lungs, however, smaller tumor deposits are likely to be missed. Histological diagnosis may be obtained via lung biopsy or pulmonary artery catheter blood aspiration. While PTTM remains primarily a post-mortem diagnosis, there have been a few cases where early diagnosis and treatment with pulmonary vasodilators, chemotherapy and anticoagulation has led to survival in months to years. In most of these cases patients had known cancer, however, cor pulmonale as the first clinical presentation is extremely rare. Had we considered PTTM, a pulmonary artery catheter blood aspiration could have been done during his RHC which could have prompted chemotherapy.

CONCLUSION: In patients with acute cor pulmonale without a clear cause, Pulmonary Tumor Thrombotic Microangiopathy from an occult malignancy should be considered.

AN UNUSUAL CASE OF ALTERED MENTAL STATUS LEADING TO A DIAGNOSIS OF PANCREATIC ADENOCARCINOMA

Nina Kogekar; Julie Sung; Priya Sehgal; Mona Krouss. Icahn School of Medicine at Mount Sinai, New York, NY. (Control ID #3178519)

LEARNING OBJECTIVE #1: Recognize non-bacterial thrombotic endocarditis in patients with pancreatic adenocarcinoma or other malignancy

CASE: An 84 year old male with atrial fibrillation on apixaban and active smoker (25 pack-year history) presented with weakness and confusion for two weeks. On presentation, the patient had normal vital signs. Physical exam revealed irregularly irregular rhythm with mental status oriented only to name and place, not date. Detailed neurologic exam was notable for decreased coordination with irregular rapid alternating movements and inability to perform finger-to-nose, upward Babinski reflexes, and shuffling, wide-based gait. Laboratory studies were normal. A CT head showed no acute process. The patient continued to be increasingly altered, so MRI brain was obtained, which revealed several acute to subacute embolic infarcts in the bilateral cerebral and cerebellar hemispheres. This raised suspicion for endocarditis, and a transesophageal echocardiogram (TEE) found small mobile masses on the cusps of the aortic valve. A diagnosis of non-bacterial thrombotic endocarditis (NBTE) was made, given negative infectious work-up, and the patient was started on enoxaparin. CT angiography of the chest was performed to rule out pulmonary embolus during work-up, which incidentally showed a mass in the pancreatic head. MRCP showed a lesion at the posterior pancreatic head with upstream dilation of the main pancreatic duct. The pancreatic mass was biopsied which showed pancreatic adenocarcinoma (PAAD).

IMPACT/DISCUSSION: Our case is unique as the diagnosis of NBTE was made despite a seemingly benign initial presentation. Regardless of the incidental finding of the tubular structure in the pancreatic head, this patient with NBTE should have undergone workup of possible PAAD as this association has been increasingly reported in the literature. Awareness of the association is critical, as diagnosing NBTE in the context of malignancy alters the management plan, from antibiotics to anticoagulation.

CONCLUSION: NBTE, also known as marantic endocarditis, is caused by deposition of fibrin and platelet thrombi on heart valves. It occurs in the setting of a hypercoagulable state, often due to underlying adenocarcinoma. The incidence of NBTE in pancreatic cancer is not known. There have been few cases of ante-mortem diagnosis of NBTE with PAAD. Our case represents a rare instance of an ante-mortem diagnosis of NBTE as the initial presentation of underlying PAAD. The treatment of NBTE consists of anticoagulation with unfractionated or low-molecular weight heparin (LMWH). LMWH overall remains the treatment of choice over DOACs for malignancy-related thrombosis, and thus was chosen for treatment in this patient who was already on apixaban at the time of

presentation. This case demonstrates that in patients with multiple cerebral infarctions, the diagnosis of NBTE and, subsequently, underlying malignancy should be included in the initial differential.

AN UNUSUAL CASE OF BLEEDING GASTRIC VARICES SECONDARY TO METASTATIC OVARIAN ADENOCARCINOMA

Randeep Kaur; Reena Salgia; Crystal Seudeal; Eric Scher. Henry Ford Hospital, Detroit, MI. (Control ID #3185409)

LEARNING OBJECTIVE #1: Recognize the presence and different potential causes of gastric varices in a patient that does not have liver disease

CASE: The patient is a 58-year-old Caucasian female with a history of metastatic ovarian cancer and no previous history of liver disease, who initially presented to the hospital with hematemesis, melanic stools, lethargy and generalized weakness. She was found to have a hemoglobin of 5.7 g/dL, which dropped to 4.5 g/dL. Liver function tests at this time were within normal limits and testing for chronic liver disease was unrevealing. Abdominal ultrasound revealed patent hepatic vasculature and splenomegaly. An emergent esophagogastroduodenoscopy (EGD) was performed which showed isolated gastric varices located in the fundus (Sarin Classification, IGV1). MRI of the abdomen confirmed a hypovascular mass in the splenic hilum concerning for possible metastasis. Pathology confirmed metastatic ovarian cancer in the splenic hilum. After presentation at tumor board, the decision was made to perform splenic artery embolization (SAE) to decrease the inflow to the spleen with subsequent splenectomy. Proximal SAE and splenectomy was done without complication. The patient has continued her care with oncology for further treatment with Paclitaxol +/- Bevacizumab. Following the patient's splenectomy, she has reported no further episodes of hematemesis or melanic stools.

IMPACT/DISCUSSION: Left sided portal hypertension (LSPH) causing gastric variceal bleeding is fortunately an infrequent cause of upper gastrointestinal hemorrhage. To the best of our knowledge, there has been one published case of metastatic ovarian cancer resulting in gastric varices which occurred 21 years following ovarian carcinoma surgery and adjuvant chemotherapy. This case demonstrates progression of ovarian metastatic disease despite chemotherapy status post debunking in the peritoneum, causing significant hemorrhage with complete resolution of bleeding gastric varices by splenic artery embolization, followed by splenectomy. It highlights the need for ongoing awareness regarding the evaluation and management of IGV in patients who do not have underlying liver disease. Ultimately, the finding of IGV on endoscopy in a non-cirrhotic patient should prompt the investigation into other causative processes that could obstruct the splenic venous system.

CONCLUSION: Portal hypertension generally develops in the setting of liver cirrhosis, and can result in subsequent esophageal and/or gastroesophageal varices. LSPH, on the other hand, can arise in non-cirrhotic patients secondary to obstruction of the splenic vein, leading to isolated gastric varices. Given that most cases of LSPH remain asymptomatic, the incidence is likely <5% of all portal hypertension cases. This is an uncommon case of metastatic ovarian adenocarcinoma to the splenic vein hilum causing outflow obstruction and resultant gastric variceal hemorrhage. This patient was ultimately treated with splenic artery embolization followed by splenectomy.

AN UNUSUAL CASE OF ILEAL NEUROENDOCRINE TUMOR PRESENTING AS HEMATOchezIA

Ahmed A. Elkafrawy²; Mahak Chauhan¹; Fredy Nehme¹. ¹University of Missouri - Kansas City, Kansas City, MO; ²UMKC School of Medicine, Mission, KS. (Control ID #3186021)

LEARNING OBJECTIVE #1: Recognize hematochezia as a rare presentation of Neuroendocrine Tumor of the small bowel. Assess small bowel bleeding with capsule endoscopy and double balloon enteroscopy.

LEARNING OBJECTIVE #2: Neuroendocrine tumors (NETs) are epithelial tumors with predominant neuroendocrine differentiation. The terminal ileum is the most common location for NETs. The symptoms of small bowel NETs are represented mainly by intermittent intestinal obstruction and carcinoid syndrome; however, hematochezia is a very rare presentation.

CASE: We present a 57-year-old Caucasian female with a past medical history of coronary artery disease with stents and alcohol abuse who presented with hematochezia. She was admitted 4 years ago with melena and low hemoglobin, she was diagnosed with erosive gastritis on EGD. She presented this time with recurrent episodes of hematochezia without hematemesis, melena or abdominal pain. She was on aspirin. Physical exam was unremarkable. Hemoglobin was 12.5 gm/dl. EGD was normal and colonoscopy showed fresh blood through the colon but no active source of bleeding. Capsule endoscopy showed a mid-small bowel ulcer with fresh blood from mid to distal small bowel. Bleeding then appeared to have ceased spontaneously and hemoglobin stabilized. Anterograde double-balloon enteroscopy (DBE) was pursued for better visualization of the small bowel ulcer and was normal. A retrograde DBE revealed a 2.5 cm ulcerated mass in the terminal ileum. Biopsies showed focal nests of neuroendocrine tumor (NET). Surgical resection of 14 cm from the small bowel including the mass, wedge of mesentery and palpable lymph nodes was done. Pathology showed grade 1 of 3 well-differentiated NET invading the visceral peritoneum with lymph node metastasis. The patient recovered well and was discharged home to follow up with oncology.

IMPACT/DISCUSSION: This case highlights the importance of direct visualization of small bowel ulcers with enteroscopy despite cessation of bleeding. In our case, the suspected small bowel ulcer noted on capsule endoscopy was, in fact, an ulcerated NET. NETs of the small intestine represent the most common small bowel tumor. Metastasis to lymph nodes and liver are common at diagnosis and can lead to carcinoid syndrome. The diagnosis is often difficult due to their rarity and the nonspecific presentation. In fact, more than 50% of patients require at least 2 years for a diagnosis of NET after symptom onset while visiting on average 4 healthcare professionals. Therefore, a high index of suspicion must be maintained and one must be aware of all variable presentations.

CONCLUSION: NETs represent a rare but important pathological condition of the gut. While capsule endoscopy was an important tool in the diagnostic work up, balloon enteroscopy was the key to making the correct diagnosis. Desmoplastic reactions involving mesenteric vessels may lead to nonspecific abdominal pain, gastrointestinal bleeding, intermittent ischemia, or bowel obstruction.

AN UNUSUAL CASE OF MENINGITIS CAUSED BY EPSTEIN-BARR VIRUS

Parma Zahid^{1, 4}; Timothy C. Edmonds^{2, 4}; Sharon Rikin^{3, 1}. ¹Montefiore Medical Center, Bronx, NY; ²Montefiore Medical Center, New York, NY; ³Montefiore - Albert Einstein College of Medicine, Bronx, NY; ⁴Albert Einstein College of Medicine, Bronx, NY. (Control ID #3186338)

LEARNING OBJECTIVE #1: Recognize the clinical features of Epstein-Barr virus (EBV) meningitis

LEARNING OBJECTIVE #2: The role of antiviral therapy in treatment of EBV meningitis

CASE: A 47 year old female with HIV (CD4 225) not currently on antiretroviral therapy presented with headaches, nausea, vomiting, and neck stiffness for four weeks. Associated symptoms included seventh nerve palsy, tinnitus and decreased hearing of the left ear. On exam, patient had a temperature of 100.8, heart rate of 120, papilledema, left ear hearing deficit, and neck stiffness. On admission, MRI brain was normal. A lumbar puncture showed opening pressure of 37 mm H2O, WBC of 15, and an elevated protein to 186. Differential diagnosis for presumed aseptic meningitis included: varicella zoster virus (VZV) reactivation at the geniculate ganglion manifesting as Ramsay Hunt Syndrome or Lyme given cranial nerve findings. The patient was empirically started on acyclovir pending

cerebrospinal fluid (CSF) results. CSF VZV PCR and Lyme antibody were negative. Results however showed CSF EBV PCR 1,100; serum EBV viral capsid antigen and antibody were also positive. As the patient's fever, headache, and hearing improved after initiation of acyclovir, treatment was continued with acyclovir IV for ten days, then with valacyclovir to complete a total of three weeks of treatment.

IMPACT/DISCUSSION: EBV meningitis is a rare illness and may present with cranial nerve deficits such as decreased hearing and facial nerve palsy along with other meningeal irritation signs. This case also reveals an opportunity to review therapeutic options for EBV-related illness. EBV should be considered in both immunocompetent and immunocompromised patients with viral meningitis/encephalitis. Supportive care is generally recommended; there is the potential for debilitating sequelae including increased intracranial pressure and death. We are aware of only one other reported case of EBV meningitis with hearing loss in which the patient was treated with hydrocortisone sodium phosphate and noted improvement in hearing acuity. While antivirals such as acyclovir are thought not to work well in vivo for EBV and thus are not recommended, there are case reports of using antiviral therapy for EBV meningitis/encephalitis. In these cases, patients treated with antiviral therapy were shown to have decreasing viral DNA in CSF and a corresponding resolution of their symptoms. Given that the literature only shows case studies of EBV meningitis treatment with antivirals, there is an opportunity for further research in this area.

CONCLUSION: EBV meningitis should be considered in the differential in patients who present with cranial nerve deficits. Antiviral treatment may be considered in EBV meningitis given observational studies which have been associated with improvement of disease manifestations.

AN UNUSUAL CASE OF NEPHROGENIC DIABETES INSIPIDUS

Michael Liu; Sandra Oza. Albert Einstein College of Medicine, Bronx, NY. (Control ID #3177877)

LEARNING OBJECTIVE #1: Recognize chronic obstructive uropathy as an etiology of nephrogenic diabetes insipidus.

CASE: The patient is a 53-year-old man with a past medical history of neurofibromatosis type 1 status post cervical and lumbar spinal surgeries, which were complicated by neurogenic bladder managed with intermittent catheterization, with which the patient was inadequately adherent. He presented with nausea, vomiting, diarrhea, and weakness prior to elective colonoscopy; the procedure was canceled and the patient was admitted. Laboratory studies were notable for: sodium 153 mEq/L, creatinine 1.7 mg/dl, white blood cell count 15,500/mm³, and urinalysis revealing large leukocytes and >100 WBCs. The patient was started on 0.45% normal saline and 1g ceftriaxone. The patient's hyponatremia did not improve with intravenous hypotonic fluids. Renal ultrasound revealed bilateral hydronephrosis. A Foley catheter was placed, and on the subsequent nine days, the patient's 24-hour urine output ranged from 4.395 L to 10.65 L. Urine osmolality was 107 mOsm/kg, serum osmolality was 308 mOsm/kg, and serum anti-diuretic hormone (ADH) was 16.4 pg/ml. Administration of 4 mcg desmopressin subcutaneously resulted in an increase in urine osmolality of less than 40%, and the diagnosis of nephrogenic diabetes insipidus (NDI) was made. The patient was started on hydrochlorothiazide 25 mg once daily by mouth with a decrease in daily urine output to 3.7 L.

IMPACT/DISCUSSION: NDI may be caused by lithium, hypercalcemia, hypokalemia, and genetic defects, but NDI secondary to chronic urinary tract obstruction is rare. Case reports have described NDI in patients with mechanical bladder neck obstruction secondary to prostate cancer and hypertrophy, ileal leiomyosarcoma, and rectal cancer. There has been only one reported case of NDI secondary to neurogenic bladder. In that case, a 48-year-old woman presented with polyuria of 4-6 L/day, and bladder catheterization led to improvement in symptoms. The

theorized pathophysiologic mechanisms underlying NDI in patients with bladder outlet obstruction are increased cortical collecting pressures damaging tubular epithelium, thus altering the kidney's ability to respond to vasopressin. After restoring normal urine flow, polyuria and hyposthenuria continue since the tubular defect remains. Three possible mechanisms have been proposed: given the reduction in functional nephrons, each nephron has a higher glomerular filtration rate; there is decreased reabsorption of sodium and water at the proximal tubule; there is decreased water absorption in the collecting duct and descending limb of the loop of Henle. After relief of urinary obstruction, thiazide diuretics can be used to increase sodium and water reabsorption in the proximal tubule, thereby decreasing delivery to ADH-sensitive sites in the collecting duct.

CONCLUSION: Chronic urinary obstruction, from both mechanical and anatomical causes including neurogenic bladders, should be considered in patients presenting with NDI.

AN UNUSUAL CAUSE OF ABDOMINAL PAIN AND CONFUSION IN A PATIENT WITH CIRRHOsis

Michelle Knees¹; Kellen Hirsch¹; Jason John¹; Katarzyna Mastalerz².

¹University of Colorado School of Medicine, Denver, CO; ²VA Eastern Colorado Health Care System, Aurora, CO. (Control ID #3138139)

LEARNING OBJECTIVE #1: Recognize Chilaiditi sign and consider corresponding syndrome complications in any patient with cirrhosis, abdominal pain, and appropriate radiographic sign.

CASE: A 72-year-old man presented with three days of worsening confusion in the setting of known cirrhosis. Notably, he was recently treated at an outside hospital for dehydration and was discharged without his lactulose or rifaximin. Lactulose and rifaximin were restarted upon admission, with gradual improvement in his confusion. However, six days into his hospitalization, he developed acute abdominal pain, vomiting, and worsening confusion. Vital signs were within normal limits; his abdomen was distended and diffusely tender with voluntary guarding but without rebound tenderness. He was lethargic and alert only to person. An abdominal x-ray showed a distended large intestine under the right hemidiaphragm without clear signs of pneumoperitoneum. A subsequent CT abdomen/pelvis further delineated moderate stool burden and interposition of the large bowel between the diaphragm and liver. The radiologist's differential included Chilaiditi sign; given the patient's symptoms, a presumptive diagnosis of Chilaiditi syndrome leading to constipation and worsening hepatic encephalopathy was made, and the patient was treated conservatively with bowel rest, IV fluids, ondansetron, and additional lactulose. He soon had one large bowel movement with improvement of his abdominal pain and confusion.

IMPACT/DISCUSSION: Normally, the colon and liver are kept in place with suspensory ligaments; however, cirrhosis is a known risk factor for Chilaiditi syndrome due to liver atrophy disrupting the normal suspensory ligament anatomy. This can lead to intermittent bowel and liver interposition with resultant abdominal symptoms. The differential for acute abdominal pain is large. The danger of Chilaiditi syndrome resides less with the syndrome itself and more with mistaken diagnoses, which can include complete bowel obstruction, subdiaphragmatic abscesses, or pneumoperitoneum, all of which can lead to surgical intervention. When diagnosed correctly, uncomplicated Chilaiditi syndrome frequently resolves with only supportive treatment. Interestingly, our patient had a years-long history of intermittent abdominal pain and difficult-to-control hepatic encephalopathy. After diagnosing Chilaiditi syndrome, our team felt that his hepatic encephalopathy was so labile due to his inability to tolerate a consistent lactulose/rifaximin dosing regimen from symptoms related to this syndrome. To avoid unwarranted invasive interventions, recognition of this rare but important diagnosis should be kept in mind in any patient with cirrhosis, abdominal pain, and the appropriate radiographic signs.

CONCLUSION: Chilaiditi radiographic sign can indicate Chilaiditi syndrome and can be easily mistaken for pneumoperitoneum. Intermittent constipation resulting from Chilaiditi syndrome can complicate the disease course of hepatic encephalopathy.

AN UNUSUAL CAUSE OF OBSTRUCTIVE JAUNDICE

Chirag Buch²; Heather L. Briggs¹. ¹University of Texas Health Science Center at San Antonio, San Antonio, TX; ²UT Health San Antonio, San Antonio, TX. (Control ID #3161334)

LEARNING OBJECTIVE #1: Review clinical presentation of obstructive jaundice

LEARNING OBJECTIVE #2: Recognize a rare complication of clip cholelithiasis after a laparoscopic cholecystectomy

CASE: 61 y/o Hispanic male with a PMH of HTN, HLD, DMII, gallstone pancreatitis s/p cholecystectomy 3 years ago complicated by gallbladder fossa abscess s/p IR drainage presented with 3 weeks of acute onset nausea, vomiting, and abdominal pain. The RUQ pain is sharp, intermittent, worsens with food, and is relieved with vomiting. He endorses dark urine, acholic stools, chills, 10 lb weight loss, and jaundice. He denies fever, neurological deficits, pruritus, hematochezia, and any symptoms of peripheral neuropathy. His admission laboratory tests were significant for elevated liver enzymes (AST 203, ALT 354, & ALP 251) with hyperbilirubinemia (T Bili 10.0 and D Bili 5.9). CT scan showed possible migrated surgical clip. Gastroenterology was consulted and endoscopic retrograde cholangio-pancreatography (ERCP) was performed, showing a prominent common bile duct with oblong distal filling defect. The patient underwent extraction of two stones (one which appeared to represent a concretion surrounding the migrated cholecystectomy clip) and subsequent ductal clearance/decompression. The following day, he was tolerating a full diet and had resolution of his post-prandial symptoms, decrease in RUQ tenderness, and a decline of his liver enzymes and bilirubin.

IMPACT/DISCUSSION: The first laparoscopic cholecystectomy was performed in 1985 in Germany. Since then, this procedure replaced the conventional open cholecystectomy and became one of the most common operations performed. There are about 300,000 of these procedures performed each year for cholecystitis, symptomatic cholelithiasis, biliary dyskinesia, acalculous cholecystitis, gallstone pancreatitis, and gallbladder masses/polyps. Complications following this procedure occur less than 5% of the time. These include bleeding, infection, and injury to surrounding structures. Most patients can be managed with close follow up, but some require extensive hospitalizations that raise mortality, morbidity, and health care costs. Less than 100 cases of clip migration following laparoscopic cholecystectomy have been reported. Though the mechanism of surgical clip migration, gallstone formation around the clip, and its obstruction is unclear, this case highlights a rare complication in a patient who presented 3 years post cholecystectomy with classic symptoms of obstruction of the biliary system.

CONCLUSION: Surgical clip migration, a rare complication of laparoscopic cholecystectomy, should be considered part of the differential diagnosis in patients that present with clinical manifestation of choledocholithiasis post procedure. Urgent imaging and management should be considered.

AN UNUSUAL CONSEQUENCE OF ALCOHOLISM AND RECURRENT PANCREATITIS

MRUDULA THIRIVEEDI; Parekha yedla. UAB, Huntsville, AL. (Control ID #3185898)

LEARNING OBJECTIVE #1: Recognize an uncommon cause of ascites in patients with alcoholic liver disease and the treatment options available.

CASE: A 41 year old woman with history of alcoholism and recurrent pancreatitis presented with a three day history of abdominal pain and

distension. She was seen in the emergency room a week ago for similar complaints, was diagnosed with cirrhosis and ascites, underwent paracentesis which was notable for a serum-ascites albumin gradient (SAAG) of 1.6 consistent with portal hypertension. During this presentation, physical exam was remarkable for ascites and diffuse tenderness to palpation. Laboratory studies were normal except for a low serum albumin of 2.1 g/dL, CT abdomen showed hepatic steatosis and cysts in the tail of the pancreas. Ascitic fluid analysis revealed total nucleated count of 414/ microliter, total protein of 3.1 g/dL and a SAAG of 0.8 after which fluid amylase levels were checked and found to be elevated at 3671 U/L. Endoscopic ultrasound was done for further evaluation of pancreatic cysts and the aspirate was noted to be benign. The patient was diagnosed with pancreatic ascites, underwent an endoscopic retrograde cholangiopancreatography (ERCP) with biliary sphincterotomy for choledocholithiasis. She came back 2 days later with worsening ascites. Fluid analysis again showed elevated amylase of 2475 U/L. Repeat ERCP revealed pancreatic duct leakage and a transpapillary stent was placed. The patient improved clinically and symptomatically over the next few days. At a follow up visit 2 weeks later, there was no recurrence of ascites.

IMPACT/DISCUSSION: Most common causes of ascites are cirrhosis, malignancy and heart failure. Pancreatic ascites is rare and is usually from leakage of the pancreatic duct or pseudocysts. It is characterized by SAAG <1.1, ascitic amylase level >1000 U/L and total protein >3 g/dL. Gold-standard for diagnosis is ERCP showing pancreatic duct disruption. The most common cause of pancreatic ascites is chronic pancreatitis, other causes include acute pancreatitis and trauma. Estimated prevalence is 4% in patients with chronic pancreatitis and 6 to 14% in patients with pseudocysts. There are only a few case reports and case series available to guide the management of pancreatic ascites. Conservative therapy includes serial paracentesis, parenteral nutrition and octreotide which decrease pancreatic secretions facilitating fistula closure. Interventions include either endoscopic therapy or surgery as the last resort. ERCP with transpapillary stent placement is a viable option in most cases. Surgical procedures include partial pancreatectomy and pancreaticojejunostomy.

CONCLUSION: Pancreatic ascites should be considered in the differential diagnosis of recurrent ascites in a patient with history of alcoholism and pancreatitis. Growing evidence supports interventional therapy as an initial treatment strategy especially endoscopic transpapillary stenting of the pancreatic duct.

AN UNUSUAL ETIOLOGY OF PNEUMOPERITONEUM

Shayan Siddiqui; Assad Mohammedzein; Nooraldin Merza; Ahmed Taha; Juan Garrido. Texas Tech University Health Science Center, Amarillo, TX. (Control ID #3147530)

LEARNING OBJECTIVE #1: Recognize emphysematous pyelonephritis as a rare cause of pneumoperitoneum.

CASE: A 63 years old male presented with one week history of diffuse abdominal pain. He denied fever or dysuria. His medical history is significant for diabetes mellitus, Hypertension, coronary artery disease, congestive heart failure, chronic hepatitis B and C with liver cirrhosis. He injects heroin and snort cocaine. He was alert, had a temperature of 34.7 C, heart rate of 66 bpm, and blood pressure of 147/69 mmhg. Abdomen was soft, diffusely tender, maximum at the right costovertebral angle, no rebound tenderness or rigidity, and bowel sounds were normal. No urethral discharge or penile ulcers. Laboratory tests showed WBC $3.0 \times 10^3/\text{cumm}$, Hb 8.1 g/dl, platelet $32 \times 10^3/\text{cumm}$, pyuria, and bacteruria. Lactic acid was 3.9 mmol/l. Toxicology screen positive for cocaine and opiate. Computed tomography (CT) abdomen showed free intraperitoneal air, foci of gas within the right renal parenchyma adjacent to the proximal right ureter and within the posterior portion of the bladder. The diagnosis of Emphysematous pyelonephritis (EP) was made. Blood cultures grew *Extended Spectrum Beta Lactamase Escherichia Coli*. He was treated with meropenem. Shortly after, he developed septic shock

requiring intravenous fluids and vasopressor support. In view of his critical condition and comorbidities, he was not operated on, instead percutaneous right nephrostomy tube was placed. However, his condition continued to deteriorate and his family opted for hospice care.

IMPACT/DISCUSSION: EP is a severe necrotizing infection characterized by gas formation within or outside the renal parenchyma. Based on the pattern of gas extension on imaging, four types have been described in the literature. As the gas extended to para-renal space, our patient's type was III B, which has poor prognosis without surgical intervention. It is extremely rare that EP presents with pneumoperitoneum; only 3 cases have been described in the literature. All 3 patients required exploratory laparotomy, 2 required radical nephrectomy, the third underwent surgical drainage with nephron-conservative therapy. Other etiologies of pneumoperitoneum must be excluded, especially bowel perforation which often prompts exploratory laparotomy. Our patient was a high risk surgical candidate and he opted for percutaneous nephrostomy.

CONCLUSION: Emphysematous pyelonephritis is a life-threatening condition and it could very rarely present with pneumoperitoneum, to our knowledge this is the 4th reported case in the literature. Such a finding should prompt an emergent exploratory laparotomy should the patient's condition permits.

AN UNUSUAL PRESENTATION OF CEREBRAL MASS IN A PATIENT WITH HIV INFECTION

Shadab Saboori; Leigh A. Medaris; Michael Leonard. Carolinas Medical Center, Charlotte, NC. (Control ID #3185467)

LEARNING OBJECTIVE #1: 1) Recognize unusual features of neurosyphilis in HIV infection

LEARNING OBJECTIVE #2: 2) Diagnose intracranial mass lesions in HIV infection

CASE: A 23-year-old-male with a past medical history significant for untreated HIV infection presented to an outside hospital with a chief complaint of left-sided headache, left-sided hearing loss and bilateral blurred vision of two weeks duration. CT head without contrast showed a less than two centimeter left temporal parietal mass with mild mass-effect, and patient was transferred to our facility for neurosurgical and infectious diseases evaluation. He denied night sweats, chills, fever or weight loss, and he had no recent head trauma. Past medical history was significant for being diagnosed with HIV while seeking treatment for gonorrhea four years earlier. He never followed up and was naïve to antiretrovirals. He has a history of smoking but denies any drug use. His housing was unstable and he identified himself as bisexual. Neurological examination was significant for decreased left sided facial sensation, impaired left sided hearing, 4 out of 5 motor strength in left upper and lower extremity, and diminished light and pinprick sensation of left upper and lower extremity. The remainder of his exam was unremarkable. The RPR was reactive at 1:64 dilutions and treponema pallidum particle antigen was positive. Toxoplasma antibodies were negative. CD4 count was 121, and HIV 1 RNA viral load of 1,356. MRI brain revealed a solid nodular enhancing lesion in the left temporal lobe. Decision made to proceed with biopsy for further assessment and pathology revealed a fibrotic, lymphoplasmacytic infiltrate with a positive stain for spirochetes. Treatment was initiated with 14 days of IV penicillin G followed by two doses intramuscular benzathine penicillin one week apart. He was started on anti-retroviral therapy consisting of Descovy and Tivicay. At his one month follow-up visit, his symptoms were all improved. A repeat head CT 4 months after presentation showed complete resolution of the lesion.

IMPACT/DISCUSSION: Intracerebral gummas are a rare presentation of neurosyphilis that are seen mainly in HIV infection. HIV co-infection has been shown to alter the clinical course of syphilis, but despite an increased

predisposition for neurosyphilis, cerebral gummas are rarely reported. Their presentation and imaging can be confused with tumors, abscesses, and other infectious lesions ie tuberculomas thus usually requiring pathology to make the diagnosis as seen in our case. Our patient showed a full recovery with radiologic evidence of complete resolution following treatment with IV penicillin G and two doses benzathine penicillin. There are no specific treatment recommendations for syphilitic gummas, but we extrapolated based on recommendations for CNS syphilis.

CONCLUSION: 1) Syphilitic gummas should be considered in patients with mass lesions and evidence of latent syphilis 2) Recognize that syphilis can have unusual presentations in HIV infection

AN UNUSUAL PRESENTATION OF GOUT: CHRONIC BACK PAIN.

JACOB L. THOMAS¹; Scott Friedberg²; Emmanuelle B. Yecies². ¹University of Pittsburgh, Pittsburgh, PA; ²University of Pittsburgh Medical Center, Pittsburgh, PA. (Control ID #3186384)

LEARNING OBJECTIVE #1: To recognize the symptoms and presentation of advanced gout

LEARNING OBJECTIVE #2: To assess how bias limited the differential diagnosis of this patient

CASE: Mr. C is a 68 year old white veteran with a history significant for diabetes mellitus, chronic kidney disease, gout, and chronic back pain who presented with acute worsening of his back pain. Patient reported 9/10 pain in his upper back that radiated with a burning sensation down his right arm and over his right rib cage. The pain interfered with his sleep and he was unable to tolerate laying flat. He denied any other neurologic symptoms. Physical exam was notable for an obese male with mild diffuse thoracic paraspinal tenderness with otherwise normal, non-focal neurological exam. In terms of relevant medications, he was taking allopurinol and furosemide. Non-contrasted CT scan of the cervical and thoracic spine were obtained. Formal Radiology interpretation described a lesion adjacent to T8/9 with erosion into the bone, suspicious for a malignancy, but the evaluation was limited due to lack of contrast. Follow-up MRI with contrast revealed the erosion was smooth suggesting possible neurofibroma. Biopsy demonstrated tophaceous lesions consistent with gout.

IMPACT/DISCUSSION: Gout is a relatively common disease that affects between 3-6% of men and 1-3% of women in the developed world. It is caused by the deposition of monosodium urate crystals into joints and soft tissues which can cause an inflammatory response and pain. Risk factors for gout include obesity, chronic kidney disease, diuretic use, heavy alcohol use, and hyperuricemia, nearly all of which were present in our patient. As gout progresses, patients can develop tophi, granulomatous nodules that form in response to the crystalline deposits. Classically, tophi form in the joints of the hands, elbows, and feet, but they can form in any bone or soft tissue. Although the spine is an uncommon location, there are many case reports of spinal gout that can cause symptoms as severe as cord compression and radiculopathy. One review by *Ribeiro da Cunha (2018)* found over 100 reported cases of spinal gout. Despite this patient's known history of gout, it was not considered in the differential until the pathology report. Part of this can be attributed to authority bias and premature closure. In our case, authority bias manifested after the initial imaging when both Radiology and Neurosurgery expressed concern for malignancy. With malignancy being common and specialists suggesting this was a consistent presentation, premature closure was reached and no other diagnoses were considered. Representative restraint bias contributed as well. With his use of allopurinol and a lack of classic joint symptoms, we did not consider this unusual presentation of a common problem, and our illness script for gout was not triggered.

CONCLUSION: Gout is a common problem that can present with many atypical symptoms and should be considered for patients at risk.

AN UNWELCOME SOUVENIR: RARE MYCOBACTERIUM INFECTION IN PATIENT WHO RECEIVED ABDOMINOPLASTY ABROAD

Ann Wang; Alexa Yuen; Priya Nori; Matthew Shaines. Montefiore Medical Center, Bronx, NY. (Control ID #3186304)

LEARNING OBJECTIVE #1: Recognize the growing incidence of rare infections in patients participating in medical tourism

LEARNING OBJECTIVE #2: Manage patients presenting with mycobacterium infections after undergoing surgical procedures abroad

CASE: A 49F presented to the hospital with abdominal pain and drainage. She had received an abdominoplasty and liposuction in the Dominican Republic 7 months prior. She reported normal healing until about 6 months post-operatively, when she began noticing a bump in her lower abdomen, and yellow drainage from her bellybutton. She then had worsening lower abdominal pain and presented to the hospital. Computed tomography scan of the abdomen and pelvis showed an intra-abdominal abscess measuring 7.2cm at the largest dimension. She underwent ultrasound-guided drainage of the abscess and was empirically started on a 2 week course of amoxicillin-clavulanate at discharge. Cultures from the abscess were then found to be growing *Mycobacterium senegalense*. The Department of Health was notified, and the cultures were sent for sensitivity testing. Approximately 1 month later, she returned to the hospital with worsening abdominal pain and drainage. She was found to have a re-accumulation of the abscess. She again underwent drainage. By this time, sensitivities of the *M. senegalense* returned. The organism was found to be pan-sensitive, and she was started on a course of oral doxycycline and levofloxacin. She was discharged with a planned 6 week course, and follow-up in Infectious Disease clinic.

IMPACT/DISCUSSION: Up to 750,000 US residents per year travel abroad for medical care. This number will likely increase due to increasing ease of travel and perceived cost savings. The American Medical Association recommends that patients seek out internationally accredited medical facilities. However, standards for accreditation vary, and there is no evidence to suggest that outcomes are improved in accredited facilities. An outbreak of mycobacterial infections has been associated with medical tourism, particularly to the Dominican Republic. A report published in 2016 identified 21 cases in 6 US states in medical tourists to the Dominican Republic. *Mycobacterium* associated with medical tourism often have significant drug resistance, requiring long courses of multiple anti-microbials for effective treatment. In addition, surgical debridement is often necessary. *Mycobacterium senegalense* has primarily been identified as a bovine pathogen affecting cattle in East Africa. There have been rare case reports of human infection by *M. senegalense*, but primarily in immunosuppressed patients.

CONCLUSION: Patients who are considering obtaining surgical procedures abroad should be counseled on the risks of infection even in accredited facilities. Clinicians should maintain a high level of suspicion for mycobacterium infection for patients who present with wound infections after receiving surgeries abroad. As the medical tourism industry expands, rate of rare infectious complications will likely also increase.

ANCHORING AND CONFIRMATION BIAS IN TERMINAL DIAGNOSES

Matthew Lipinski¹; Ronald Miller². ¹Penn State University at Hershey Medical Center, Hummelstown, PA; ²Penn State University at Hershey Medical Center, Hershey, PA. (Control ID #3185714)

LEARNING OBJECTIVE #1: Review anchoring and confirmation bias.

LEARNING OBJECTIVE #2: Discuss the importance of ruling out reversible causes before diagnosing a terminal illness.

CASE: A 64 year-old man presented with new onset abdominal swelling. He has alcoholic cirrhosis and heart failure with preserved ejection fraction, and takes furosemide and spironolactone. Four liters of ascites was drained by paracentesis, and there was no spontaneous bacterial peritonitis. Creatinine was elevated to more than double his baseline, urine sodium was low. Hepatic duplex ruled out any venous thromboses. Diuretics were held due to concern for hepatorenal syndrome, and he was given large volumes of 25% albumin infusions. His creatinine continued to worsen, and he was started on midodrine and octreotide. Echocardiogram showed he was not a candidate for transjugular intrahepatic portosystemic shunt (TIPS) due to elevated right heart pressures. Given his thoracic aortic aneurysm, he was not a candidate for liver transplant. He was not interested in hemodialysis. In light of him being a candidate for neither TIPS nor liver transplant, he was given a terminal diagnosis of hepatorenal syndrome. Palliative Care was consulted, and the plan was for the patient to go home on hospice. We were consulted as the Nephrology service to help prognosticate regarding hepatorenal syndrome. We noticed he never received diuretics during his hospital stay. Given lack of diuretic trial and elevated right heart pressures, we did not feel that cardiorenal syndrome was fully ruled out. We recommended a trial of aggressive diuresis. Over the next three days his net output was several liters more than his net intake, and his creatinine markedly improved. After reaching euolemia, echocardiogram was repeated and right heart pressures were remarkably lower. His creatinine returned to his baseline, and cardiorenal syndrome was determined to be the actual diagnosis. He was discharged home on higher doses of diuretics, and continues to do well with no further kidney issues.

IMPACT/DISCUSSION: Anchoring and confirmation bias occur when a clinician relies too heavily on an initial diagnosis and does not re-evaluate the thought process as more clinical information becomes available. They are among the more common of the cognitive biases frequently encountered in medicine. These closely related biases can be incredibly detrimental to patient care, often leading to misdiagnosis. Since incorrectly diagnosing a terminal condition can lead to premature withdrawal of care and subsequent loss of potential time and health, it behooves us to constantly analyze our clinical data.

CONCLUSION: Cognitive biases can be difficult to avoid, and can cause patient harm if not corrected. Constantly reassessing the available clinical information from different angles helps prevent it. Any patient being given a terminal diagnosis requires a thorough re-evaluation of the clinical data, given the life-altering and potentially life-limiting impact of this news.

ANCHORS AWAY: DIAGNOSING ACUTE HEPATITIS C IN A PATIENT WITH RECENT NONREACTIVE HEP C ANTIBODY AND HISTORY OF ACETAMINOPHEN INGESTION

Raj Dalsania; Jill Allenbaugh. Temple University, Philadelphia, PA. (Control ID #3160165)

LEARNING OBJECTIVE #1: Cite the importance of the time course of an acute Hepatitis C infection

LEARNING OBJECTIVE #2: Name consequences of anchoring bias in clinical reasoning

CASE: A 29 year old Spanish-speaking male with a past medical history of intravenous drug use (last use 3 months ago), depression, and chronic back pain presented to the ED complaining 4 days of dark urine, abdominal pain, nausea, and vomiting. Pertinent labs included an elevated total bilirubin of 5.2, ALT 927 and AST 564 with normal alkaline phosphatase and PT, INR, PTT. The patient reported taking about 8-10 acetaminophen tablets a day along with 2-3 oxycodone/acetaminophen pills over the past 3 weeks in order to better control his back pain. A chart review showed a negative Hepatitis C antibody from 16 days prior. An acetaminophen level was <10 ug/mL, but there was high suspicion for acetaminophen overdose so the patient was admitted and started on NAC. Despite NAC treatment, the patient's LFTs rose, peaking at ALT 1143 and AST 679.

Further work up included an infectious work up which was negative for CMV, HSV, EBV, Hep A, and Hep B, and an autoimmune work up which revealed a positive smooth muscle antibody. A repeat Hep C antibody was positive with RNA of 752,428. Based on these new findings, NAC was stopped, he was managed conservatively with symptom improvement, and he was discharged to follow up with Hepatology.

IMPACT/DISCUSSION: This case represents the importance of avoiding anchoring bias in medicine. The patient's presentation seemed like a "slam dunk" diagnosis with elevated liver enzymes, abdominal pain, excess acetaminophen use, and a recent negative Hep C antibody screen. However, the negative acetaminophen level, and lack of improvement on NAC forced a reevaluation of the patient that ultimately led to a conclusive diagnosis. Although the majority of patients acutely infected with Hepatitis C are asymptomatic, some experience jaundice, nausea, vomiting, and abdominal pain. These symptoms manifest anywhere from 2 and 26 weeks after Hepatitis C exposure with RNA being detectable by PCR within a few days, but anti-HCV antibodies needing weeks to become detectable. This patient had a negative HCV antibody just 16 days prior. At that time, the patient's immune system had not mounted a sufficient enough antibody response for detection and thus the diagnosis was almost missed. Had this diagnosis been missed again the patient would have had above 50% chance of developing chronic Hepatitis C and the sequela that comes with that diagnosis.

CONCLUSION: Anchoring bias is one of the most common clinical reasoning biases. This reinforces the importance of investigating all causes of a disease manifestation especially when clinical data does not support the suspected diagnosis. In this case, the negative acetaminophen level and continued worsening LFTs despite treatment led us to reevaluate the diagnosis and we were able to successfully diagnose this patient with acute Hepatitis C which reduced chances of transmission to others and allowed for treatment.

ANCHORS AWAY: DRIFTING ON A SEA OF ASSUMPTIONS

Tiffany L. Brazile²; Briana P. Patton¹; Tanya Nikiforova². ¹University of Pittsburgh School of Medicine, Pittsburgh, PA; ²University Of Pittsburgh Medical Center, Pittsburgh, PA. (Control ID #3180789)

LEARNING OBJECTIVE #1: Identify three essential tests to evaluate a patient with new-onset dyspnea

LEARNING OBJECTIVE #2: Define framing, anchoring, and availability biases and identify how they can contribute to diagnostic error

CASE: MG is a 60 y.o. female nurse who presented with one year of dyspnea. Over the last 3 months, her symptoms evolved to dyspnea, chest pressure, and fatigue with activity at 4 METS, as well as abdominal cramping and non-bloody emesis. Her history included subtotal colectomy, GI bleed, HTN, and left ventricular hypertrophy. MG initially presented to her cardiologist. On exam she was afebrile, had normal S1, S2 without murmurs or gallops, no JVD, and lungs were clear to auscultation. Her EKG showed a chronic left bundle branch block (LBBB). A stress cardiac MRI showed normal EF and absence of ischemic or infiltrative disease. MG was then referred to a pulmonologist. PFTs and CXR were negative. An ABG showed normal oxygenation and incidentally revealed a hemoglobin of 5. She was subsequently hospitalized. Her labs were consistent with profound iron deficiency anemia (IDA). Upon further questioning, MG reported taking ibuprofen daily for the past 8 months and recent dark stools. EGD and flexible sigmoidoscopy were concerning for an occult GI bleed from her ileosigmoid anastomosis.

IMPACT/DISCUSSION: Blood loss is the most common cause of IDA worldwide and can be difficult to recognize if the source is not obvious. MG's presentation of exertional dyspnea, exercise intolerance, and angina are common symptoms of anemia, however, the biases of the patient and her physicians delayed diagnosis and treatment by 3 months. The workup for dyspnea depends on the history and physical exam, and almost always begins with a CBC, SpO₂, and EKG. Despite an unremarkable physical

exam, the clinicians pursued a costly workup of cardiac and pulmonary etiologies and did not include anemia in their initial differential. Diagnostic error may result in up to 80,000 hospital deaths per year and is most commonly caused by cognitive biases. Three biases that affected this case are: **Framing:** MG assumed her symptoms were cardiac in nature and framed them in this context, which impacted how the clinicians viewed her case. **Anchoring:** The cardiologist may have relied too heavily on the patient's chest pain and LBBB, leading to a focused cardiac workup instead of exploring other etiologies. **Availability:** The specialists may have overestimated the likelihood of a cardiac or pulmonary cause of her dyspnea based on their familiarity with those diseases. Strategies to overcome these biases include recognition of these cognitive phenomena, enhanced communication among clinicians, and use of a cognitive forcing strategy to promote sound clinical reasoning.

CONCLUSION: Diagnostic error, most commonly caused by cognitive biases, remains an underestimated threat to patient safety and high-value health care. Acknowledging and assessing one's biases is an important first step in developing mindful practices to improve diagnostic accuracy and patient care.

ANGIOEDEMA UNMASKING DIAGNOSIS OF COLORECTAL CANCER

Niaz Memon; Kathleen McCabe; Emily Silverman; Imran Naqvi. Mercy Health Jewish Hospital of Cincinnati, West Chester, OH. (Control ID #3186379)

LEARNING OBJECTIVE #1: Recognize various presentations of CRC.

LEARNING OBJECTIVE #2: Understand the relationship between severe iron deficiency anemia and the possibility of developing chronic urticaria and acute angioedema

CASE: A 75 yo African American male with PMHx HTN, CKD, and DM-2 presents to the ED with tongue swelling, dysphagia, and shortness of breath. He tried epinephrine shot without relief. History includes previous episodes of angioedema over a one-year period with no triggering event. He was seen by allergist and was negative for complement disorders or allergies. He was not on ACE-I. Patient had unintentional weight loss of 50lbs and complained of nausea/vomiting. Denied significant family history. Physical exam revealed cachectic appearing male with tenderness to palpitation over abdomen. Labs showed hemoglobin of 8.3 with iron studies consistent with iron deficiency anemia. CT scan of abdomen revealed large mass within proximal ascending colon. Colonoscopy showed circumferential mass with biopsies consistent with adenocarcinoma. Patient underwent laparoscopic and did well post-operatively.

IMPACT/DISCUSSION: Angioedema is a common disorder that is seen in both children and adults. Typically, it is mast cell- and bradykinin-mediated. We introduce an elderly patient who has been intubated multiple times from anaphylaxis over a 1-year period without a clear underlying cause. There are reports that link iron deficiency anemia with the development of chronic urticaria leading to acute angioedema. Murine models suggest that the pathophysiology involves uninhibited histamine release by iron binding proteins. Though our patient was anemic, his workup was delayed due to larger concern for recurrent anaphylaxis. However, after treating the anemia, he showed resolution of the angioedema. This case highlights the various presentations of colorectal cancer, and we believe clinicians should include iron deficiency anemia as a differential for angioedema when other causes are absent.

CONCLUSION: Colorectal carcinoma with iron deficiency anemia may lead to the development of chronic urticaria presenting as acute angioedema

ANKYLOSING SPONDYLITIS FLARE MASQUERADE AS RECURRENT DIGIT SWELLING

Yen Cao; Ahl Jeffrey Caseja; John Cadavona. UNLV, Las Vegas, NV. (Control ID #3186121)

LEARNING OBJECTIVE #1: Recognize ankylosing spondylitis as a possible cause of recurrent digit pain and swelling

LEARNING OBJECTIVE #2: Recognize the importance of careful history taking in the diagnosis ankylosing spondylitis flare in order to avoid delay in treatment

CASE: An 85 year old male with a medical history of hypertension, chronic back pain, hyperlipidemia, and uveitis, presented with diarrhea, knee swelling, and recurrent right third digit swelling. Patient reports a history of recurrent third digit swelling and was seen in the emergency department four times and treated for cellulitis with clindamycin. On evaluation, patient had right 3rd proximal interphalangeal pain with left knee swelling and bilateral ankle pain swellings. Further history taking reveals patient had history of recurrent left knee and ankle swelling, back and knee stiffness. X-rays show calcific enthesopathy of Achilles tendon of right ankle and left knee. Chart review revealed an old lumbar spine x-ray from two years ago that missed the documentation of classic bamboo spine with flowing ossification of annulus fibrosus and succinct syndesmophytes. Patient was treated with methylprednisolone IV followed by a prednisone taper on discharge with reported resolution of acute symptoms.

IMPACT/DISCUSSION: Ankylosing spondylitis is a chronic inflammatory disease that involves the axial skeleton, entheses, and peripheral joints. Ankylosing spondylitis has a male predominance of 2:1 with a peak age of diagnosis between age 20-30 years and onset can occur in adolescence. The most common presenting symptom is back pain but the disease can manifest as hip pain and peripheral arthritis. Active inflammation, or flares, can present with joint tenderness, particularly sacroiliac joints tenderness. Enthesitis has been reported to occur in 29% of patient and most often manifests as Achilles tendinitis while dactylitis occurs in about 6% of patient. Diagnosis of ankylosing spondylitis is non-specific. Clinical diagnosis of ankylosing spondylitis should be considered in patients even with later age onset who presents with continuous chronic back pain enthesitis and dactylitis. X-ray imaging can assist in diagnosis by revealing syndesmophyte formation, squaring of the vertebral bodies, vertebral endplate destruction, and Achilles tendinitis.

CONCLUSION: Ankylosing spondylitis can present with digit swellings or dactylitis. When the diagnosis of ankylosing spondylitis is suspected, a careful history taking is key making the correct diagnosis and guide further evaluations and treatment.

ANTI-MDA5-ASSOCIATED DERMATOMYOSITIS: AN UNCOMMON VARIANT OF INFLAMMATORY MYOPATHY

Shilpa Vasishta¹; Joshua Khalili²; Nasheed Jamal³; Jay Persselin¹. ¹UCLA, Los Angeles, CA; ²UCLA School of Medicine/UCLA Health, Los Angeles, CA; ³UCLA, Los Angeles, CA. (Control ID #3186630)

LEARNING OBJECTIVE #1: Recognize clinical features of anti-MDA5-associated dermatomyositis

CASE: A 60-year-old female with no significant medical history presented with forty pounds of unintentional weight loss. Outpatient imaging, upper endoscopy, and age-appropriate cancer screening had been unrevealing. The patient reported dyspnea on exertion, proximal myalgias, generalized fatigue, and painful bilateral hand rash. Review of systems was otherwise negative. Vital signs, head, neck, cardiopulmonary, and abdominal exams were normal. Strength was 4/5 in bilateral deltoids and iloapsoas. Skin demonstrated bilateral palmar papules and periungual ulcerations; joint exam was normal. Labs revealed pancytopenia (WBC 2.2, Hb 9.7, plt 135) with elevated inflammatory markers (ESR 65, ferritin 1968) and positive ANA (1:640, speckled). Further serologies including dsDNA, Sm, RNP, SSA/B, Scl70, centromere, Jo1, Mi2, PL-7/12, Mi2, Ku, EJ, OJ, and SRP antibodies were normal. Workup was pursued for suspected dermatomyositis (DM). CK and aldolase were normal, however EMG of the right deltoid revealed irritable myopathy. CT chest showed bibasilar reticulation, and PFTs showed reduced DLCO of 53% predicted. Skin biopsy of the periungual ulcerations demonstrated

vasculopathy with fibrin thrombi. Further myositis-specific serologic testing revealed elevated anti-melanoma differentiation-associated gene 5 (MDA5) antibody titers. The patient was thus diagnosed with anti-MDA5-associated DM.

IMPACT/DISCUSSION: Anti-MDA5-associated DM is a unique entity characterized by absent or mild proximal myopathy and rapidly progressive interstitial lung disease (ILD). Though pathogenesis is unknown, MDA5 serves immune functions as a RIG I-like receptor in sensing viral antigens, suggesting a possible viral mediator. Anti-MDA5-associated DM was first noted in Japan and accounts for approximately 22% of DM cases in East Asian populations, versus 7-13% of those in the US and Europe. Anti-MDA5-associated DM presents with tender palmar papules and digital ulcerations, with histologic features of vasculopathy. The condition is classically "amyopathic" or "hypomyopathic", given prominent skin findings in the presence of normal or only mildly reduced strength and normal CK. Significant weight loss may reflect esophageal dysfunction. Ferritin levels may be markedly elevated and correlate with disease activity. MDA5-associated ILD tends to progress rapidly and confers poor prognosis. Our patient presented with several hallmark features of anti-MDA5-associated DM. She is currently undergoing evaluation for immunosuppressive therapy. While optimal treatment remains unknown, case series note favorable responses to steroids, calcineurin inhibitors, cyclophosphamide, rituximab, and in refractory cases, IVIG or plasma exchange.

CONCLUSION: Anti-MDA5-associated DM is a unique entity to be considered in suspected DM cases with prominent cutaneous and pulmonary features with or without muscle involvement.

ANTIBIOTIC-INDUCED RADIATION RECALL DERMATITIS

Ian Garrahy¹; Daniel Forman²; Kyle Macaulay¹. ¹Tower Health System, Wyomissing, PA; ²Tower Health, Reading, PA. (Control ID #3186296)

LEARNING OBJECTIVE #1: Radiation recall dermatitis is a rare inflammatory skin condition that occurs over a previously irradiated field most commonly triggered by chemotherapy.

LEARNING OBJECTIVE #2: There are rare instances of antibiotic-induced RRD.

CASE: Radiation recall dermatitis (RRD) is an inflammatory skin reaction that develops in a previously quiescent radiation field triggered most commonly by chemotherapy, particularly anthracyclines and taxanes. Radiation-recall dermatitis secondary to antibiotic therapy is quite rare. The patient is 61 year old female with a past history of squamous cell carcinoma of the left breast treated with neoadjuvant carboplatin, paclitaxel, and anthracycline chemotherapy followed surgery, then subsequent whole breast radiation to 6040cGy. Eight years after completion of her radiation she developed diffuse redness of the left breast after two doses of nitrofurantoin taken for a urinary tract infection. On examination, vital signs were stable and she had an erythematous and excoriated rash on her left breast that clinically appeared to be cellulitis. Given her clinical history, coupled with the temporal relationship of starting an antibiotic, strong consideration was given for antibiotic-induced RRD. Nitrofurantoin was discontinued and the rash progressively resolved within several days. This case demonstrates an example of RRD which is the development of an acute inflammatory skin reaction of a previously irradiated area most commonly triggered by chemotherapeutic agents. This case highlights antimicrobial therapy as a rare cause of RRD and underscores the importance of considering RRD in a patient presenting with an acute rash over a previously irradiated area while on antimicrobial therapy.

IMPACT/DISCUSSION: RRD is an inflammatory skin condition that occurs over a previously quiescent irradiated field. It is most commonly caused by chemotherapeutic agents particularly the taxanes. However, this case highlights one of the rare instances in which antibiotics can cause RRD.

CONCLUSION: RRD should be considered in all patients taking antibiotics who present with a rash over a previously quiescent irradiated field.

APPLICATION OF A NEW NONINVASIVE DIAGNOSTIC APPROACH TO TRANSTHYRETIN CARDIAC AMYLOIDOSIS

Katryna Lim. Emory University, Atlanta, GA. (Control ID #3185844)

LEARNING OBJECTIVE #1: Recognize the unique clinical features of transthyretin amyloidosis.

LEARNING OBJECTIVE #2: Consider a new noninvasive diagnostic approach to cardiac amyloidosis.

CASE: A 75 year-old African American male presented with two months of progressive dyspnea on exertion, orthopnea, and bilateral leg swelling. He had a history of carpal tunnel syndrome, hypertension, atrial fibrillation, chronic kidney disease, chronic heart failure with an ejection fraction of 25%, and had an implantable cardiac defibrillator placed two years prior to this admission. Past workup included a left heart catheterization without coronary artery disease. He had been taking bumetanide, carvedilol, losartan, hydralazine HCL/isosorbide dinitrate, and apixaban. His blood pressure was 119/85, heart rate 101, respiratory rate 18 and oxygen saturation 98% on 2L nasal cannula. He appeared comfortable sitting upright with jugular venous distention to the level of his mid-neck at 90 degrees. He had an irregularly irregular rhythm, an S3 gallop and a grade 3/6 systolic murmur at the left lower sternal border. Lung exam revealed bibasilar crackles. There was pitting edema to the knees bilaterally and his extremities were cool. Initial laboratory evaluated revealed sodium 138, potassium 3.7, BUN 48 and creatinine 2.29. BNP was 2,403 and troponin 0.13. EKG revealed atrial fibrillation with low voltage. Chest x-ray revealed bilateral pleural effusions. Echocardiogram revealed left ventricular ejection fraction of 10%, grade 2 diastolic dysfunction, severely reduced right ventricular systolic function and a bright, thick myocardium. Further workup included a normal serum and urine immunofixation and serum free light chain assay. Nuclear bone scintigraphy findings were positive for transthyretin cardiac amyloid. Clinically, he worsened despite aggressive diuresis and inotropic support. He was discharged to home hospice.

IMPACT/DISCUSSION: Hospitalists commonly care for patients with chronic diastolic heart failure and evidence of hypertrophy; however, the etiology is not always clear. The prevalence of cardiac amyloidosis is surprisingly high and should be considered. Unique clinical features of transthyretin amyloidosis (the most common subtype) include bilateral carpal tunnel syndrome, spinal stenosis, peripheral neuropathy, and spontaneous biceps tendon rupture. Once cardiac amyloidosis is suspected and AL amyloidosis is ruled out, recent data support the use of nuclear bone scintigraphy to detect and confirm transthyretin cardiac amyloid. This is a noninvasive alternative to biopsy in making this diagnosis. We successfully confirmed that our patient had transthyretin cardiac amyloidosis using this approach.

CONCLUSION: Cardiac amyloidosis, specifically transthyretin subtype, is common and often underdiagnosed. Thus, it is important for clinicians to recognize its unique clinical features, including carpal tunnel syndrome, spinal stenosis and biceps tendon rupture, and to consider using nuclear bone scintigraphy when making this diagnosis.

APPRECIATING AMBIGUITY: ATYPICAL TYPHOID FEVER COUPLED WITH UNCERTAINTY IN SUSCEPTIBILITY TESTING

Sarah W. Takimoto; Therese Chan Tack. University of California, San Francisco, San Francisco, CA. (Control ID #3162818)

LEARNING OBJECTIVE #1: Diagnose typhoid fever in a returning traveler.

LEARNING OBJECTIVE #2: Recognize treatment failure due to antibiotic resistance despite reassuring susceptibility testing.

CASE: A 32-year-old man presented to the emergency room with one week of intermittent fevers that began after returning from Pakistan. He reported a previous sore throat, but had no localizing symptoms and was

afebrile in the ED. He was diagnosed with a viral upper respiratory infection. Two weeks later, he presented again for ongoing fevers with a new 12lb weight loss. He denied cough, diarrhea, abdominal pain, or rash. He was afebrile with a normal CBC and BMP. He was discharged with plans for further outpatient work up. The next day he was called back for positive blood cultures. At this presentation, he was tachycardic and febrile to 39.4C. He was admitted and given one dose of piperacillin-tazobactam 4.5g IV. On Hospital Day 2, cultures grew *Salmonella enterica* serotype Typhi (S. Typhi). The California Department of Public Health was notified and he was narrowed to ceftriaxone 2g IV QD x 4 days. He was discharged on Hospital Day 4 on ciprofloxacin 500mg PO BID x 10 days. One month later, the patient presented to his primary care physician with three days of fevers and fatigue. A blood culture was positive for S. Typhi. He was restarted on ciprofloxacin, and an e-consult was sent to infectious disease. Per infectious disease, susceptibility testing showed a ciprofloxacin minimum inhibitory concentration (MIC) of 0.5 µg/mL. This was reported as susceptible; however, a review of antimicrobial break points set by the US Food and Drug Administration revealed a recent change. Previously, S. Typhi was under *Enterobacteriaceae* (< 1 µg/mL = Susceptible), but increasing ciprofloxacin resistance resulted in new break points for extra-intestinal S. Typhi infections (< 0.06 µg/mL = Susceptible, 0.12 - 0.5 µg/mL = Intermediate, > 1 µg/mL = Resistant). The report for ciprofloxacin was amended to intermediate. A comment on intermediate results stated that ciprofloxacin-treated patients may have delayed response or clinical failure. After reviewing this, the patient was started on ceftriaxone 2g IV QD x 14 days. He had a resolution of symptoms and negative cultures.

IMPACT/DISCUSSION: S. Typhi is a gram-negative enteric rod that causes extra-intestinal infection, often referred to as typhoid fever. In the United States, 200 to 300 cases are reported each year with 80 percent in returning travelers. The infrequency with which providers encounter this disease creates a diagnostic challenge when patients present atypically. This is compounded by increasing ciprofloxacin resistance. Both early diagnosis and appropriate break point interpretation are critical to effective treatment of this communicable disease.

CONCLUSION: - Typhoid fever should be on the differential for an acute/subacute fever in a returning traveler. - Clinicians and laboratory workers need to be aware of increasing antibiotic resistance and resulting changes in susceptibility guidelines.

AT A STUDENT-RUN FREE CLINIC, MULTIDISCIPLINARY ADVOCACY LEADS TO IMPROVED CANCER CARE

Lisle Winston²; Ilana S. Lavina²; Sonia Iosim²; Pamela Charney¹. ¹Weill Cornell Medical College, New York City, NY; ²Weill Cornell Medicine, New York, NY. (Control ID #3185925)

LEARNING OBJECTIVE #1: Student's advocacy efforts are often multidisciplinary and time intensive, but can assure high quality patient care.

CASE: A 57-year-old G4P1031 woman with no past medical history presented to a student-run free clinic for her annual well-woman exam. She had menarche at age 14, menopause at age 49, and never used HRT. Family history included a sister diagnosed with stage III breast cancer three years prior. Of note, the patient had a BIRADS-2 mammogram 2 years prior, but had been unwilling to schedule interval screening breast imaging. The patient's physical exam, including breast and axillary lymph node exam, was unremarkable. Routine screening mammogram and ultrasound were scheduled. Mammography demonstrated a spiculated mass in the upper outer quadrant of the left breast, corresponding to an irregular vascular mass seen on ultrasound. Ultrasound-guided needle biopsy revealed invasive ductal carcinoma and DCIS, and the patient was scheduled for the next available appointment at the free clinic. During the interval 4 days, team members representing multiple disciplines collaborated to coordinate care for this patient. Medical student Clinical Directors arranged breast surgery appointments at two public hospitals

and obtained discs of the breast imaging studies and pathology slides for the accepting breast surgeon. Simultaneously, team members worked with the affiliate hospital's social work and finance departments to re-enrolling the patient in health insurance because the patient desired to seek care from the same breast surgeon who had operated on her sister, who was in private practice. With effort, a internist who spoke her language was identified who would accept her limited insurance as well. When the patient arrived to her follow-up appointment, medical students used the SPIKES protocol to communicate the diagnosis. The patient's primary language was not English, but she had been paired with a volunteer first-year medical student who spoke her primary language through our program aimed to maximize culturally competent care. This student played a key role in communication about the myriad of logistical arrangements. The patient was ultimately re-enrolled in health insurance. The same surgeon who operated on the patient's sister operated on the patient. She completed radiation therapy and is now taking hormone therapy. She now follows with a primary care physician near her home that speaks her language. Her prognosis is excellent.

IMPACT/DISCUSSION: Team members from several disciplines and levels of training, including medical students, attending physicians, social workers, and finance administrators, worked together to care for a vulnerable patient. After this case, our clinic implemented a "triage" system, which can be used when routine screening in a primary care setting detects life-threatening time-sensitive disease.

CONCLUSION: Effective advocacy for underserved patients often requires multi-disciplinary collaboration.

ATELZOLIZUMAB INDUCED MYOCARDITIS ON A BACKGROUND OF CARDIAC AMYLOIDOSIS

Rahul Gupta¹; Syed Zaid¹; Amer Sayed¹; Purva Ranchal²; Leonardo L. Zelaya Castillo¹; Elliot Levine¹; Julio Panza¹. ¹Westchester Medical Center, Valhalla, NY; ²westchester medical center, Valhalla, NY. (Control ID #3174840)

LEARNING OBJECTIVE #1: Diagnose cardiovascular complications related to immunotherapy

LEARNING OBJECTIVE #2: Assess patients with myocarditis on background of amyloidosis

CASE: 81 year old man with history of stage 2B lung adenocarcinoma, treated with lobectomy, adjuvant chemotherapy with cisplatin followed by immunotherapy with Atelzolizumab presented to the hospital two weeks after his last infusion of Atelzolizumab with nausea, lightheadedness, diaphoresis and syncope. Vitals and physical exam were unremarkable. EKG demonstrated normal sinus rhythm with first degree AV block, right bundle branch block and left anterior fascicular block. Lab work was notable for troponin level of 19. Transthoracic echocardiogram revealed normal left ventricular systolic function, increased left ventricular wall thickness with an abnormal speckled myocardial appearance. Cardiac catheterization revealed one small vessel coronary artery disease which was not amenable for stenting. The patient subsequently developed slow sustained hemodynamically stable monomorphic ventricular tachycardia refractory to amiodarone and lidocaine. Cardiac MRI showed diffusely elevated T1 signal with apical wall motion abnormalities. Endomyocardial biopsy of the right ventricular septum revealed changes consistent with acute myocarditis, on a background of transthyretin-type cardiac amyloidosis. Patient was started on high dose intravenous methylprednisolone along with beta blocker therapy with resolution of the ventricular tachycardia. However, the patient subsequently developed complete heart block requiring temporary pacemaker. Unfortunately, six days later, the patient developed sudden pulseless electrical activity with cardiac arrest, and despite aggressive resuscitative efforts, the patient expired.

IMPACT/DISCUSSION: Atezolizumab is a monoclonal antibody against programmed death ligand-1 that has shown efficacy against multiple malignancies. Suppression of immune system with immune check points

inhibitors (ICI) has also been associated with adverse effects on multiple organ systems, including the development of myocarditis, though it is very rare with reported incidence of 0.27-1.14%. There is no evidence to suggest a patient with underlying cardiac amyloidosis is more or less susceptible to the development of an inflammatory process such as myocarditis, even when subjected to an unrestrained immune response. In fact, there is only one case report in the literature of combined myocarditis and amyloidosis. Here we have presented a unique case of a patient who developed acute myocarditis from treatment with ICI's and was found on endomyocardial biopsy to also have a background of cardiac amyloidosis.

CONCLUSION: This case illustrates a possible severe cardiovascular complication of immunotherapy, the utility of myocardial biopsy and possibly the predisposition of this complication by undiagnosed cardiac amyloidosis. Rapid diagnosis of myocarditis in patients with immunotherapy and treatment with steroid therapy might be critical to reduce the immune attack.

ATORVASTATIN-TRIGGERED AUTOIMMUNE HEPATITIS

M.Uzman Ghani¹; Harish Guddati²; Hilary Hertan². ¹Montefiore Medical Center, Wakefield Campus, Bronx, NY; ²Montefiore Medical Center, Wakefield Campus, Bronx, NY. (Control ID #3184053)

LEARNING OBJECTIVE #1: -Recognize statins as a rare cause of autoimmune hepatitis

LEARNING OBJECTIVE #2: -To differentiate autoimmune hepatitis from drug induced liver injury

CASE: A 65 year-old woman with primary hypercholesterolemia was admitted to the hospital for generalized weakness with new onset jaundice. She was prescribed atorvastatin 80mg daily 3 months prior to the onset of her symptoms. Labs revealed Alanine transaminase (ALT): 1786 U/L, Aspartate transaminase (AST): 2763 U/L, Alkaline phosphatase (ALP): 1008 U/L, and total bilirubin 10.4 mg/dl (direct 7.2 mg/dl). Hepatitis serology was negative. Abdominal ultrasound and magnetic resonance cholangiopancreatography was negative for choledocholithiasis. Autoimmune workup was pursued at that time. Serum anti-nuclear antibody was negative; however smooth muscle antibody titers were positive at 1:80 dilutions. Immunoglobulin panel revealed increased serum IgG (3.5g). Liver biopsy was done due to persistently elevated liver enzymes, which revealed plasma cells mixed with eosinophils, neutrophils, lymphocytes, and neutrophils in the portal tracts, with focal centrilobular perivenular inflammation. There was no histologic evidence of fibrosis. Diagnosis of drug-induced AIH was made in view of absence of significant fibrosis, which was most likely triggered by atorvastatin. Atorvastatin was stopped and she was started on prednisone and azathioprine, with gradual normalization of liver tests.

IMPACT/DISCUSSION: Autoimmune hepatitis (AIH) is a chronic inflammatory disease of the liver with unknown etiology. Drugs such as minocycline, nitrofurantoin, and hydralazine are associated with AIH. Only a few cases of statin-induced AIH have been reported in literature. We describe a case of AIH that was potentially triggered by high-dose atorvastatin. Statins are commonly prescribed cholesterol lowering therapy, and are known to cause mild asymptomatic elevations in liver enzymes. In rare cases, especially with high doses, they may trigger AIH and liver failure. In this patient, presence of circulating auto-antibodies and hypergammaglobulinemia indicated an underlying autoimmune process. Liver biopsy was considered because of persistently high transaminases with bilirubin elevation despite discontinuation of atorvastatin. One of the helpful points in distinguishing AIH from drug-induced liver injury is absence of fibrosis and eosinophilic infiltration, like in our case. Treatment includes stopping the offending drug and immunosuppression with prednisone with or without azathioprine in severe cases.

CONCLUSION: Statins are rarely implicated in autoimmune hepatitis. Patients who are on statins and have persistently abnormal liver should be worked up for autoimmune hepatitis. The diagnosis is confirmed by serologic evidence of autoantibodies and gamma globulins, followed by liver biopsy.

ATYPICAL PRESENTATION OF CRYPTOCOCCAL MENINGO-ENCEPHALITIS IN A SARCOIDOSIS PATIENT.

Shreya Gor; Taimoor Khan; Deborah Alpert. Jersey shore university medical center, Neptune, NJ. (Control ID #3179763)

LEARNING OBJECTIVE #1: Appreciate the differential diagnosis of new neurologic symptoms in a sarcoidosis patient.

LEARNING OBJECTIVE #2: Recognize the importance of lumbar puncture in establishing a diagnosis for neurologic symptoms in an immunocompromised patient.

CASE: 41 year-old male with a history of sarcoidosis presented with right upper extremity paresthesias, facial droop and slurred speech. He was previously treated with intermittent steroids and methotrexate, but had not received immunosuppressive therapy for two years. He had a normal complete blood count, metabolic panel and inflammatory markers. CT brain revealed a curvilinear diminished attenuation within the left temporal lobe. MRI brain demonstrated an abnormal area of enhancement in the left Sylvian fissure, concerning for venous thrombosis, meningoencephalitis or focal vasculitis; there was no leptomeningeal enhancement. MR venogram was suspicious for left transverse and sigmoid sinus thromboses and cerebral angiogram showed irregularity in left middle cerebral artery. Antiphospholipid antibodies were not detected. Neurological symptoms promptly resolved after empiric treatment with intravenous dexamethasone for presumed neurosarcoidosis. He refused lumbar puncture until hospital day 5. At that time, cerebrospinal fluid (CSF) demonstrated a white blood cell (WBC) count of 308/mm³ with 95% neutrophils (normal 0-5 WBC), glucose 18 mg/dl (40-60 mg/dl), protein 115 mg/dl (15-60 mg/dl) and a positive cryptococcal antigen. Opening pressure was not obtained. Serum latex agglutination and CSF cultures were positive for *Cryptococcus neoformans*. HIV testing was negative and flow cytometry revealed lymphopenia with an absolute CD4 count of 293. Intravenous steroids were discontinued and the patient was treated with intravenous amphotericin and flucytosine. He was discharged on oral fluconazole for eight weeks

IMPACT/DISCUSSION: Cryptococcal meningitis typically presents as chronic meningitis with symptoms including headache, fever, lethargy, sensory and memory deficits, cranial nerve paresis, vision deficits and meningismus. Our sarcoidosis patient presented with symptoms mimicking a transient ischemic attack, and his presentation and imaging findings were initially attributed to neurosarcoidosis. Although neurologic symptoms responded to empiric high-dose steroids, CSF findings were concerning for infection and cryptococcal meningitis was diagnosed. Sarcoidosis patients are predisposed to opportunistic infections due to impairment of cell-mediated immunity and immunosuppressive therapy. Cryptococcal meningitis may be confused with neurosarcoidosis, as both may present with cranial mononeuropathy and meningeal involvement. Leonhard *et al.*(2016) reviewed 40 cases of cryptococcal meningitis in sarcoidosis patients and noted CD4 lymphopenia in all, similar to our patient.

CONCLUSION: It is crucial to have a high index of suspicion for infectious etiology in a sarcoidosis patient presenting with new neurological symptoms. Delay in diagnosis may lead to unfavorable outcomes.

ATYPICAL PRESENTATION OF SEVERE HYPOTHYROIDISM AS CARDIAC TAMPOONADE

Saliha Saleem; Ejaz Shah; Colette Knight. Montefiore Medical Center, Bronx, NY. (Control ID #3185724)

LEARNING OBJECTIVE #1: Recognize cardiac tamponade as one of the presentations of severe hypothyroidism

LEARNING OBJECTIVE #2: Distinguish between signs and symptoms of cardiac tamponade in a hypothyroid patient versus a classic presentation

CASE: 46 year-old woman with hypertension and hypothyroidism came with shortness of breath (SOB) for 1 week. She reported being non-adherent to all medications. On presentation blood pressure (BP) was 202/112 mmHg, heart rate (HR) 62 bpm and Oxygen saturation was 98%. Physical examination was significant for bibasilar crackles. No pedal edema or JVD was found. Initial labs revealed normal troponin but elevated Pro Brain - Natriuretic Peptide. Thyroid function tests (TFT) showed TSH > 1000U/ml and Free T4 0.5 ng/dl. Electrocardiogram (EKG) revealed sinus rhythm and nonspecific ST-T wave changes. Chest X-ray was consistent with pulmonary vascular congestion. She was initially treated for hypertensive emergency with nitroglycerin drip and furosemide. Blood pressure improved but she continued to complain of SOB. Transthoracic Echocardiography (TTE) was done that showed left ventricular hypertrophy (LVH) and large pericardial effusion with evidence of early diastolic right heart collapse. Echo guided pericardiocentesis was done. Her symptoms improved drastically. She was restarted on levothyroxine and her antihypertensives.

IMPACT/DISCUSSION: Commonly reported cardiac manifestations of hypothyroidism include decrease in cardiac output, systolic and diastolic cardiac dysfunction, bradycardia and hypertension. Mild pericardial effusion is common, especially in cases of moderate to severe hypothyroidism. However, presentation of severe hypothyroidism as cardiac tamponade is rare. Our case reports an atypical presentation of hypothyroidism as cardiac tamponade and hypertensive emergency. Cardiac tamponade classically presents as Becks' triad of low blood pressure, distended neck veins and distant muffled heart sounds. Interestingly all these signs can be absent in patient with hypothyroidism which makes the diagnosis on clinical presentation even more challenging. Moreover, the classic EKG findings of cardiac tamponade: tachycardia, electrical alternans and low voltage EKG may be absent. Long-standing untreated hypothyroidism can result in increased arterial stiffness leading to hypertrophy giving LVH in EKG. Potential combination of LVH and large pericardial effusion can lead to a normal voltage EKG. Management of early tamponade is currently unclear and can involve medical management with close observation versus pericardiocentesis. Our case required pericardiocentesis for symptom control.

CONCLUSION: Severe Hypothyroidism if left untreated can present rarely with cardiac tamponade. Diagnosing cardiac tamponade in a hypothyroid person can be tricky and can delay diagnosis and treatment of this life-threatening presentation. Physicians should keep this rare presentation in mind while managing hypothyroid patients.

ATYPICAL PRESENTATION OF SQUAMOUS CELL CARCINOMA OF THE LUNG IN A NON-SMOKER

Manasa Kalluri. Kern Medical Center, Bakersfield, CA. (Control ID #3186030)

LEARNING OBJECTIVE #1: Recognize risk factors for squamous cell carcinoma of the lung in a never smoker in order to decrease exposure

CASE: A 63-year-old Caucasian male with hypertension was admitted for worsening dyspnea and productive cough. The patient was a never smoker. He had a 40-year occupational history in mechanical special effects for the movie industry, which involved handling chemicals that included propane, asbestos, silica, and diesel fumes. His occupation also involved extensive foreign travel to Hong Kong, Mexico, Brazil, Philippines, Spain, and Africa. The patient had a 6-year history of chronic cough productive that was diagnosed as "post nasal drip". However, over time, sputum became a dry, thick, coarse dark brown material. In the past year his cough became associated with progressively worsening dyspnea. One month prior to admission, he experienced chills, night sweats, and worsening cough for which he was given a course of levofloxacin with minimal relief. At time of admission, the patient's peripheral oxygen saturation level was 92% on 3 L/min of supplemental oxygen. Physical examination revealed positive retractions and diffuse inspiratory and

expiratory wheezes. Complete blood count and comprehensive metabolic panel were unremarkable. Chest X-ray showed innumerable small nodular opacities in the lungs bilaterally and patchy confluent alveolar densities in the right lower lobe. Chest CT angiography demonstrated mediastinal and confluent bilateral hilar adenopathy, with calcifications of the tracheal and bronchial cartilage rings. Bronchoscopy was performed and pathology results from biopsy of bronchotracheal tissue and bronchioalveolar lavage washings were significant for squamous cell carcinoma.

IMPACT/DISCUSSION: While smoking is the most important risk factor in lung cancers, approximately 10-15% of cases occur in never smokers. An even smaller percentage contribute to prevalence of squamous cell carcinoma of the lung. Lung cancers in never smokers differ from those in smokers in molecular profile and response to targeted therapy. Thus, the identification of environmental risk factors is important in diagnosing lung cancers. Environmental toxins including asbestos, radon, heavy metals and especially diesel fuel are all considerable risk factors for squamous cell carcinoma of the lung. This particular patient had a 40 year exposure to multiple environmental toxins which placed him at increased risk. Low suspicion of lung cancer, because of he is a nonsmoker with an atypical presentation, may have delayed diagnosis and initiation of treatment.

CONCLUSION: Importance of understanding occupational hazards patient may be exposed to and providing adequate counseling Awareness of atypical presentation of squamous cell carcinoma of the lung in non smoker

B MINDFUL OF PERSISTENT HYPOGAMMAGLOBULINEMIA AFTER RITUXIMAB TREATMENT

Laurie Edelman; Rachel Solomon. Icahn School of Medicine at Mount Sinai, New York, NY. (Control ID #3184444)

LEARNING OBJECTIVE #1: Recognize that hypogammaglobulinemia from rituximab can persist long after therapy.

LEARNING OBJECTIVE #2: Identify patients at high risk for recurrent infections who may benefit from ongoing immunoglobulin level monitoring.

CASE: A 59-year-old woman with history of stage 4 follicular lymphoma, treated with 6 cycles of rituximab-bendamustine followed by rituximab maintenance was observed by her PCP to have recurrent and refractory bacterial infections (including sinusitis, conjunctivitis, and a pneumonia) starting more than a year after completing treatment for her cancer. In between infections, the patient felt well. She denied weight loss, night sweats, fevers, and chills. There was no lymphadenopathy on exam. Objective weight remained stable. Labs including HIV, CBC, CMP and hemoglobin A1C were unremarkable; CT / PET was reassuring against recurrence of disease. However at 18 months post-treatment with rituximab, an immunofixation panel revealed undetectable IgA and IgM and IgG 356 (700-1600). She was referred to an immunologist. Assessment for immunoglobulin functionality revealed low IgG subclass 1 levels. Her titers for MMR, Diphtheria, and pneumococcal IgG were undetectable despite prior vaccinations. A single dose of intravenous immunoglobulin (IVIG) quieted her infections for six months. She then developed severe, recurrent sinus infections. Administration of another dose of IVIG again showed benefit. She continues with active monitoring to determine appropriate treatment intervals.

IMPACT/DISCUSSION: Rituximab is a B-cell depleting monoclonal anti-CD20 antibody used to treat Non-Hodgkin Lymphoma, Rheumatoid Arthritis and other autoimmune diseases. While nearly half of the patients who receive rituximab have a decrease in their immunoglobulin levels, very few manifest clinically with severe infections from hypogammaglobulinemia. A small subset will have persistent hypogammaglobulinemia beyond a year. Risk factors include older age, pre-treatment low IgG levels, concomitant chemotherapy, and multiple courses of rituximab. There is currently no guideline for monitoring immunoglobulin levels in patients treated with rituximab nor is there a defined treatment course.

CONCLUSION: Primary care providers should have a low threshold to assess for hypogammaglobulinemia in patients treated with rituximab who present with recurrent or persistent infections. Immunology consultation and IgG therapy should be considered in patients with severe infections.

BACTEREMIA AND RENAL/PERINEPHRIC ABSCESES WITH LACTOBACILLUS JENSENII AND PREVOTELLA BIVIA IN A YOUNG WOMAN FOLLOWING URETERAL STENTING

Abhinav Mohan¹; Jacob Rubin²; Priyank Chauhan¹; German E. Giese¹; Juan C. Lemos Ramirez¹. ¹Memorial Healthcare System, Pembroke Pines, FL; ²Florida Atlantic University, Fort Lauderdale, FL. (Control ID #3182159)

LEARNING OBJECTIVE #1: To describe predisposing factors leading to renal and perinephric abscesses caused by *L. jensenii* and *P. bivia* in a young immunocompetent individual.

LEARNING OBJECTIVE #2: To present a successful antibiotic treatment regimen against *L. jensenii* and *P. bivia*.

CASE: We report a 26-year-old woman with history of renal cyst, recent nephrolithiasis with lithotripsy and ureteral stenting, hematuria with stent, and recent antibiotic use who presented to ED with right flank pain, fever, tachycardia, and leukocytosis. CT abdomen/pelvis showed right-sided renal and perinephric abscesses. Empiric meropenem was started. Renal abscess was percutaneously drained, and cultures grew *Lactobacillus*, *Streptococcus anginosus* and mixed anaerobes. Blood cultures grew *Lactobacillus jensenii*. Patient was switched to ceftriaxone and metronidazole and repeat blood cultures taken three days later were negative. One week later, repeat CT scan showed growing right perinephric abscesses. The largest was percutaneously drained and culture grew *Prevotella bivia*. CT urogram revealed no abnormal fistulous tracts. Patient clinically improved and was discharged on ceftriaxone and metronidazole with percutaneous drains in place. After 2 weeks, repeat CT scan showed near-complete resolution of all abscesses. Drains were removed and antibiotics discontinued. Patient was clinically asymptomatic until two months later, when she developed *Gardnerella*-positive bacterial vaginosis with undetectable *Lactobacillus* levels in the vaginal flora.

IMPACT/DISCUSSION: *Lactobacillus jensenii* and *Prevotella bivia* are normally protective, commensal organisms in the female genital tract. Clinical disease caused by these organisms is rare in young and/or immunocompetent persons; in fact, *Lactobacillus* infection is associated with high mortality due to frequent co-presentation with severe comorbid illness. In our patient, nephrolithiasis-induced urinary stasis, elimination of competing microflora with prior antibiotics, recent ureteral stenting, and history of renal cyst all created a favorable environment for *L. jensenii* abscess development. Subsequent clearance of *L. jensenii*, which normally inhibits *P. bivia*, then allowed for *P. bivia* abscess growth. Clinical resolution with ceftriaxone and metronidazole (along with interventional drainage) confirmed data from in vitro antibiotic susceptibility testing studies. Overtreatment of *Lactobacillus* may increase risk of bacterial vaginosis.

CONCLUSION: To our knowledge, there are no existing reports of a single patient with multiple, simultaneous abscesses in the renal system caused by *L. jensenii* and *P. bivia*, two normally commensal microorganisms. However, in our case, a series of factors led to a favorable environment for these organisms to produce clinical kidney infection in an immunocompetent patient. Resolution required targeted interventional drainage and appropriate antibiotic therapy.

BACTERIAL MENINGITIS MASQUERADE AS ACUTE ST ELEVATION MI

Eric W. Leland¹; Rahul Dasgupta². ¹Summa Akron City Hospital, University Heights, OH, OH; ²Summa Health, New Abany, OH. (Control ID #3186440)

LEARNING OBJECTIVE #1: Diagnose and treat CNS infections despite disparate symptomatology

LEARNING OBJECTIVE #2: Quickly and effectively amend your treatment approach when presented with new information

CASE: 50 year old male with hypertension and moderate alcohol and tobacco use presents to the ER complaining of "pain all over" including headache which woke him from sleep, right sided chest, back, and leg pain. Upon arrival to the ER, he was hypertensive with a blood pressure of 178/128 and bradycardic with a heart rate in the 40s. EKG showed ST elevation in leads II, III and aVF, and troponin was 13. He was sent to the cath lab where a 100 percent right coronary artery occlusion was noted. Multiple attempts were made to cross the RCA lesion without success and therefore this was thought to be a chronic total occlusion. He was then sent to the ICU for post-procedure monitoring at which time his mental status precipitously deteriorated. He was intubated for airway protection and a team stroke was initiated. CT head showed no acute hemorrhage or cortical infarction and no other significant pathology. During this time, he became febrile and his level of consciousness continued to decline. Later on day hospital day two, his blood cultures showed positive streptococcus pneumoniae, and he was started on broad spectrum antibiotics with ampicillin, ceftriaxone and vancomycin. MRI showed cerebral edema concerning for meningitis which was confirmed with positive LP on hospital day 5. His antibiotic regimen was deescalated to ceftriaxone after sensitivities resulted, and was prescribed six weeks of antibiotic therapy. His hospital course was further complicated by a GI bleed caused by duodenal ulcers which resulted in bi-hemispheric cortical ischemic stroke on MRI which resulted from acute anemia. A tracheostomy and PEG tube was placed 13 days into his hospitalization. He also developed C diff colitis and a re-bleed of his duodenal ulcers on hospital day 20. He was discharged 25 days after initial presentation to a rehab facility for further antibiotics and therapy.

IMPACT/DISCUSSION: This case highlights the importance of having a broad differential diagnosis for every patient, no matter how vague the complaint. This patient presented with non-focal complaints other than a headache that woke him up from sleep. The care team then was forced to pursue a cardiac pathology as the cause of his complaints due to EKG changes and elevated troponins. However, the true culprit of his illness was quickly identified less than 24 hours after presentation due to his declining mental status and worsening encephalopathy. The care team did well to swiftly and empirically treat his bacterial meningitis.

CONCLUSION: Although his hospital course was complicated by downstream effects of a long ICU, his prognosis very well could have been much graver had the care team not quickly identified a central nervous system infection. This case presentation reiterates the importance of having the ability to quickly amend one's diagnosis and resultant management.

BACTRIM INDUCED HYPERKALEMIA: A WIDELY USED ANTIOTIC WITH A SERIOUS ADVERS EFFECT

Shahrzad Shidfar. umassmemorial, Worcester, MA. (Control ID #3184337)

LEARNING OBJECTIVE #1: Recognize hyperkalemia as a less common but clinically important adverse effect of hyperkalemia

LEARNING OBJECTIVE #2: Assess need for antibiotic treatment even if it is a generally well tolerated antibiotic

CASE: A 53-year-old man with seizure disorder, hypertension controlled with lisinopril and enucleated right eye due to neurofibromatosis type 2 and chronic osteomyelitis of frontal bone presented with two-day history of worsening left-sided muscle twitching and pain. Pain was severe and aching from the left side of his face down to his leg. He described the aching as a "twitching" but without visible rhythmic motions. This was in conjunction with left lip numbness and associated dysarthria and worsening left-sided weakness. He had these symptoms before though they happened infrequently and lasted no more than five minutes. Now, the

pain was reoccurring hourly and through the night. He had 3/5 flexion and extension strength in left upper and lower extremities and 4/5 flexion and extension in right upper and lower extremities. Reflexes were 1+ bilaterally. He had a left-sided facial droop and was unable to open his left eye. There was whitish pus-appearing material in the right orbit but without orbital or periorbital erythema. Potassium was 7.7 mmol/L, creatinine 1.19 mg/dL (baseline of 0.7-0.8 mg/dL) and normal creatine kinase. Hyperkalemia resolved after receiving insulin, normal saline bolus, and furosemide. His presenting symptoms also improved in severity and he no longer felt the twitching nor the weakness. A more detailed review of his medications revealed that he had recently been started on Bactrim for presumed eye infection in the enucleated right eye a week prior to admission. He was evaluated by ophthalmology and otolaryngology and they concluded that presumed pus was in fact old necrotic tissue at the base of right orbit likely secondary to chronic osteomyelitis of his frontal bone which didn't require antibiotic treatment. His Bactrim was discontinued. Potassium level remained within normal limit.

IMPACT/DISCUSSION: Bactrim is commonly prescribed for a wide range of infections in the outpatient setting and is generally well tolerated. Given its ubiquity, it is important to recognize its many and varying adverse drug reactions. Hyperkalemia is a well-known side-effect of administering Bactrim though it happens less commonly than gastrointestinal upset or rash. Previous studies have demonstrated that hyperkalemia is much more likely to occur in patients receiving ACE inhibitors.

CONCLUSION: Hyperkalemia is a serious adverse event associated with Bactrim and clinicians should consider laboratory monitoring of serum creatinine and potassium concentrations at baseline and during therapy in out patient setting with concomitant use of ACE inhibitors. This case exemplifies the importance of detailed history taking, medication administration, a thorough physical exam, as well as judicious antibiotic treatment to avoid patient harm.

BAD TO THE BONE: A CHALLENGING DIAGNOSIS

Letisha Ferris; Michael P. Smith. University of Nebraska Medical Center, Omaha, NE. (Control ID #3185811)

LEARNING OBJECTIVE #1: Develop an approach to sterile osteomyelitis

LEARNING OBJECTIVE #2: Understand the diagnostic criteria and therapeutic options for SAPHO in order to prevent unnecessary and painful testing and treatments

CASE: A 76-year-old woman with past medical history of sero-negative polyarthritides presented with bilateral wrist pain and swelling. She had failed multiple immune-modulators. Synovial wrist biopsies were consistent with synovitis and osteomyelitis. She developed increased swelling, warmth, and a purulent drainage from her right wrist shortly after the biopsies prompting antibiotic treatment that resolved the purulence but joint pain and swelling persisted. She ultimately received multiple courses of antibiotics. There was never any significant culture growth. Wrist x-rays revealed polyostotic destructive changes. MRI confirmed extensive osteolytic and cystic changes in multiple bones of both upper extremities. Ultrasound of her sternoclavicular joint revealed erosive disease without synovitis, effusion, or hyperemia, highly suggestive of SAPHO. There was hesitation to diagnose due to her lack of skin manifestations but given her lack of culture results and her clavicle imaging findings, Anakinra (an IL-1 inhibitor) was initiated. Disease progressed to involve bilateral elbows and left shoulder but when last seen, approximately one year since initiation of Anakinra, symptoms had completely resolved.

IMPACT/DISCUSSION: CNO or CRMO (thought to be the severe form of CNO) is an auto-inflammatory disorder characterized by painful sterile bone inflammation that most commonly presents early in life and predominantly in females. SAPHO is a variant of this disease that exhibits skin manifestations prior to bone involvement. SAPHO is classically thought to be the adult version of CNO/CRMO but has been described in adolescents.

Reliable serum markers for this disease have yet to be identified and routinely checked inflammatory markers may be elevated. Diagnosis is made by imaging, most reliably MRI. Whole body imaging is recommended when CNO/CRMO or SAPHO are suspected as it can identify non-symptomatic lesions. To the same effect, whole body imaging is used for treatment surveillance. Biopsy is warranted when the diagnosis is unclear. First-line therapy is non-steroidal anti-inflammatory drugs. Second-line therapies include steroids, bisphosphonates, and immunosuppressive agents. All these treatments have had mixed results, related to the fact that the pathogenesis of this disease remains unclear but likely involves multiple inflammatory pathways.

CONCLUSION: SAPHO, CNO, and CRMO are essential for the general internist to be aware of as these conditions are often misdiagnosed as bone cancer or infection leading to inappropriate interventions that carry morbidity and mortality risk. Conversely, bone sclerosis and subsequent deformity with disability can result when appropriate treatment is not provided.

BARKING UP THE WRONG TREE: A CASE OF STREPTOCOCUS CANIS AND ANCHORING BIAS

Josue R. Flores Balderas¹; Evelyn C. Chan². ¹Medical College of Wisconsin and Affiliated Hospitals, Wauwatosa, WI; ²Medical College of Wisconsin, Milwaukee, WI. (Control ID #3186044)

LEARNING OBJECTIVE #1: Appreciate that *S. canis* a rising zoonotic pathogen in humans.

LEARNING OBJECTIVE #2: Recognize that anchoring bias can delay a correct diagnosis and lead to overlooking the significance of a physical exam finding.

CASE: A 67-year-old man presented with three days of progressive dyspnea at rest. On day four, over breakfast, he panted with no response to albuterol. He had a history of obstructive sleep apnea, asthma, and chronic venous insufficiency. His medications included fluticasone/salmeterol, montelukast, and furosemide. In the ED he had a fever to 102.7 F, tachypnea to 34, and hypoxemia to 80. Distressed, he spoke in short sentences. He had a neutrophilic leukocytosis to 19. Chest X-Ray and CT pulmonary angiography were unrevealing. His admission diagnosis was asthma exacerbation and sepsis due to community-acquired pneumonia. He was treated with BiPAP, broad-spectrum antibiotics, steroids and nebulizers. Two days later he reported pain in the medial right leg proximal to the ankle so sharp that he required support for transfers. On exam he was noted to have erythema in the lower right leg that was somewhat obscured by the hyperpigmentation seen in venous stasis dermatitis. Once blood cultures grew *S. canis/dysgalactiae*, the team asked if he had pets. He reported that he lived with four dogs who licked his legs. At that point that the team realized that the respiratory symptoms had arisen from sepsis due to *S. canis* cellulitis and sepsis with the portal of entry being the venous stasis dermatitis. Infectious disease discouraged dog removal since the bacteria had likely colonized him. He went home on ceftriaxone to complete 14 days of antibiotics. Compression stockings and emollients were recommended. At follow-up his skin flaked as the cellulitis resolved.

IMPACT/DISCUSSION: As this case shows, anchoring bias can lead to errors in clinical judgment. Biased toward finding a pulmonary source for the respiratory distress, the team overlooked the significance of erythema on the leg and pet exposures in the social history. Anchoring bias is one of many cognitive errors such as premature closure and confirmation bias, an area of clinical reasoning that merits more attention as it can impact patient safety. This case also raises awareness of *S. canis* as a zoonotic pathogen. It is a commensal pathogen in the canine oral and genital flora that can cause opportunistic infections in humans such as cellulitis, pneumonia, urinary tract infections, osteomyelitis and infective endocarditis. The first case of *S. canis* was reported in 1997. As such, it is a relatively new pathogen that ought to be kept in mind as a potential source of infection in dog owners.

CONCLUSION: - Anchoring bias can lead to cognitive error in diagnostic evaluations. - *S. canis* is an emerging zoonotic opportunistic infection that can cause sepsis.

BE MINDFUL OF DISCREPANCIES BETWEEN GLUCOSE AND HEMOGLOBIN A1C MEASUREMENTS — THERE MAY BE IMPORTANT CONSEQUENCES FOR YOUR PATIENT

Jeffrey R. Borgeson¹; Alice Cusick². ¹Michigan Medicine, Fenton, MI; ²Michigan Medicine, Ann Arbor, MI. (Control ID #3160743)

LEARNING OBJECTIVE #1: Identify discrepancies between glucose measurements and hemoglobin a1c measurements

LEARNING OBJECTIVE #2: Understand the possible causes for discrepant glucose and hemoglobin a1c measurements

CASE: The patient is a 73-year-old woman with a history of asthma who presented for a routine health maintenance examination. At the time of the office visit she had no specific concerns. Specifically, she had no fatigue, jaundice, dyspnea, polyuria, polydipsia, or unexplained weight loss. Physical examination was normal. Screening laboratories revealed a fasted glucose of 140 mg/dl, a hemoglobin a1c level of 4.5%, and a hemoglobin of 11.9 g/dl. Otherwise, the complete blood count, comprehensive metabolic panel, and lipid panel were normal. A repeat fasted glucose level was ordered and found to be 129 mg/dl, confirming the diagnosis of diabetes. A repeat hemoglobin a1c was 4.4%. Fructosamine level was 265 micromol/L (high end of normal). Due to what appeared to be an inappropriately low hemoglobin a1c level, a lab investigation was initiated to explore causes of accelerated red blood destruction. This workup produced the following results: reticulocyte count 8.55% (high), LDH 266 IU/L (high), haptoglobin <10 mg/dl, total bilirubin 1.9 mg/dl (high), and a negative direct antiglobulin test (DAT). The peripheral smear showed polychromasia and numerous spherocytes. A CT scan of the chest, abdomen, and pelvis showed mild splenomegaly but was otherwise unremarkable. An osmotic fragility test showed increased erythrocyte osmotic fragility. The evidence of hemolytic anemia, presence of spherocytes on the manual differential, and positive osmotic fragility test confirmed the diagnosis of hereditary spherocytosis.

IMPACT/DISCUSSION: This case shows how the identification of a discrepancy between glucose and hemoglobin a1c measurements may lead to the discovery of a significant hematological condition. A fasted glucose level measurement of 140 mg/dl correlates to a hba1c of approximately 7%. The measured hba1c of 4.5% in this case was therefore much lower than expected. This observation in turn led to the diagnosis of hereditary spherocytosis. Conditions that cause increased red cell turnover lead to a shorter lifespan for hemoglobin and subsequently less time for hemoglobin glycosylation, which in turn leads to misleadingly low hemoglobin a1c levels. Correspondingly, conditions associated with decreased red cell destruction may cause misleadingly high hemoglobin a1c levels. In situations with such a discrepancy, a reasonable workup may include a fructosamine level to confirm the discrepancy, lab testing directed at hemolysis and other disorders of red blood cell metabolism such as iron and B12 deficiency, and imaging to look for splenomegaly.

CONCLUSION: When the hemoglobin a1c is much lower than what would be expected based on an individual's glucose measurements, disorders associated with increased red cell turnover should be investigated.

BECOMING ADEPT IN AGEP: RECOGNIZING ACUTE GENERALIZED EXANTHEMATOUS PUSTULOSIS (AGEP) AS A DISTINCT SEVERE CUTANEOUS ADVERSE REACTION

Alaina C. Chodoff; Kristen M. Livesey; Margaret Shang. University of Pittsburgh Medical Center, Pittsburgh, PA. (Control ID #3167664)

LEARNING OBJECTIVE #1: Distinguish the features of a severe cutaneous adverse drug reaction

LEARNING OBJECTIVE #2: Demonstrate the importance of a thorough physical examination for prompt diagnosis of acute generalized exanthematous pustulosis

CASE: A 84-year-old gentleman with a history of dermatomyositis, treated with prednisone and methotrexate, was admitted with a rapidly progressive pruritic skin eruption that began abruptly after taking clindamycin for a dental extraction. He was afebrile, normotensive and tachycardic. Skin exam revealed widespread erythematous papules coalescing into plaques across his neck, chest, back, abdomen and extremities. Discrete, non-follicular, pin-head sized pustules were scattered across his neck and upper chest. There was no mucosal membrane involvement or lymphadenopathy. Laboratory testing revealed a white cell count of 20,000 cells per microliter of blood of which 80% were neutrophils and 15% eosinophils. He had an acute kidney injury and liver function tests were normal. Cultures of the blood and urine were negative. Histology from a punch biopsy revealed focal parakeratosis and spongiosis with lymphocyte and neutrophil exocytosis, consistent with a pustular drug eruption. A diagnosis of AGEP was confirmed. The rash underwent desquamation and the patient gradually improved with supportive care.

IMPACT/DISCUSSION: AGEP, Stevens Johnson syndrome (SJS), toxic epidermal necrolysis (TEN) and drug rash with eosinophilia and systemic symptoms (DRESS) are categorized as severe cutaneous drug adverse reactions. A thorough physical examination enables detection of the early signs and symptoms of severe cutaneous adverse drug reactions including mucosal membrane involvement, lymphadenopathy, facial edema, blisters and high-grade fevers. Identification of the classic pinpoint, nonfollicular, pustules of AGEP is essential to distinguish this rash from other self-limited exanthematous eruptions. Skin biopsy is confirmatory for diagnosis. As pustular desquamation occurs, classically after 10 days, topical corticosteroids can be applied for symptomatic relief.

CONCLUSION: AGEP is a rare, idiosyncratic, T-cell-mediated, hypersensitivity drug reaction. It is distinguished by its rapid onset after administration of the offending agent, generally within 1-2 days. Over 90% of cases are drug-related, most commonly attributed to antibiotics, antiepileptic agents and antihypertensive agents. Although considered less severe than SJS-TEN and DRESS, there can be overlapping features including mucosal involvement, extensive skin blistering and severe systemic symptoms with end organ damage due to profound neutrophilia and subsequent tissue damage. Up to one-third of patients can also present with eosinophilia, further complicating the differentiation of AGEP. Treatment remains supportive with removal of the offending agent. Once AGEP is suspected, there is no evidence supporting the use of systemic corticosteroids.

BEER-DRINKERS' CARDIOMYOPATHY REVISITED: COBALT TOXICITY AFTER A NON-METAL-ON-METAL HIP ARTHROPLASTY

Daniel Davies; Panithaya Chareonthaitawee. Mayo Clinic, Rochester, MN. (Control ID #3174131)

LEARNING OBJECTIVE #1: Diagnose the cobalt toxicidrome.

LEARNING OBJECTIVE #2: Recognize risk factors for cobalt toxicity.

CASE: A 59-year-old woman with new-onset ankle edema and fatigue presented for pre-operative evaluation prior to revision left hip arthroplasty. A cobalt prosthesis was placed 18 months ago after catastrophic failure of a ceramic-on-ceramic left hip arthroplasty, but subsequently developed "run-away wear". She denied other cardiovascular symptoms, but did note severe progressive hearing loss over the last eight months. A month later, she was diagnosed with hypothyroidism and was started on replacement. Her vision also markedly worsened despite normal ophthalmologic evaluations. She described minimal alcohol use and had no significant cardiovascular or neurologic family history. Physical examination was significant for regular tachycardia of 110 bpm, normal S1 and S2 without murmur, bilateral ankle edema, severe hearing and vision loss, no thyromegaly or nodules, and an

otherwise normal exam. Basic laboratory evaluations, including CBC, creatinine, and thyroid function studies, were normal. An ECG showed only sinus tachycardia. Review of recent brain MRI revealed no significant findings. Due to her signs of new-onset heart failure, an echocardiogram was performed, showing mild concentric left ventricular (LV) hypertrophy, LV enlargement, ejection fraction of 45%, and resting regional wall abnormalities. A follow up stress myocardial perfusion imaging study was performed, which revealed no significant perfusion defects, together suggesting a new underlying cardiomyopathy. Due to her known "runaway wear" of the joint prosthesis and her new constellation of heart failure, hearing loss, vision loss, and hypothyroidism, serum heavy metal levels were obtained with normal titanium, chromium, and markedly elevated cobalt at 953 (normal 0.0-0.9) ng/ml.

IMPACT/DISCUSSION: Our case describes joint prosthesis-related systemic cobalt poisoning. The cobalt toxicodrome classically involves cardiomyopathy, peripheral neuropathy, hearing and vision loss, and hypothyroidism. Cobalt toxicity was first described in the 1965 in nutritionally deficient alcoholics after breweries began using it as an additive agent. A rare, but emerging, modern cause of toxicity is cobalt joint prosthesis wear in the setting of retained ceramic particles from previous joint failure. Treatment includes joint replacement and occasionally chelation therapy.

CONCLUSION: Cobalt toxicodrome includes cardiomyopathy, peripheral neuropathy, hearing and vision loss, and hypothyroidism. Prosthetic joint failure is a new, emerging cause of cobalt toxicity.

BEHIND THE VEIL OF RENAL FAILURE

Brian J. Kinsman; Justin B. Roy; Stephanie L. Harris. PennState Health Hershey Medical Center, Hershey, PA. (Control ID #3184909)

LEARNING OBJECTIVE #1: Identify common clinical manifestations of multiple myeloma.

LEARNING OBJECTIVE #2: Recognize overlap between endocrine disturbances in end stage renal disease and multiple myeloma.

CASE: A 66-year-old Caucasian male with a history of hip osteoarthritis, primary sclerosing cholangitis with cirrhosis, and end stage renal disease (ESRD) due to focal segmental glomerulosclerosis on hemodialysis (HD) presented with three days of acute or chronic right hip pain without an inciting trauma. Medications included lisinopril, bumetanide, sevelamer, calcitriol, and cholecalciferol. On examination, he was afebrile, blood pressure 205/95mmHg, heart rate 69bpm, respiratory rate 16 breaths/min. His right hip was swollen, euthermic, nonerythematous and diffusely tender. Attempts at right hip flexion, extension, or abduction elicited severe pain. Lower extremities were neurovascularly intact. The remainder of his exam was benign. X-ray of the right femur revealed an intertrochanteric fracture with associated lytic lesion. CT chest, abdomen, and pelvis also revealed lytic lesions in the left 9th rib and iliac wing. Initial laboratories showed K 5.6 mEq/L, Ca 9.7 mEq/L, PTH 34 pg/mL, 1,25-OH-Vit-D3 16.5pg/mL, BUN 70 mg/dL, serum creatinine 5.14 mg/dL, Hgb 8.5 g/dL, MCV 91.3 fL, Albumin 3.7 g/dL, 2-microglobulin 15.47mg/L. Serum protein electrophoresis was negative for monoclonal immunoglobulins (Ig); however, urine fixation revealed elevated free-monoclonal Ig, and serum free-chain was elevated 35.3mg/dL with a low : (0.13). This evidence led us to suspect a diagnosis of multiple myeloma (MM), rather than an alternative malignancy. HD was continued while inpatient and his femur surgically repaired. Subsequent results from biopsy of the lytic femur lesion revealed abundant -restricted, CD138+ plasma cells, confirming the diagnosis of MM.

IMPACT/DISCUSSION: The most common clinical manifestations of MM are anemia, bone pain, elevated creatinine, fatigue, hypercalcemia, and weight loss, which result from clonal plasma cell hyperproliferation and secretion of monoclonal Ig's and light chains. Although these manifestations of MM may also be attributed to ESRD-mediated secondary hyperparathyroidism, renal osteodystrophy, and impaired erythropoietin production. This man presented with worsening bone pain, anemia, elevated creatinine, and fatigue. He also had borderline hypercalcemia for a year prior to this

presentation, which could be appropriate while taking calcitriol, cholecalciferol and sevelamer on HD. However, at presentation PTH was normal and 1,25-OH-Vit-D3 depressed, which hints hypercalcemia of malignancy masked by HD. Were it not for his pathologic fracture and lytic lesions, his MM may have progressed undiagnosed.

CONCLUSION: - Shared clinical manifestations to MM and ESRD include anemia, bone pain, elevated serum creatinine, fatigue, hypercalcemia, and weight loss. - Avoid anchoring on existing diagnoses in patients with multiple morbidities and new complaints.

BENEATH THE SURFACE OF A PRURITIC, ERYTHEMATOUS RASH

Megan K. Veglia; Meghan Thomas; Andrew Schreiner. Medical University of South Carolina, Charleston, SC. (Control ID #3185477)

LEARNING OBJECTIVE #1: Recognize the physical signs of dermatomyositis (DM) and how to distinguish them from systemic lupus erythematosus (SLE).

LEARNING OBJECTIVE #2: Assess the therapeutic options for dermatomyositis and determine when intravenous immunoglobulin is a viable treatment.

CASE: A 60-year-old male smoker developed an erythematous, pruritic rash on his abdomen, face, and hands. Skin biopsy revealed hyperkeratosis, apoptotic cells, and a lymphocytic infiltrate with a crowded, band-like pattern. He was diagnosed with cutaneous lupus and treated with a topical corticosteroid. The rash spread and pruritis intensified despite corticosteroid use. He reported increased difficulty swallowing and myalgias so severe that he lost his job. Physical exam revealed erythema of the eyelids and cheeks, including the nasolabial folds. He had erythematous papules symmetrically over the elbows, knees, ankles, and the dorsal aspect of the metacarpophalangeal and interphalangeal joints. Strength was 4/5 in his proximal musculature and 5/5 elsewhere. His skin biopsy was reviewed with immunohistochemical staining and revealed many CD4+ and CXCR3+ cells. He was diagnosed with dermatomyositis and admitted to the hospital. Labs revealed a creatinine kinase of 781 and a sedimentation rate of 6. A swallow study showed silent aspiration. A PEG tube was placed for nutrition. He was treated with high dose intravenous steroids and IVIG for 2 days and discharged to inpatient rehabilitation on prednisone and azathioprine with monthly IVIG infusions.

IMPACT/DISCUSSION: Skin findings of DM are often mistaken for those of SLE. These two diseases are often initially evaluated and managed by general internists, and early diagnosis is crucial to a good prognosis. Classic DM is an idiopathic inflammatory myopathy characterized by proximal muscle weakness and a variety of skin manifestations, including Gottron's papules and heliotrope rash. Skin findings in DM can be distinguished from SLE by (1) the facial rash in DM involving the nasolabial folds; (2) the photo-eruption, which is pruritic in dermatomyositis but not in SLE. The hallmark treatment of DM involves glucocorticoids, and IVIG is used in resistant cases when there is severe dysphagia, or with severe, life threatening illness.

CONCLUSION: DM is an idiopathic inflammatory myopathy characterized by proximal muscle weakness and a variety of skin manifestations, most classically including Gottron's papules and a heliotrope rash. Skin findings in DM can be distinguished from SLE by (1) the facial rash in DM which, when present, involves the nasolabial folds, and (2) the photo-eruption, which is pruritic in dermatomyositis unlike the photo-eruption seen in SLE. The hallmark of treatment of DM involves glucocorticoids, and IVIG is used in resistant/recurrent cases, when there is severe dysphagia, or with severe, life threatening illness.

BETA-BLOCKERS LEADING TO CARDIAC ARREST IN THYROID STORM, EVEN IN NORMAL HEARTS

Nooraldin Merza¹; Phyoe P. Kyaw²; Assad Mohammedzein¹; Sameer Prakash¹; Ahmed Taha¹; Manish Patel². ¹Texas Tech University Health

Science Center, Amarillo, TX; ²Texas Tech Univ HSC Amarillo, Amarillo, TX. (Control ID #3147482)

LEARNING OBJECTIVE #1: Recognize thyroid storm as a potential cause of cardiac arrest.

LEARNING OBJECTIVE #2: Recognize the potential risk of administering Intravenous beta blockers in thyroid storm.

CASE: A 24-year-old female with no past medical history was brought from jail due to altered mental status and abdominal pain for several days. She was febrile, tachycardic, tachypneic, drowsy and restless. She had dry mucous membranes and proptosis. CBC showed WBC 33.3×10^3 , 88% neutrophils, Hb 11 g/dl, pH 7.08, PCO₂ 5, anion gap 24, beta-hydroxybutyrate 78 (0.2 - 2.8), lactate 1.2, free T₃ 23 pg/ml (2.2-6.2), free T₄ 4.7 ng/dl (0.2-2.0), TSH<0.01 units/ml. EKG showed sinus tachycardia with early repolarization. A diagnosis of thyroid storm was made. She was intubated for airway protection and resuscitated with intravenous fluids, she also received hydrocortisone and propylthiouracil to block conversion of T₄ to T₃ and reduce synthesis of thyroid hormones respectively. Intravenous propranolol 1 mg IV push was given, immediately after receiving propranolol, she went into asystole. ROSC was achieved after 4 minutes of cardiopulmonary resuscitation. She required more intravenous fluids and vasopressor support. Bicarbonate infusion was started for severe metabolic acidosis. Echocardiogram showed ejection fraction 70% with no hypokinesia; and Troponin I 1.3 ng/ml and trended down afterwards. Thyroid stimulating immunoglobulin and thyrotropin receptor antibodies were significantly elevated, confirming Graves' disease. Thereafter, she was stabilized and successfully extubated and was discharged on propranolol, methimazole and prednisone.

IMPACT/DISCUSSION: Although there is no definite diagnostic criteria for thyroid storm, Burch-Wartofsky score 45 is highly suggestive of thyroid storm. Our patient's score was 45. No acute coronary syndrome was evident, despite the elevated troponin I, no ST-T changes were seen in EKG. The likely mechanism of Asystole is myocardial depression due to profound acidosis, worsened by propranolol-induced hypotension and bradycardia. Unlike most of the reported cases of cardiac arrest in thyroid storm after propranolol administration, when impaired left ventricular function was evident; our patient had a good left ventricle function with no hypokinesia.

CONCLUSION: Thyroid storm is a rare but a life-threatening condition with significant mortality rate. Beta blockers should be used cautiously in this setting due to potential circulatory collapse. It should be considered as a cause of cardiac arrest in the absence of other identifiable etiologies.

BETWEEN THE BULLETS: A CASE OF MISSED OPPORTUNITY IN PRIMARY CARE

Brittany Badesch¹; Ivy Sledge²; Katherine Shaw². ¹Johns Hopkins Hospital, Baltimore, MD; ²Johns Hopkins Community Physicians East Baltimore Medical Center, Baltimore, MD. (Control ID #3184104)

LEARNING OBJECTIVE #1: Identify young adults who are at acute risk of death by gun violence.

LEARNING OBJECTIVE #2: Describe the need to develop evidence-based strategies to minimize risk of death by gun violence for young adults in urban settings.

CASE: A 32 year-old African-American male with history of chronic left lower extremity pain after a gun shot wound and prior substance use disorder presents to establish primary care. He complains of a burning pain in his left lower extremity, radiating from his knee to his foot, associated with muscle spasms, hyperalgesia and allodynia. He takes Ibuprofen. Recently released from a year of incarceration, he is living with his girlfriend. He has a four year-old daughter. He is not working due to pain. He has 4/5 strength of left foot plantar and dorsiflexion and a painful tingling sensation with touch of the medial left ankle. He endorses anxiety, but denies homicidal or suicidal ideation. He continued to follow in the clinic monthly and

was referred to pain management. Adjustments to his medications improved his pain. He returned to work and increased involvement in his daughter's life. Six months after initial presentation, he was shot and killed.

IMPACT/DISCUSSION: Unfortunately, this is not a unique clinical presentation or outcome. In 2017, the year this patient was killed, there were 39,773 gun deaths in the U.S. Homicide is leading cause of death in 15-34 year old black males, accounting for 49% of deaths for 15-24 year-olds compared to 7-8% in same-aged white males. The ACP's recent update of their Position Statement on reducing firearm deaths largely focused on prevention of mass casualty events and regulation of assault style weapons. Less guidance exists for prevention of everyday gun violence in urban settings, where poverty, unemployment, transiency, addiction, institutional racism and criminalization contribute to increased risk of death by firearm. The patient not only experienced many of these risk factors, but had elevated risk simply based on his previous gunshot wound. His enhanced risk and multiple visits to clinic before the fatal re-injury indicate potential missed opportunity to intervene.

CONCLUSION: Primary care teams are uniquely positioned to serve as navigators for community resources, yet care is limited by a lack of evidence-based practices aiming to address the complex social conditions that generate violence. Since this patient's death, the authors of this vignette, a medical assistant and resident doctor team, continue to encounter young black men who are at acute risk of death, but feel helpless to treat them without coordinated approaches to individualized intervention, community care, and policy change. The authors hope this case will highlight how primary care clinics could be potential staging grounds for interdisciplinary teams, including members of the community who have been affected by gun violence, to fight against this epidemic of young violent death.

BEWARE THE DANGERS OF HOME REMEDIES

Syeda A. Raza. Methodist Health Systems Dallas, Dallas, TX. (Control ID #3185718)

LEARNING OBJECTIVE #1: Recognize the dangers of common home remedies in the immunocompromised patients

LEARNING OBJECTIVE #2: Recognize Burkholderia cepacia as an opportunistic pathogen in immunocompromised patients

CASE: A 68-year-old African-American woman with known history of refractory IgG kappa multiple myeloma presented with fever, congestion, and purulent drainage from both ears that had been progressively worsening over the past week. She initially attributed her symptoms to sinus infection and self-treated with a Neti Pot using non-sterile water. The Neti Pot was several months old and had not been disinfected since purchase. Physical examination revealed an acutely ill-appearing woman with obstructed visualization of both ears due to purulent drainage. The remainder of her physical examination was unremarkable and she did not have indwelling intravascular access. Computed tomography (CT) and magnetic resonance imaging (MRI) of the head and sinuses demonstrated fluid in the tympanic cavities and mastoid air cells bilaterally with paranasal sinus mucosal density and air fluid levels in the maxillary sinuses. Blood cultures grew Burkholderia cepacia susceptible to piperacillin-tazobactam and meropenem. She was treated with four weeks of intravenous (IV) piperacillin-tazobactam along with micro-debridement of both ears. She responded well to therapy, repeat blood cultures were sterile, and she made a complete recovery.

IMPACT/DISCUSSION: Burkholderia cepacia is an aerobic gram-negative bacillus commonly seen in soil and moist environments and has propensity to survive in aquatic environments. Most cases of B. cepacia bacteremia reported in the literature are in patients with cystic fibrosis. However, B. cepacia has recently been identified as an important opportunistic pathogen in hospitalized and immunocompromised patients. There have been several studies reporting hospital outbreaks of B. cepacia emerging from a single contaminated source such as nebulizer

solutions, medical devices, and intravenous solutions. There have even been reports documenting the growth of *B. cepacia* in water systems and colonizing bottled water. *B. cepacia* pseudobacteremia is also noted in numerous reports, but true bacteremia caused by *B. cepacia* is rare. In our case, the patient was not hospitalized in the ICU, did not have cystic fibrosis, did not have an indwelling line, and had not had invasive procedures. Instead, this was a unique case of *B. cepacia* isolation caused by probable environmental contamination after improper use of a Neti Pot with non-sterile water. It is important to note *B. cepacia* is often resistant to many common antibiotics and therefore treatment plans can be complicated. Management primarily focuses on prevention of the infection.

CONCLUSION: *Burkholderia cepacian* has recently been identified as an important opportunistic pathogen in hospitalized and immunocompromised patients. It is important to educate immunocompromised patients about the dangers of common home remedies, which may increase their risk of infections.

BILATERAL ADRENAL HEMORRHAGE PRESENTING WITH ACUTE ADRENAL INSUFFICIENCY IN A PATIENT WITH SUBDURAL HEMATOMA ON RIVAROXABAN

Zachary S. Bugos; Fnu Abhishek. UPMC Mercy, Etna, PA. (Control ID #3185728)

LEARNING OBJECTIVE #1: Recognize ADRs associated with rivaroxaban

LEARNING OBJECTIVE #2: Identify adrenal insufficiency in difficult clinical scenarios

CASE: 70yo morbidly obese F with PMHx of HTN, DM2, hypothyroidism and h/o spontaneous DVT now on rivaroxaban was admitted from OSH for SDH. Pt had been experiencing nocturnal HA and nausea x2d, then while taking a shower the night before admission, suddenly felt weak, sat on bathtub, denies LOC or trauma. Later presented to ED, CT head revealed left tentorial SDH. Pt was transferred to our hospital for further management. Upon arrival to our ICU, factor complex was weight-based dosed for rivaroxaban reversal. Of note, pt has been on rivaroxaban for a year in setting of chronic LLE DVT, but was held on admission and no further AC was given for the duration of hospital course. Pt remained A&O w/o focal deficits, transferred to the floors on HD3 for further monitoring of comorbidities. However, the AM of HD10, during routine nursing check, a rapid response was called for unresponsiveness. BP 51/38, agonal breathing and pulse ox 62%. Initial concern for worsening SDH, pt was intubated and underwent CT head, which was unremarkable. Pt was transferred to ICU and started on norepinephrine plus vasopressin due to persistent hypotension refractory to IVF resuscitation. Initial workup focused on questionable infectious etiology causing septic shock, as pt had leukocytosis to 17K but was afibrile. Due to unknown etiology, a CT abdomen/pelvis was performed which revealed b/l adrenal mass vs hemorrhage. Endocrine consulted, initiated stress-dose hydrocortisone 50mg q8h plus fludrocortisone 0.05mg daily. Repeat CT abdomen/pelvis on HD12 confirmed the diagnosis of adrenal insufficiency caused by b/l adrenal hemorrhage.

IMPACT/DISCUSSION: Rivaroxaban is part of a class of agents known as direct oral anticoagulants (DOACs). Rivaroxaban inhibits both free and bound Factor Xa, ultimately leading to interruption of both intrinsic and extrinsic pathways of the coagulation cascade. Common ADRs include prolonged bleeding from wounds or surgical sites, hematuria, epistaxis and melanotic stool. Notably, cerebrovascular or gastrointestinal sites are considered major bleed events, are acute and easily recognized by providers. However, rare delayed-onset complications, such as b/l adrenal hemorrhage leading to adrenal insufficiency, must be considered in patients presenting with worsening mentation, non-specific systemic symptoms and worsening lab findings. To the best of our knowledge, this is the first case report in which rivaroxaban was the implicated factor for both a cerebrovascular hemorrhage and a delayed b/l adrenal hemorrhage in the same patient.

CONCLUSION: Adrenal hemorrhage should be considered in anti-coagulated patients with refractory hypotension including new direct anticoagulants Diagnostic measures should never delay the treatment in the case of strong clinical suspicion of acute adrenal insufficiency Acute adrenal hemorrhage should be managed as an acute adrenal crisis with IV hydrocortisone

BILE IS VILE: CARDIAC COMPLICATIONS OF CHOLESTASIS

Archana Sridhar; Sophie Barbant. Highland Hospital, Alameda Health System, Oakland, CA. (Control ID #3184295)

LEARNING OBJECTIVE #1: Recognize cardiac complications of elevated bile acid levels

LEARNING OBJECTIVE #2: Treat arrhythmias caused by cholestatic liver disease

CASE: A 32-year-old woman at 38 weeks gestation was admitted to the obstetrics service for intrahepatic cholestasis of pregnancy (ICP). Prior to admission, the patient was seen in clinic reporting pruritis. Serum bile acid levels were ordered and returned elevated at 67umol/L, prompting admission for induction of labor (IOL). The patient's past medical history included an uncomplicated vaginal delivery 3 years prior. She took prenatal vitamins and had no allergies. On hospital day 2, after receiving misoprostol and oxytocin, internal medicine consultation was requested to evaluate her for sustained bradycardia. On examination, the patient appeared well with a heart rate of 35 beats per minute (bpm) and blood pressure of 95/60. Prior to IOL her heart rate was 56 bpm, and her outpatient baseline was 76-88 bpm. Cardiac examination revealed marked bradycardia; the remainder of her exam was unremarkable. Fetal monitoring was reassuring. An electrocardiogram showed sinus bradycardia and ultrasonography revealed normal cardiac structure and function. The differential diagnosis included a paradoxical vagal reaction from pain or positioning, medication side-effect, or thyroid dysfunction. These were considered unlikely given that her heart rate did not change significantly with positioning or contractions, she had received no anesthesia or medications known to cause bradycardia, and thyroid testing was normal. Elevated bile acid levels were ultimately felt to be driving her arrhythmia, and ursodeoxycholic acid (UDCA) therapy was started. Her heart rate improved to 58 bpm one day after UDCA initiation and fetal delivery. In out-patient follow-up, her heart rate was 75 bpm.

IMPACT/DISCUSSION: ICP is known to cause stillbirth through placental transfer of bile acids leading to fetal bradycardia and cardiac arrest. The role of circulating bile acids on maternal cardiovascular health is less well-described, with few reported cases in the literature. Recent animal studies have shown an association between elevated bile acid levels and arrhythmias. Interruption of the cardiac cell membrane by hydrophobic bile acids may alter transcellular calcium exchange, one of the many proposed mechanisms of arrhythmogenesis. Treatment with UDCA, a water-soluble bile acid that decreases levels of hydrophobic bile acids, mitigates cardiotoxicity. Despite newer research examining the role of bile acids in inducing bradyarrhythmias, this relationship remains underrecognized by clinicians. Prompt identification is vital, as treatment with UDCA can prevent morbidity. Further study should explore whether UDCA may ameliorate cardiovascular dysfunction seen in liver cirrhosis, where bile acid secretion is impaired.

CONCLUSION: Elevated bile acid levels in cholestatic liver disease may cause bradycardia. UDCA treats arrhythmias associated with cholestasis.

BILE, THOU SHALT NOT PASS! A CASE OF SYMPTOMATIC HEPATIC SARCOIDOSIS

Kamesh Gupta; Ali Shami; Vellayat Ali. Baystate Medical Center, Springfield, MA. (Control ID #3179967)

LEARNING OBJECTIVE #1: Describe the presentation of symptomatic hepatic sarcoidosis

LEARNING OBJECTIVE #2: Recognize treatment and outcomes for hepatic sarcoidosis

CASE: A 59 year-old African-American male presented to clinic with a several week history of pruritis, jaundice, nausea and weight loss. He had a medical history of hypertension and no history of significant alcohol, drug, or herbal supplement use. Physical examination revealed jaundice without signs of chronic liver disease and a benign abdomen without hepatosplenomegaly. Labs showed elevated liver chemistries including alkaline phosphatase (475 U/L), alanine aminotransferase (88 U/L), aspartate aminotransferase (82 U/L), total bilirubin (3.6 mg/dL) and direct bilirubin (2.2 mg/dL). Extensive hepatic workup was negative including viral hepatitis panel, alpha-1 anti-trypsin, carbohydrate antigen 19-9, as well as negative workup for IgG-4 related disease and other infectious causes for hepatitis. Ultrasound showed only hepatic steatosis, though further abdominal computed tomography (CT) showed an enlarged celiac axis lymph node (>1cm) and portal lymphadenopathy. He underwent endoscopic ultrasound which was negative for bile duct dilatation, and fine needle aspiration cytology of the enlarged lymph node was non-diagnostic. An ultrasound-guided liver biopsy was therefore performed. This showed non-caseating granulomas and bile duct injury, highly suggestive of sarcoidosis. Sarcoidosis was further confirmed with CT of the chest showing mediastinal and hilar lymphadenopathy. There was also high activity of angiotensin converting enzyme in the blood. The patient was started on budesonide and 6-mercaptopurine therapy and responded well to treatment.

IMPACT/DISCUSSION: Sarcoidosis is a multi-system disease characterized by non-caseating granulomas in various organs. Hepatic involvement is common and seen in around 50-80% of patients, but the vast majority of those affected are asymptomatic. Approximately 35-40% of all cases may have abnormal liver chemistries. In some cases, however, hepatic sarcoidosis may present suddenly with symptoms and signs including jaundice, abdominal pain, nausea and vomiting. Hepatic sarcoidosis can lead to cholestasis, portal hypertension and cirrhosis. Extrinsic compression of the biliary tree due to sarcoid granulomas has been reported, as well as an association with increased risk of hepatobiliary cancers. Liver biopsy is the gold standard for diagnosis. Steroids are the mainstay of treatment though their efficacy is variable with only about one-third of patients achieving a complete clinical response. Definitive treatment is liver transplantation; however, recurrence of granulomatous disease is still possible in the transplanted organ.

CONCLUSION: Hepatic sarcoidosis is a common entity that may occasionally present as obstructive jaundice and other signs of liver injury.

BONES AND STONES: RECOGNIZING HYPERPARATHYROIDISM AS A SECONDARY CAUSE OF OSTEOPOROSIS

Callie Plafkin¹; Elaine Pelley². ¹University of Wisconsin Hospital and Clinics, Madison, WI; ²University of Wisconsin School of Medicine and Public Health, Madison, WI. (Control ID #3150221)

LEARNING OBJECTIVE #1: Recognize primary hyperparathyroidism as a secondary cause of osteoporosis

LEARNING OBJECTIVE #2: Suspect hyperparathyroidism in cases with disproportionate loss of bone at the distal radius, which can represent PTH-mediated loss of cortical bone

CASE: A 74-year-old woman with a history of osteoporosis, erosive seronegative arthritis, osteoarthritis status post bilateral hip arthroplasty, and a single bout of nephrolithiasis in 2010 presented to Osteoporosis Clinic in 2017 for further evaluation and management of bone health. Her initial dual-emission X-ray absorptiometry (DXA) scans in 2003 and 2009 had demonstrated only mild osteopenia, with spine T-scores of -0.7 and -1.1, respectively. Due to intervening bilateral hip replacements, her next scan in 2013 measured bone density at the lumbar spine and, for the first time, the distal radius. The spinal bone density was statistically unchanged, but the distal radius had a T-score of -3.4. She was diagnosed with osteoporosis and started on therapy with weekly alendronate and

supplementation with calcium and vitamin D. Labs were notable for intermittent mild hypercalcemia dating back to 2010. The reported worsening in T-score from 2009 to 2013 represented a function of the new measurement site, rather than a true decline in overall bone mineral density. The discrepancy in bone mineral density between the distal radius (primarily cortical bone) and the lumbar spine (primarily trabecular bone), in conjunction with her hypercalcemia and nephrolithiasis, was highly concerning for primary hyperparathyroidism. Further testing revealed an elevated parathyroid hormone (PTH) of 124 pg/mL, normal renal function, normal 25-hydroxy-vitamin D level, and normal 24-hour urine calcium, consistent with a diagnosis of primary hyperparathyroidism (PHPT). She underwent left inferior parathyroidectomy, with subsequent normalization of PTH and serum calcium levels.

IMPACT/DISCUSSION: While the majority of cases of PHPT in the United States are diagnosed prior to the development of obvious skeletal manifestations via incidentally-noted lab abnormalities, PHPT remains an important secondary cause of bone mineral density loss. Excess PTH causes preferential demineralization of cortical bone, frequently manifesting as low bone density at the distal radius site. Such discrepancies should raise suspicion for hyperparathyroidism even in the absence of persistent hypercalcemia.

CONCLUSION: Disproportionately low bone density at the distal radius site compared to axial (spine, hip) sites should prompt evaluation for hyperparathyroidism. Early in its course, primary hyperparathyroidism can manifest as high-normal or intermittent hypercalcemia. Complications of bone loss and nephrolithiasis can occur prior to the development of persistent hypercalcemia.

BRADYCARDIA: THE ONLY PARENCHYMAL MANIFESTATION OF RARE HSV-2 ENCEPHALITIS

Daymon Peterson; Tanaz Salimnia. Wayne State University, Shelby Township, MI. (Control ID #3183051)

LEARNING OBJECTIVE #1: To recognize atypical presentations for improved outcomes of common central nervous system infections.

CASE: A 39-year-old male presented with debilitating headache and fever. Exam demonstrated overt meningismus, however extensive neurologic exam was unremarkable. He was febrile and bradycardic with significant leukocytosis. Lumbar puncture revealed lymphocyte predominate pleocytosis, and indices consistent with viral pathogen. He was hospitalized for empirical antimicrobial therapy, including Acyclovir. Over the first 48 hours, his clinical condition worsened. He developed profound bradycardia consistently in the 20's and serial neurological exams remained unchanged. The following day he began exhibiting severe neuropsychiatric disturbances, lethargy, and loss of gustatory function. CSF testing confirmed HSV-2 by PCR. Patient ultimately responded to Acyclovir therapy in the following days, with parallel resolution of neuropsychiatric symptoms and bradycardia, however had permanent gustatory changes.

IMPACT/DISCUSSION: Although encephalitis often presents with easily identifiable phenotypes, diagnostic challenge arises when encephalitis is encountered in the setting of atypical parenchymal manifestations. Here we present bradycardia as a sign of parenchymal infection associated with pathognomonic involvement of the temporal lobes in HSV encephalitis. Bradycardia is not conceptualized as having relation to encephalitis or temporal lobes, however, bradycardia has previously been linked to temporal lobe dysfunction in other disease processes. Ictal bradycardia syndrome, is a rare event seen in epilepsy, where seizures are accompanied by cardiac arrhythmias, specifically bradycardia. This phenomenon almost exclusively is seen in epileptic disease localized to the temporal lobes and there is no evidence to suggest that this effect is limited to epileptiform activity. Additionally, HSV encephalitis can lead to seizures, suggesting the inflammation of encephalitic disease shares provoking features on temporal lobe neurons, and can trigger a similar cardiac response. Comparable temporal lobe insults with parallel results support a mechanism for which the parenchymal disruption of encephalitis manifests as brady-arrhythmias.

CONCLUSION: Encephalitis is a devastating central nervous system infection that requires early antiviral therapy to optimize management for improved outcomes, however is dependent upon clinician detection of focal parenchymal dysfunction in the setting of CNS infection. Traditional encephalopathic features are well recognized, however concern should extend to atypical signs and symptoms that could represent brain tissue dysfunction. The above case describes bradycardia as the presenting manifestation of encephalitis. HSV encephalitis shares the target insult location with the established Temporal-Lobe Epilepsy induced Ictal Bradycardia Syndrome, and suggest bradyarrhythmia as both a temporal lobe neuronal insult, and previously unrecognized encephalitis defining syndrome.

BREATHING NOT PROPERLY? IT IS MORE THAN JUST HEART FAILURE

Kendall Downer, UPMC, Pittsburgh, PA. (Control ID #3185997)

LEARNING OBJECTIVE #1: Illustrate the value of the negative likelihood ratio of BNP in patients with undifferentiated dyspnea

LEARNING OBJECTIVE #2: Define anchoring bias and recognize the importance of cognitive forcing strategies

CASE: A 71 y/o man with a history of heart failure and COPD on chronic prednisone presented with two months of progressive dyspnea on exertion in addition to weight gain, lower extremity edema and nonproductive cough. He was recently hospitalized for a CHF exacerbation and did not restrict salt or fluid after discharge. He denied paroxysmal nocturnal dyspnea or orthopnea. Physical exam was notable for oxygen saturation 83% on room air. Crackles were present in all lung fields. No gallops or jugular venous distension was appreciated. Marked pitting edema was present in his lower extremities. Labs were notable for BNP 22. Chest x-ray showed patchy, bilateral lung opacities. He was treated for a CHF exacerbation with two rounds of diuresis without improvement in symptoms. At that time, the diagnosis was reconsidered, and a chest CT showed pulmonary fibrosis in a usual interstitial pneumonia pattern. His clinical trajectory was most consistent with an IPF flare as he progressed to respiratory failure and passed away a few days after presentation.

IMPACT/DISCUSSION: Dyspnea is a common complaint faced by internists in all clinical settings and has a large differential. That differential can be narrowed with clinical tools such as The Rational Clinical Exam that allow quick access to and comparison of likelihood ratios (LRs). The negative likelihood ratio of BNP for heart failure in patients with dyspnea in the ED is 0.11. With a pre-test probability of 50%, this patient's post-test probability of heart failure is 9.9%. Other signs and symptoms with high predictive value include an S3 gallop, pulmonary venous congestion, and absence of cardiomegaly with LRs of 11, 12, and 0.33, respectively. In contrast, PND, orthopnea and lack of JVD are of less predictive value, with LRs of only 2.6, 2.2 and 0.66 respectively. Failing to modify the initial clinical impression when discordant information arises - such as adjusting the post-test probability based on the BNP value - is termed anchoring bias. When contradictory data emerges, an appropriate next step is deliberate, systematic reconsideration of the diagnosis, called a cognitive forcing strategy. When these steps do not occur, there is an increased risk of diagnostic error and potential patient harm.

CONCLUSION: Physicians should be aware of the signs, symptoms and tests with the greatest predictive values in common conditions, including the powerful negative predictive value of BNP for heart failure in patients with dyspnea. When a highly predictive test is discordant with the initial clinical impression, physicians should deliberately consider potential biases and alternative diagnoses.

BROADENING YOUR DIFFERENTIAL FOR ABDOMINAL PAIN TO EXTRA-ABDOMINAL CAUSES

Nida Waheed; Kelsey Pan; James Smith; Zareen Zaidi. University of Florida, Gainesville, FL. (Control ID #3185435)

LEARNING OBJECTIVE #1: To recognize not all generalized abdominal pain stems from an intra-abdominal source

CASE: A 47-year-old triathlon runner presented to his primary care clinic due to abdominal pain that was initially epigastric and then generalized and associated with nausea, poor oral intake, and a 15-20 pound unintended weight loss over two months. Physical examination revealed generalized abdominal pain with no organomegaly, point tenderness, guarding, or rebound on palpation. The pain was not associated with referred pain, exercise, or gait abnormalities. Initial work up revealed a negative upper endoscopy and normal lipase. Due to persistent symptoms, a CT abdomen and pelvis was ordered and revealed a soft tissue mass in the right anterior quadriceps femoris muscle measuring 7.3x8.3cm with mass effect upon the vastus lateralis, vastus medialis, and rectus femoris muscles. A biopsy revealed high-grade synovial sarcoma, spindle cell type. He is currently being treated with radiation therapy and neoadjuvant ifosfamide and mesna.

IMPACT/DISCUSSION: The differential diagnosis for generalized abdominal pain is extensive, including IBD, IBS, viral gastroenteritis, constipation, malignancy, chronic mesenteric ischemia and more. Given the clinical presentation of unintentional weight loss, GI malignancy was high on the differential. Although the CT abdomen was unrevealing for intra-abdominal etiologies, it serendipitously led to the discovery of the synovial sarcoma of the right thigh. This case highlights the importance of understanding abdominal and quadriceps muscle anatomy, specifically their origin, insertion, and action. It is also important to pursue further imaging in the setting of "red-flag" symptoms, such as unintentional weight loss. There are no prior cases found in the literature of thigh masses presenting with abdominal pain. Both mass effect on the abdominal and quadriceps muscles and nerve irritation leading to referred pain along the abdominal sheath were considered to be the culprit for this patient's abdominal pain. Synovial sarcoma is a high-grade soft tissue sarcoma with a high mortality rate, making up 5 to 10 percent of all soft-tissue sarcomas. It commonly occurs in children and young adults. Synovial sarcomas often present as a chronic pain at the local tumor site prior to the appearance of a noticeable tumor bulge. Diagnosis is made by biopsy and mainstay treatment for non-metastatic sarcoma consists of surgical resection, followed by radiation and possible adjuvant chemotherapy. Large tumor size (>5 cm), along with high histologic grade, increased age, and invasion of bone or vessels are often associated with poor prognosis. Delay in diagnosis is common, and early recognition has significant prognostic impact.

CONCLUSION: Abdominal pain does not always stem from an intraabdominal source, and it is crucial to pursue further workup for suspected sources of malignancy, despite negative workup of the most likely source.

BRODIFACOUM COAGULOPATHY IN A 23 YEAR-OLD WOMAN AFTER SYNTHETIC CANNABINOID USE

Evans Brown. Johns Hopkins Bayview, Baltimore, MD. (Control ID #3185542)

LEARNING OBJECTIVE #1: Recognize signs, symptoms, and historical details of Brodifacoum toxicity

LEARNING OBJECTIVE #2: Understand basic treatment of Brodifacoum toxicity

CASE: A 23 year-old woman presented with a several day history of unexplained extremity bruising, bleeding from inside of her mouth/lips, epistaxis, and progressive menorrhagia. Review of systems was notable for headache and abdominal discomfort. She had no personal or family history of bleeding or clotting disorders. She reported smoking synthetic marijuana with friends two weeks prior to presentation. Her physical exam revealed scattered ecchymosis on all extremities, varying in size and color, and petechiae on her legs. There was a large amount of blood in the vaginal vault. Laboratory results were most notable for INR >9.6 , and PTT 94.1. Cat scan of the head, abdomen, and pelvis revealed no acute internal

bleeding. She was empirically treated for Brodifacoum exposure with high dose vitamin K for one month, and was transfused 1 unit of fresh frozen plasma. Laboratory analysis returned positive for Brodifacoum.

IMPACT/DISCUSSION: Brodifacoum is a long-acting and potent Vitamin K antagonist commonly used as a rodenticide. Since it was discovered in 1978, there have been reports of human exposure—predominantly via unintentional ingestion among children and intentional ingestion among adults causing significant coagulopathy and death. Recently there has been a dramatic increase in Brodifacoum coagulopathy related to contaminated synthetic cannabinoids. Per the CDC, as of 11/23/2018, at least 320 people nationwide have presented to healthcare facilities with coagulopathy attributed to Vitamin-K antagonist coagulopathy from synthetic cannabinoid use. Brodifacoum coagulopathy presents a diagnostic challenge for clinicians in part because of the delay between exposure and symptom onset; the half-life of Brodifacoum is 16–24 days relative to 17–37 hours for Warfarin. The most common presenting symptoms are spontaneous ecchymoses, mucocutaneous bleeding, and intramuscular hemorrhage¹. The most common cause of death associated with Brodifacoum coagulopathy is intracranial hemorrhage. The mainstay of treatment for Brodifacoum coagulopathy is high dose vitamin K, often with treatment courses that last months. Red-cell transfusion, 4-factor prothrombin complex concentrate (Kcentra), and fresh-frozen plasma can be used to reverse coagulopathy and treat bleeding depending on the severity of presentation. Brodifacoum is teratogenic and poses an additional risk to women of childbearing age. It crosses the placenta and increases the risk of bleeding for both mother and fetus.

CONCLUSION: Brodifacoum coagulopathy should be on the differential for any patient that presents with unexplained bleeding and coagulation abnormalities. Synthetic cannabinoid use should be part of history taking and risk factor analysis for all patients. The mainstay of treatment for brodifacoum coagulopathy is high dose vitamin K, with typical treatment length of several month.

BRUGADA UNMASKING IN THE SETTING OF CITALOPRAM OVERDOSE: A NOVEL ASSOCIATION

Nicholas J. Beccarino¹; Rishi K. Pandya². ¹NYU Langone Medical Center, Greenlawn, NY; ²NYU, New York, NY. (Control ID #3164405)

LEARNING OBJECTIVE #1: Review the Brugada phenotype and its classic pharmacologic triggers.

LEARNING OBJECTIVE #2: Discuss the potential impact of citalopram in unmasking the Brugada phenotype.

CASE: A 25 year old man with depression was brought to our institution within thirty minutes of intentionally ingesting 125mg of citalopram. The patient was initially asymptomatic without significant abnormalities on EKG. An EKG the following morning showed ST elevations in V1-2 consistent with a type 1 Brugada pattern. The patient denied a personal or family history of syncope, palpitations, or sudden cardiac death. ICD placement was deferred considering the lack of high risk features. The patient's EKG normalized over the next few days and he was ultimately discharged on aripiprazole.

IMPACT/DISCUSSION: Brugada syndrome is an autosomal dominant condition associated with malignant ventricular arrhythmia and sudden cardiac death, most often caused by mutations in the alpha subunit of the cardiac sodium channel. Diagnosis requires characteristic EKG findings in the setting of unexplained syncope, ventricular tachycardia or fibrillation, or a family history of sudden cardiac death. While sodium channel blocking anti-arrhythmics such as procainamide are classically associated with the Brugada phenotype, tricyclic antidepressants, analgesics, and illicit drugs have also been implicated. Data regarding selective serotonin reuptake inhibitors (SSRIs) in Brugada syndrome are limited. Paroxetine, fluoxetine, and fluvoxamine have been shown to have sodium channel blocking properties with rare reports of worsening the Brugada phenotype although it is not clear how this correlates to cardiac risk. While it is recommended to

avoid these agents in Brugada syndrome, no similar recommendations exist for Citalopram. Furthermore, there are no previous reports of an association between Citalopram and Brugada syndrome to our knowledge. In fact, very little data exists regarding the cardiac effects of Citalopram. One study of the impact of Citalopram on rodent myocardium noted a shortening of action potential duration, depression of plateau, and reduction of depolarization velocity consistent with sodium channel inhibition, although these findings have not been replicated in humans. Nevertheless, these data suggest citalopram may share the sodium channel blocking effects and impact on the Brugada pattern seen with other SSRIs.

CONCLUSION: Our case represents a young man who developed a Brugada phenotype after a relatively mild citalopram overdose highlighting the possible implication of citalopram in the exacerbation of the syndrome, presumably through an interaction with cardiac sodium channels. Further research on Citalopram's effect on the cardiac action potential and its association with Brugada syndrome is necessary to determine its safety profile within this high risk patient population.

BULLOUS ERYSIPelas WITH FAT HERNIATION

Layla Al bizri; Yusuf Alalwan; Kutayba Alsafadi; Eric Scher. Henry Ford Hospital, Detroit, MI. (Control ID #3181788)

LEARNING OBJECTIVE #1: Recognize that fat herniation is a possible complication of erysipelas

LEARNING OBJECTIVE #2: Distinguish bullous erysipelas from cellulitis or skin abscesses

CASE: A 68 year old female presented with acute onset left leg skin erythema and tenderness of two days duration. She attributed her symptoms following a sting to her left leg which woke her up from her sleep. She also reported mild systemic symptoms including fever and chills. Upon presentation she was found to be febrile and tachycardic. Inspection of the left leg showed a raised, well demarcated area of erythema and mild swelling. A presumptive diagnosis of erysipelas was made and the patient was started on a first-generation cephalosporin. Over the next two days her pain and erythema worsened. She began to form very large bullae which were filled with yellow, gelatinous material. She was initially treated with Cefazolin but was escalated to Vancomycin because of her worsening course. A soft tissue ultrasound ruled out any underlying collection of fluid. Dermatology was consulted on day two of admission and made a diagnosis of erysipelas with fat herniation secondary to elevated subcutaneous pressures from the inflammation. She was started on Prednisone to help reduce the inflammation and her antibiotics were switched back from Vancomycin to cefazolin. The Infectious disease service recommended treating for 14 days. During outpatient follow up in dermatology clinic, patient was noted to have resolution of leg pain and improvement of skin lesions after completion of antibiotic treatment.

IMPACT/DISCUSSION: Initially, the acute onset of symptoms: fever, pain, erythema and swelling with the appearance of a raised well demarcated skin lesion, made erysipelas the most likely diagnosis. However, the sudden appearance of bullae containing gelatinous-like material while on an appropriate antibiotic regimen forced the primary service to reconsider this diagnosis. Necrosis, abscess formation, deep thrombophlebitis and hemorrhagic purpura are known complications of erysipelas that have been reported previously in the literature. Therefore, our reported case of fat herniation resembles a unique complication of erysipelas. According to the literature, fat herniation has been described in piezogenic papules which are benign mostly painless skin-colored papules made of fat associated with exercise, repetitive pressure forces, and connective tissue diseases. To our knowledge, cases of soft tissue infections with described fat herniation have not been reported before. The appearance of bullae on the epidermal surface with subcutaneous fat may have dissipated the pressure within the skin and prevented the formation of compartment syndrome within the patient's lower extremity.

CONCLUSION: Erysipelas can present as a severe soft tissue infection creating a challenge for physicians in both diagnosis and management. Fat herniation represents a unique local complication of Bullous erysipelas.

BULLOUS LUPUS RESEMBLING STEVENS-JOHNSON SYNDROME (SJS) AS THE INITIAL MANIFESTATION OF SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)

Juhu Bhargava. Medstar Washington Hospital Center, Washington, DC. (Control ID #3176567)

LEARNING OBJECTIVE #1: Recognize bullous lesions as the first manifestation of SLE to come to a timely diagnosis.

CASE: We describe a previously healthy 24-year-old woman who presented with vesiculobullous lesions raising concern for Stevens-Johnson syndrome (SJS) who was subsequently diagnosed with bullous lupus as an initial manifestation of SLE. 24 year old female with PMH of anxiety and depression presented with painful pruritic bullous rash for 2-3 weeks. Blisters appeared first on one of her extremities at the site of a recent tattoo and subsequently spread to her face, upper arms, abdomen and legs. The patient also endorsed fever and malaise. Of note, she presented to different ERs twice, where she was initially diagnosed with possible scabies and eventually with possible SJS and was subsequently transferred to our tertiary care facility for further management. Physical examination showed numerous tense bullae of varying sizes and circular ulcerated lesions with overlying hemorrhagic crust. Numerous oral ulcers and tongue papillitis were detected although no conjunctival or genital mucosal involvement. Symmetric inflammatory polyarthritides was present on joint exam. Infectious etiology including HSV and VZV were ruled out by negative viral serologies. Drug reaction and SJS-TEN was also considered given prior use of risperidone and involvement of skin and oral mucosa but this was thought less likely because the agent had been discontinued a month prior to onset of symptoms. Immunologic workup revealed positive ANA, anti-ds DNA, anti-Smith, anti U1RNP and low complement C3. A skin 'punch' biopsy revealed acute cutaneous bullous lesions. Direct immunofluorescence showed strong IgG, C3, IgA and IgM deposition on basement membrane consistent with bullous lupus vs epidermolysis bullosa aquitita (EBA). The clinical presentation (skin/oral lesions, arthritis and constitutional symptoms), positive SLE serologies and biopsy findings clinched the diagnosis of bullous lupus in the setting of SLE based on fulfillment of SLICC criteria. Treatment with prednisone and dapsone led to dramatic improvement.

IMPACT/DISCUSSION: Bullous lesions are seen in known cases of SLE but only rarely do they occur as the initial manifestation of SLE. This case highlights the importance of awareness of bullous lesions as the first manifestation of SLE. Furthermore, distinguishing BSLE from SJS-TEN is essential as the treatment and prognosis differs substantially. Our patient was repeatedly misdiagnosed which led to significant treatment delay and progression of her symptoms. Dapsone leads to rapid resolution of BSLE lesions with rituximab (B-cell depletion therapy) used as a second-line agent in refractory cases.

CONCLUSION: Bullous lesions may be the first manifestation of SLE and thus it is important to be cognizant of it to come to a timely diagnosis.

BULLOUS PEMPHIGOID AS A CONSEQUENCE OF DPP-4 INHIBITORS

Ryann Quinn; Frank Cacace. Northwell Health, Manhasset, NY. (Control ID #3175569)

LEARNING OBJECTIVE #1: Recognize bullous pemphigoid as a potential consequence of DPP-4 Inhibitors in patients with Diabetes Mellitus

CASE: A 91 year-old female with a history of type 2 diabetes mellitus presented to the emergency department with a pruritic rash worsened over the past six weeks. The rash started on her neck, progressed down her

arms, chest, abdomen, back, and thighs. She also began to have tense blisters on her palms. She did not recall any triggering event prior to the rash, insect bites, new medications, or new skin products. She had previously gone to a dermatologist and was prescribed triamcinolone cream twice daily. Her medications included sitagliptin, which she had been on for 2 years, and glimepiride. Her vital signs were unremarkable. Exam revealed erythematous plaques with exfoliative scaling on her arms, back, abdomen, and legs, sparing skin folds, soles, and mucus membranes. She also had tense bullae on both palms. Labs significant for WBC $22 \times 10^9/L$ with 24% eosinophils, hemoglobin A1c 7.8%. Skin biopsy of lesion on right abdomen showed superficial perivascular infiltrate with lymphocytes and eosinophils, with direct immunofluorescence showing positive IgG and C3 staining in linear pattern at the dermoepidermal junction, consistent with bullous pemphigoid. Patient was started on an oral prednisone taper, changed to mycophenolate mofetil at discharge. Her diabetes regimen was changed to insulin and repaglinide, glimepiride and sitagliptin were discontinued. At 16 week follow up, patient had clear skin and eosinophilia resolved, patient continues on mycophenolate mofetil for a 3 month course.

IMPACT/DISCUSSION: Bullous pemphigoid is an autoimmune blistering disease that is most often seen in adults over 60 years old. There is a prodromal phase that can last weeks to months where pruritic eczematous or papular lesions may precede the development of tense bullae, therefore causing a delay in diagnosis. The gold standard for diagnosis is skin biopsy with direct immunofluorescence with linear IgG and/or linear C3 staining along the basement membrane. Bullous pemphigoid is associated with neurologic disorders, malignancy, and certain drugs (spironolactone, furosemide, several antibiotics). DPP-4 inhibitors are now commonly used agents in treating diabetes. The association between bullous pemphigoid and DPP-4 inhibitors has been demonstrated in case series, case-control studies, and registry studies, although the mechanism remains unclear. In reported cases, the development of bullous pemphigoid began 10 days - 5 years after exposure, seen across different drugs in this class.

CONCLUSION: DPP-4 inhibitors are commonly used in primary care for management of diabetes. Primary care clinicians should be aware of the association between DPP-4 inhibitors and bullous pemphigoid. Patients who are taking these agents who present with a new rash suspicious of bullous pemphigoid should be referred for skin biopsy and the DPP-4 inhibitor should be discontinued.

BUPRENORPHINE/NALOXONE INDUCTION IN A PATIENT WITH SEVERE OPIOID USE DISORDER COMPLICATED BY ACUTE HEPATITIS A

Devin Oller. University of Kentucky, Lexington, KY. (Control ID #3182891)

LEARNING OBJECTIVE #1: Recognize the risks and benefits of buprenorphine/naloxone (BUP/NX) in patients with acute hepatitis A (HAV) and Opioid Use Disorder (OUD)

CASE: A 32 year-old woman with OUD presented to the hospital with abdominal pain, nausea and jaundice. She reported daily IV heroin and methamphetamine use in the month prior to presentation. On exam, vitals were within normal range and no confusion, asterixis, or ascites were noted. She scored 10 on the Clinical Opioid Withdrawal Scale. She had marked AST and ALT elevations (2897 and 2203 U/L, respectively), a total bilirubin (TBili) of 7.2 mg/dL, and an INR of 1.5. HAV IgM was positive, HBV Surface Ag negative, HCV viral load negative, and acetaminophen level below assay. Urine drug screen showed amphetamine and fentanyl. Ultrasound of the abdomen revealed normal liver echogenicity and no gallstones. She was diagnosed with acute HAV. On hospital day 2, she was seen by the addiction consult team, and BUP/NX was recommended. She underwent a modified induction protocol, receiving a total of 4 mg of BUP/NX on the first day of induction. Over 3 days her dose was titrated to 8 mg daily. She tolerated the induction without

issues; LFTs were stable at discharge. She was linked to an outpatient BUP/NX clinic. Two months following her discharge, she was seen in clinic and AST, ALT and TBili had returned to normal. Her OUD was in early remission on BUP/NX 16 mg/day.

IMPACT/DISCUSSION: There are 3 FDA-approved medications for OUD (BUP/NX, Naltrexone, Methadone), but in patients with moderate or severe hepatic impairment BUP/NX initiation is not recommended. Our patient faced transportation and cost barriers for methadone maintenance, prompting a shared decision-making conversation about the risks and merits of BUP/NX in the setting of acute HAV. The team explained the risks of BUP/NX in patients with impaired liver function: worsened liver function, increased sedation with impaired BUP/NX clearance, and risk of withdrawal with increased exposure to naloxone component.¹ The patient reported reduced overdose risk, prior success with BUP/NX, and low cost as benefits. She tolerated BUP/NX without complications. 3 other cases of BUP/NX induction in the setting of acute HAV from our addiction consult team show similar tolerability of BUP/NX and stable LFTs at time of discharge—findings not previously described in the literature. Some OUD patients hospitalized with acute HAV can and should be offered BUP/NX. 1.Nasser et al. Pharmacokinetics of sublingual buprenorphine and naloxone in subjects with mild to severe hepatic impairment. *Clin Pharm.* 2015 Aug;54(8): 837-49

CONCLUSION: The risks of BUP/NX initiation in patients with acute hepatitis A may be significant—including worsened liver injury. The benefits of BUP/NX initiation may outweigh those risks for patients with stable LFTs and no altered mental status, especially when they lack other viable options for medication treatment.

CALCIUM CONFUSION: HYPERCALCEMIA AND MENTAL STATUS CHANGES AS A HARBINGER OF METASTATIC MALIGNANCY

Robert N. Stuver¹; Dillon Schafer¹; Alicia Clark². ¹Beth Israel Deaconess Medical Center, Boston, MA; ²Beth Israel Deaconess Medical Center, Wellesley, MA. (Control ID #3176643)

LEARNING OBJECTIVE #1: Initiate emergent management and workup for hypercalcemia.

LEARNING OBJECTIVE #2: Recognize severe hypercalcemia of unknown etiology as a possible presentation of undiagnosed malignancy.

CASE: A 54-year-old male was found wandering the street. On initial examination, the patient was cachectic and disoriented. Laboratory testing showed total calcium of 14.8 mg per deciliter (mg/dL). He was volume fluid resuscitated with subsequent normalization of his calcium within 48 hours. Additional laboratory studies showed low 25-hydroxyvitamin D, normal parathyroid hormone (PTH), and elevated PTH-related peptide (PTHrP). With normalization of calcium, the patient became fully oriented. He had no medical history but reported heavy alcohol use and one month of unintentional weight loss and nausea. Computed tomography of the chest showed an enhancing 2.8 centimeter gastroesophageal mass. Subsequent imaging showed additional lesions in the bones, liver, and brain. Biopsy revealed squamous cell carcinoma of the esophagus.

IMPACT/DISCUSSION: In this case, we present a man with confusion and hypercalcemia ultimately found to have metastatic cancer. The initial management and workup of hypercalcemia were critical in normalizing his neurological status and obtaining a diagnosis, and this case allows for a review of these fundamental principles. Severe hypercalcemia is a medical emergency. Initial treatment is aimed at correction via volume expansion with isotonic saline at rates of at least 200 mL/hour, titrated to maintain urine output of at least 100 mL/hour. Calcium should be monitored at least every 6 hours during this initial correction period. In symptomatic patients with initial calcium greater than 14 mg/dL, calcitonin can be given. Hypercalcemia is never a normal physiological occurrence. The most common causes are parathyroid-related disease or malignancy, though rarer causes include vitamin D intoxication and

granulomatous disease. Diagnosis is initiated by measuring PTH. If elevated, hyperparathyroidism is confirmed. If normal or low, levels of PTHrP, 1,25- and 1-hydroxyvitamin D should be obtained. Elevated vitamin D levels point towards granulomatous diseases or hypervitaminosis, whereas elevated PTHrP suggests humoral hypercalcemia of malignancy, such as in our case. Humoral hypercalcemia of malignancy is secondary to elevations in PTHrP, which acts via physiologic PTH pathways to increase bone resorption and calcium reabsorption in the distal tubule. In these cases, a thorough review of systems, along with age-appropriate cancer screening, should be completed in order to clue in on an underlying cancer. In summary, we present a case of "calcium confusion"—hypercalcemia and altered mental status—a clinical presentation that should always force the clinician to think of malignancy.

CONCLUSION: 1. Hypercalcemia is a medical emergency and should be treated with immediate, aggressive fluid resuscitation. 2. Severe hypercalcemia of unknown etiology should prompt an evaluation for underlying malignancy.

CANAGLIFLOZIN-INDUCED EUGLYCEMIC DIABETIC KETOACIDOSIS IN A TYPE 2 DIABETIC

Nour Chams. Emory, Atlanta, GA. (Control ID #3185713)

LEARNING OBJECTIVE #1: Defining and understanding euglycemic DKA and potential risk factors.

LEARNING OBJECTIVE #2: Timely diagnosis of euglycemic DKA.

CASE: A 47-year-old man with a past medical history significant for diabetes mellitus type 2 presented to the emergency department for diffuse abdominal pain, nausea and vomiting of 2-day duration. He was recently started on canagliflozin 100 mg daily for tighter glycemic control. On exam, the patient was hemodynamically stable with a benign physical examination except for lack of skin turgor and mild diffuse abdominal tenderness on deep palpation. Laboratory workup showed normal blood glucose, high anion gap metabolic acidosis, low bicarbonate, and high beta-hydroxybutyrate. Further blood tests revealed hemoconcentration and normal kidney function, with no evidence of pancreatitis or liver disease. He was diagnosed with euglycemic DKA and treated following the DKA protocol and he was advised to discontinue canagliflozin.

IMPACT/DISCUSSION: Our case presents a patient with non-insulin dependent T2D who recently started canagliflozin and later developed euglycemic DKA, with canagliflozin as the most likely culprit after excluding all other causes of eDKA. SGLT2 inhibitors are a class of oral hypoglycemic drugs that block the reabsorption of glucose in the proximal renal tubules of the kidney leading to excretion of glucose in urine and thus decreasing blood glucose levels. The mechanism behind SGLT2 inhibitor-induced eDKA is not yet well studied. One of the proposed theories is that SGLT2 inhibitors reduce insulin secretion from pancreatic beta cells through its hypoglycemic effect thus stimulating lipolysis and the production of free fatty acids, which are then converted to ketones. Decreased insulin production also promotes the production of ketone bodies through the activation of carnitine palmitoyltransferase-I (CPT-I). Another mechanism through which SGLT2 inhibitors could cause eDKA is through stimulating the secretion of glucagon, either as a direct effect of SGLT2 inhibitors on pancreatic alpha cells or the secondary effect of decreased insulin secretion; glucagon contributes to the overproduction of ketones through increased CPT-I activity. Euglycemic DKA in the setting of SGLT2 inhibitor use develops mostly in individuals with type 1 diabetes and rarely occurs in type 2 diabetes. It is especially rare in those who still have insulin reserves. Our patient was a type 2 diabetic with negative GAD65 antibodies and normal C-peptide levels. These findings indicate that he might still have functioning pancreatic beta cells. Nevertheless, he still developed eDKA while using canagliflozin without having any known precipitating factors.

CONCLUSION: Given that SGLT2 inhibitors, which are widely used for tighter glycemic control, are associated with the development of eDKA in

approximately 20 reported cases, this should trigger further investigations to better understand the mechanism and possible contributing factors.

CAPNOCYTOPHAGA CANIMORSUS: A NOT-SO-RARE CAUSE OF ZOONOTIC BACTERIAL MENINGITIS

Patrick M. Azcarate¹; Julie Caplow². ¹UCSF, San Francisco, CA; ²Northern Navajo Medical Center, Shiprock, NM. (Control ID #3184599)

LEARNING OBJECTIVE #1: Appreciate the challenge in diagnosing early meningitis

LEARNING OBJECTIVE #2: Learn about an emerging cause of meningitis from dog bite exposure

CASE: A 58 year-old previously healthy woman presented to the emergency room with 1 day of fever, headache, and neck stiffness, and two weeks of a non-productive cough. She had no history of alcohol use, intravenous drug use, recent travel or sick contacts, but reported a dog bite to the left hand one week prior. Review of systems was otherwise negative. Exam was notable for a fever of 102.2 F and a healing puncture wound on her left 4th finger. The WBC was 10,200/mm³ (84% neutrophils), and lumbar puncture (LP) was normal. After IV fluids her symptoms improved and she was discharged home with a diagnosis of an upper respiratory infection. She returned the following day with worsening symptoms and new bilateral hearing loss. She was febrile with a blood pressure of 86/70 mmHg and a pulse of 102. She appeared ill and lethargic with nuchal rigidity but an otherwise normal neurologic exam. WBC had increased to 14,500/mm³. Blood cultures were sent. She was admitted to the ICU and given acyclovir, vancomycin, ceftriaxone, and ampicillin. Repeat LP 48 hours after the first revealed WBC 158/mm³ (73% PMNs), RBC 530/mm³, glucose 46mg/dL, protein 112mg/dL and negative gram stain consistent with meningitis. Three days later blood cultures grew gram negative rods, and antibiotics were changed to ceftriaxone and ampicillin. Negative workup included repeat blood cultures, HIV, CSF bacterial culture, and CSF testing for *S. pneumoniae*, *H. influenzae*, and *Listeria*. She completed ten days of antibiotics and the fever, headache and neck stiffness resolved. After thirty-five days, an outside lab identified the bacterium as *Capnocytophaga canimorsus*.

IMPACT/DISCUSSION: Once considered rare, *Capnocytophaga canimorsus* is now recognized as the second-most common infection transmitted by dog bites. Risk factors include asplenia, heavy alcohol use, and immunodeficiency. In half of cases there is a history of bite or saliva exposure from a dog and occasionally a cat. Both species have high prevalence of the bacteria in the oral cavity (20%). Patients typically present with sepsis or meningitis, which may be complicated by hearing loss. The average incubation period is 6 days, but may take up to 30, and requires enriched agar making laboratory isolation difficult. Bacterium are most commonly isolated in blood cultures and rarely in CSF cultures. Patients with severe infections may be treated for 21 days with a third-generation cephalosporin and narrowed to clindamycin or amoxicillin-clavulanate. Immunocompromised patients who experience a dog bite should be prescribed amoxicillin-clavulanate for five days for prophylaxis.

CONCLUSION: -Initial LP may be normal in early bacterial meningitis. Consider repeat LP if no improvement after 48 hours. -In patients with a recent dog or cat bite and sepsis, *Capnocytophaga canimorsus* should be considered and blood cultures incubated for at least 2 weeks.

CAPS: A CATASTROPHIC EVENT

Sneha Patel. Montefiore Medical Center, Bronx, NY. (Control ID #3185866)

LEARNING OBJECTIVE #1: Recognize Catastrophic Antiphospholipid Syndrome (CAPS) as a rare cause of multiorgan failure

LEARNING OBJECTIVE #2: Review the diagnostic criteria and management of CAPS

CASE: A 41 year-old male was admitted after he was found unresponsive at home. On admission, the patient was found to have encephalopathy, acute liver failure, acute renal failure, and severe abdominal pain. Urine toxicology, ethanol levels and acetaminophen levels were negative. Infectious workup was unremarkable. Abdominal CT scan revealed renal and splenic infarcts, bowel ischemia and pneumoperitoneum. The patient underwent exploratory laparotomy, right hemicolectomy, and splenectomy. Liver biopsy showed large areas of thrombi formation. Workup for hypercoagulable state showed positive antinuclear antibody and lupus anticoagulant. ADAMSTS13, fibrinogen, PT, and JAK2 levels were normal. Direct antiglobulin testing was negative. The patient was diagnosed with CAPS. He was immediately started on a course of intravenous immunoglobulin (IVIG), plasma exchange, methylprednisolone, and heparin. Rituximab was started soon after. The patient made a drastic recovery with improvement in liver and kidney function, and was discharged after 45 days of hospitalization.

IMPACT/DISCUSSION: Antiphospholipid syndrome (APS) is an autoimmune condition that is encountered by internists, often in the setting of recurrent thrombosis and/or pregnancy loss. An estimated 0.8% of patients with APS develop CAPS, a rare condition characterized by rapid development of multiorgan arterial and venous thromboses. With mortality close to 50%, early diagnosis and aggressive therapy is crucial for management. CAPS may be diagnosed in individuals with a prior history of APS or can be the first manifestation of APS. Although rare, preliminary criteria for "definite diagnosis" of CAPS have been developed. The criteria require 1) involvement of three or more organ systems; 2) development of symptoms in less than one week; 3) confirmation of small vessel thrombosis by histopathology in at least one organ; and 4) presence of antiphospholipid antibodies. The diagnosis is further supported by ruling out other causes of multiorgan thrombosis, such as disseminated intravascular coagulation, heparin-induced thrombocytopenia, thrombotic microangiopathy, and myeloproliferative neoplasms. Management of this life-threatening syndrome requires urgent initiation of anticoagulation, high dose systemic glucocorticoids and use of plasma exchange, with or without IVIG. If resistant to standard therapy, rituximab or eculizumab can be added. Mortality rate is reduced to 30% with early and aggressive treatment. A retrospective study of 600 patients with CAPS showed that 66% do not have recurrent clotting or emboli.

CONCLUSION: CAPS is a rapid-onset rheumatologic emergency that causes multiorgan failure due to arterial and venous thromboses. Prognosis is extremely poor without treatment, but being aware of this syndrome may allow for prompt recognition and aggressive therapy.

CARDIAC AMYLOIDOSIS AN OVERLOOKED CAUSE OF NEW ONSET HEART FAILURE IN THE ELDERLY

Seda Babroudi¹; James Udelson². ¹Tufts Medical Center, Lincoln, MA; ²Tufts Medical Center, Boston, MA. (Control ID #3185923)

LEARNING OBJECTIVE #1: Recognize key clinical features of that distinguish cardiac amyloidosis from other causes of heart failure

CASE: A 74 year-old Caucasian woman with a past medical history of MGUS, mitral valve regurgitation (MVR), and prior negative cardiac stress test with normal ejection fraction, presented with progressive fatigue and exercise intolerance. Blood pressure was 90/57, but other vitals were within normal limits. Exam was notable for jugular venous distension, symmetric crackles, and bilateral lower extremity pitting edema. Labs were notable for troponin 0.5 and pro-BNP 27,000, but TSH and CK were within normal limits. ECG showed normal voltage with no ischemic changes. Echocardiogram revealed an ejection fraction of 20-25%, severe global hypokinesis of the left ventricle, and moderate to severe MVR. The patient was empirically treated with diuresis and ACE-inhibition, and subsequently became profoundly hypotensive. Endometrial biopsy obtained was positive for Congo red staining, consistent with cardiac amyloidosis. Later subtyping revealed AL amyloid, and the patient was noted to have nephrotic-range proteinuria. The patient passed away before chemotherapy could be initiated.

IMPACT/DISCUSSION: It is estimated that there are approximately 1000 cases of cardiac involvement of AL amyloidosis per year in the United States, with a median age at presentation between 55 and 60 years. Prognosis is poor, with a median survival of 6 months from the onset of heart failure in the untreated population. Swift diagnosis and treatment is therefore crucial in potentially modifying the natural history of this disease. Clinical features suggestive of amyloidosis include the disproportionate degree of BNP elevation as compared to a patient's clinical presentation, intolerance to ACE-inhibition, and nephrotic-range proteinuria. It is postulated that the degree of BNP production in cardiac amyloidosis is secondary to abnormal hormonal activation of myocytes. Similarly, intolerance to ACE-inhibition has been attributed to autonomic involvement of systemic amyloid. Proteinuria is indicative of systemic involvement of disease. An additional feature of this case that may have assisted in the diagnosis included the patient's history of MGUS, a rare precursor of AL amyloidosis. The mainstay of treatment for AL cardiac amyloidosis is diuretics, chemotherapy, and stem cell transplant in select patients. Usual guideline-directed medical therapies for heart failure with reduced ejection fraction are often poorly tolerated.

CONCLUSION: In elderly patients with new-onset heart failure without significant valvular disease, who are low risk for ischemic heart disease, should be evaluated for cardiac amyloidosis. Discrepant BNP elevation and intolerance to ACE-inhibition should be considered potential markers of cardiac amyloidosis.

CARDIOMYOPATHY UNMASKED BY PHEOCHROMOCYTOMA
Younghwa Kwon; Niaz Memon; Yi Xiong. Mercy Health Jewish Hospital of Cincinnati, West Chester, OH. (Control ID #3184610)

LEARNING OBJECTIVE #1: Recognizing the rare presentations of pheochromocytoma

LEARNING OBJECTIVE #2: Understanding the pathophysiology behind pheochromocytoma

CASE: A 53-year old female presented with palpitations, headache, and chest pain. Patient reported emesis and bilateral paresthesia. She recently had flu-like symptoms that resolved 6 weeks ago. Her BP was 182/87 mmHg, and appeared diaphoretic. Labs revealed blood glucose of 497 mg/dL, troponin of 0.26 ng/mL, Lactic acid of 6.9 mmol/L, Anion Gap of 21, and WBC of 21.6 K/uL. Blood gas revealed metabolic acidosis. There were no ketones and A1c was 5.9%. EKG showed anterior and lateral ST-segment elevations, concerning for a ST-elevated myocardial infarction (STEMI). She was started on an insulin drip, heparin drip, and clopidogrel. Patient was transferred to the catheterization lab, which revealed normal coronary arteries, non-dilated cardiomyopathy with reduced ejection fraction of 40%. She continued to complain of pounding palpitations followed by a hot flash sensation. These episodes had been ongoing for seven years. CT abdomen was obtained and showed right adrenal nodule. Plasma metanephrenes were tested, which showed elevated metanephrenes and normetanephrene. These were elevated on repeated labs, as well as in 24-hour urine collection. She had robotic-assisted right adrenalectomy. Repeat plasma metanephrenes 6 months later showed normalization.

IMPACT/DISCUSSION: Pheochromocytoma is able to present in a variety of ways. Typically, it presents as the classic triad: headache, sweating, and tachycardia. Rarely it can present as hypertension and insulin resistance. We present a case of a female who developed STEMI and underwent cardiac angiogram, which revealed clean arteries and resembled stress-induced cardiomyopathy. Further investigations showed elevated metanephrenes and concern for pheochromocytoma. Though our patient had the classic triad, these symptoms were overlooked due to concerns for acute coronary syndrome and DKA (without history of diabetes mellitus). She also had leukocytosis and lactic acidemia with anion gap acidosis, suggesting infection. It is speculated that catecholamine can increase myocardial demand and cause coronary artery vasoconstriction, which may mimic ACS. Additionally, the hyperglycemia can

be explained by alpha-1 and beta-2 adrenergic receptor-induced gluconeogenesis and glycogenolysis. This case highlights the various presentations of pheochromocytoma, and clinicians ought to include pheochromocytoma as a differential for acute coronary syndrome when other causes are unexplainable.

CONCLUSION: Pheochromocytoma can have various presentations due to various catecholamine induced pathways. When classic triad of sweating, headache and palpitation is present, especially in combination with hypertension, pheochromocytoma should always be on the differential diagnosis. Pheochromocytoma in the setting of "pheo crisis" can induce stroke, heart attack, organ failure, coma, and death. In this case, STEMI and DKA was demonstrated.

CARDIOVASCULAR COLLAPSE AND SEIZURES: AN UNINTENDED QUETIAPINE OVERDOSE

Elena Jimenez Gutierrez¹; Spencer Winters²; Siobhan Proksell³. ¹The University of Texas Health Science Center at San Antonio, San Antonio, TX; ²Bronson Medical Group, Kalamazoo, MI; ³University of Pittsburgh Medical Center Presbyterian Hospital, Pittsburgh, PA. (Control ID #3145056)

LEARNING OBJECTIVE #1: Identify rare presentation of quetiapine overdose as part of differential diagnosis for shock

LEARNING OBJECTIVE #2: Recognize risks posed by concomitant use of antipsychotic agent and CYP3A4 inhibitor

CASE: A 58-year-old man presented with two days of confusion, tremors and seizures. Past medical history included schizophrenia, epilepsy, HCV infection and right hemiparesis due to ischemic strokes. He initiated dasabuvir, ombitasvir, paritaprevir and ritonavir (Viekira Pak) three days earlier. His epilepsy had been controlled on lamotrigine for years. Review of systems was unremarkable. Vital signs were notable for tachycardia to 120 and hypotension to 73/51. Physical exam revealed disorientation, miosis, dry oral mucosa, tremors in all extremities, normal reflexes, and no new focal neurologic deficits, meningeal signs, thrush, jugular venous distention or stigmata of cirrhosis. BMP was notable for hypokalemia, acute kidney injury, metabolic acidosis with high anion gap, and normal osmolal gap. VBG revealed mild respiratory acidosis. CBC showed mild anemia. Drug testing was positive for tetrahydrocannabinol. Hepatic function panel, PT/PTT, ammonia, lamotrigine, CK, troponin, cortisol, and D-dimer levels were unremarkable. Urine and blood cultures, HIV serology and CXR were negative. Head CT showed no acute process. EEG revealed only diffuse slowing. EKG showed sinus tachycardia, prolonged QTc, and no ST or T-wave changes. TTE showed hyperdynamic LV function without wall motion abnormalities (WMA) and no RV dysfunction. The quetiapine level was 1434 ng/mL (therapeutic range 100-500 ng/mL).

IMPACT/DISCUSSION: Patient presented in distributive shock due to quetiapine overdose from interaction with ritonavir. Negative infectious work-up and no fever or leukocytosis made septic shock improbable. Cortisol levels ruled out addisonian crisis. Serotonin and neuroleptic malignant syndromes were unlikely given lack of muscular rigidity, abnormal reflexes and elevated CK levels. Normal osmolal gap and unremarkable toxicology screen did not favor toxic ingestions. No arrhythmias or ischemic changes on EKG, negative troponins, and preserved EF without WMA or severe valve insufficiency on TTE ruled out cardiogenic shock. Lack of significant hemorrhage and fluid depletion made hypovolemic shock unlikely. Given no evidence of massive pulmonary embolism, pneumothorax or pericardial tamponade on imaging, obstructive shock was improbable.

CONCLUSION: The case enforced the need to exclude other causes of shock and highlighted a rare presentation of overdose due to drug interactions. Patient experienced delirium, seizures, tachycardia, hypotension, hypokalemia and QTc prolongation as manifestations of quetiapine intoxication. Since quetiapine is metabolized by cytochrome P450 (CYP)

3A4 and ritonavir is an inhibitor of CYP3A4, concomitant use caused toxicity in the patient. Given heightened use of antivirals for HCV therapy, it is important to be aware of potential interactions between these drugs and patients' current medications.

CARPAL TUNNEL, A PRECURSOR TO CARDIOMYOPATHY

Amanda Satterthwaite. Tulane University School of Medicine, New Orleans, LA. (Control ID #3184032)

LEARNING OBJECTIVE #1: 1. Recognize the clinical presentation of TTR cardiac amyloidosis

LEARNING OBJECTIVE #2: 2. Differentiate light chain amyloidosis from TTR amyloidosis

CASE: A 73-year-old man with a 5-year history of non-ischemic cardiomyopathy presented with worsening lower extremity edema and arthralgias that resulted in immobilization. He has a previous history of bilateral carpal tunnel syndrome, atrial fibrillation, and chronic kidney disease. Exam revealed abdominal distention with ascites and bilateral pitting edema of the lower extremities extending to the knee. Laboratory studies are significant for BNP of 4000 pg/mL, BUN and creatinine of 76 mg/dL and 2 mg/dL, and troponin of 0.240 ng/dL. Chest radiograph revealed an enlarged, boot-shaped cardiac silhouette. Echocardiogram revealed an ejection fraction of 25%, severe concentric hypertrophy of the left ventricle, right ventricular dilation, severe bi-atrial dilation, and severe mitral regurgitation. Findings were concerning for infiltrative cardiomyopathy. A technetium pyrophosphate scan revealed diffuse uptake of radiotracer consistent with a diagnosis of TTR cardiac amyloidosis.

IMPACT/DISCUSSION: Transthyretin (TTR) is a tetrameric protein rich in beta strands that is present in human serum. It is synthesized primarily in the liver, as well as the choroid plexus, and retinal pigment epithelium. It is involved in the transportation of thyroxine and retinol-binding protein. Systemic deposition of TTR can lead to amyloidosis, particularly either wild type TTR amyloidosis, or mutant TTR amyloidosis. Mutant TTR is characterized by single point mutations that increase the likelihood of misfolding of TTR. Wild type TTR amyloidosis is sporadic, not associated with any specific biomarkers or mutations, and occurs almost exclusively in men over the age of 60. This patient exhibits many clinical features that are key in recognizing TTR amyloidosis including the presence of atrial arrhythmia, ventricular septal and free wall thickening on echocardiogram without history of uncontrolled hypertension, right-sided heart failure, and presence of peripheral neuropathy (carpal tunnel). Nearly one half of patients with wild type TTR have associated carpal tunnel, that typically precedes cardiac sequelae by up to 8-10 years. Spontaneous symmetric peripheral neuropathy or carpal tunnel in an elderly man should raise suspicion for an amyloid process. Relative reported frequencies of light chain and TTR amyloid are 8 per million/year and 0.4 per million/year for mutant TTR. The prevalence of wild type TTR is largely unknown. The Tc-pyrophosphate scan is simple and effective imaging modality to differentiate the two types of amyloid, with a sensitivity and specificity of 97% and 100% for TTR amyloid.

CONCLUSION: It is important to distinguish light chain amyloidosis from TTR amyloidosis. Compared to light chain cardiac amyloidosis, TTR amyloid has a prolonged survival rate, decreased severity of illness, and different management.

CASE REPORT: DISSEMINATED TOXOPLASMOSIS WITH NONSPECIFIC GASTROINTESTINAL SYMPTOMS

Michael G. Gindi^{1, 2}; Angela Montoya^{1, 2}; Robert Mas^{1, 2}; Lyndsey Turbow¹; Evan Sternberg¹; Parisa Geraminejad¹. ¹Mount Sinai Hospital, Chicago, IL; ²Ross University School of Medicine, Miramar, FL. (Control ID #3184897)

LEARNING OBJECTIVE #1: Recognize clinical features of gastrointestinal and disseminated toxoplasmosis

CASE: A 36-year-old male with a PMH of HIV (on HAART) presented with one month of diarrhea, melena, anorexia, weight loss, fatigue and a week of non-bloody non-bilious emesis. On admission his vital signs, physical exam, CBC and CMP were unremarkable. His CD4 count was 206 cells/ μ L and HIV viral load was 826 copies/mL. In the ED, the patient had an episode of emesis, urinary incontinence, left foot myoclonus and became unresponsive at which point he was intubated and transferred to the ICU. CT and MRI of the brain showed two ring-enhancing lesions (RELs) with surrounding edema and a 5.2 mm midline shift. CT abdomen and pelvis showed mild wall thickening of the proximal colon and a fluid filled distal colon. Cultures, hepatitis panel and serology for *Cryptosporidium*, *Blastomyces*, and *Histoplasma* were negative. IgG titers for *Toxoplasma* were positive, treatment was initiated and repeat MRI showed reduction in the size of the RELs and midline shift as well as full resolution of his gastrointestinal (GI) symptoms.

IMPACT/DISCUSSION: *T. gondii* is a protozoan parasite acquired via ingestion of oocysts in contaminated food or water. Most infections are asymptomatic as the immunocompetent can overcome the parasite burden. Latent infection exists in 15% of both HIV positive and negative populations and reactivation occurs in up to 30% of patients with a CD4 count <100 cells/ μ L. While 89% of patients with active toxoplasmosis have intracerebral manifestations, extra-cerebral toxoplasmosis (ECT) only has a prevalence of 1.5-2%. The most significant risk factor for ECT is a CD4 count <100 cells/ μ L and 41% of cases have concurrent CNS infection. While brain biopsy is the only way to definitively diagnose toxoplasmic encephalitis (TE), patients with positive *T. gondii* serology, brain imaging with multiple RELs, neurological symptoms and immunosuppression have a 90% probability of TE and treatment is usually initiated without further work up. Due to vague symptomatology, ECT is difficult to diagnose and often leads to a delay in treatment. Symptoms of GIT include anorexia, nausea, vomiting and diarrhea and, while definitive diagnosis is by endoscopic biopsy, this test is invasive and time consuming. The prevalence of ECT is thought to be underestimated as post-mortem analysis of seropositive patients reveals higher rates of dissemination and extra-cranial manifestations.

CONCLUSION: Though the greatest risk of reactivation of *T. gondii* is a CD4 counts <100 cells/ μ L, this case demonstrates that toxoplasmosis must be considered in any immunocompromised patient with or without neurological symptoms. Due to the difficulty in diagnosis and the rapidly progressive, often fatal course of toxoplasmosis we suggest a presumptive diagnosis in immunocompromised hosts with positive *T. gondii* titers, GI symptoms, negative stool cultures and alternative serology. Early diagnosis is crucial for successful treatment and prevention of mortality.

CENTRAL FEVER: THE PARKINSONISM-HYPERPYREXIA SYNDROME

Sarabjeet S. Suri¹; Dharmarajan S. Thiruvinvamalai². ¹Montefiore Medical center, Bronx, NY; ²Montefiore Medical Center (Wakefield Campus), Bronx, NY. (Control ID #3183034)

LEARNING OBJECTIVE #1: Recognize that fever can result from causes other than infection, such as central fever.

LEARNING OBJECTIVE #2: Understand the importance of home medication reconciliation, and fever resulting from not taking medications.

CASE: 74 year old woman sent from nursing home with hypotension and lethargy. She could not provide a significant history due to lethargy. Initial vitals: temperature of 99.3F, BP-67/31 mm Hg. She received intravenous fluid resuscitation without appropriate response and now required pressor support. The patient had a large decubitus ulcer with necrosis and was placed on broad spectrum antibiotics. Initial labs: WBC 25,000, creatinine of 1.9 mg/dL (baseline 0.6), lactate 5.5. X-Ray chest normal. The patient had a history of Parkinson's disease, atrial fibrillation and hypertension. She was on aspirin 81 mg, apixaban, selegiline, carbidopa-levodopa, amiodarone

and metoprolol. On day 2, she required intubation for airway protection. Repeat x-ray chest revealed new left lower lobe opacity compatible with aspiration pneumonia. On day 3, she had sustained episodes of high grade fever (107.9 F) while on appropriate antibiotics for her wound and aspiration pneumonia. Neuroleptic malignant syndrome was less likely as she had normal muscle tone and normal creatinine kinase. She was given intravenous levodopa as she had missed 2 days of medication, and was given dantrolene following which she became afebrile within 2 hours.

IMPACT/DISCUSSION: Parkinsonism-hyperpyrexia Syndrome (PHS) was first described in 1981, initially termed dopamine withdrawal syndrome. It occurs following the sudden withdrawal of levodopa/carbidopa or reduction in dose. It resembles neuroleptic malignant syndrome with rigidity, pyrexia and altered consciousness. Rare causes include deep brain stimulation. Symptoms usually present 24 hours to 7 days after missed doses. Clinical features include hyperpyrexia, altered sensorium and leukocytosis. Rhabdomyolysis may occur. Complications include acute renal failure, aspiration pneumonia, pulmonary embolism and DIC. Pathophysiology may involve sudden depletion of dopamine. Mortality may be 4% mortality if recognized early, 16% if untreated. Treatment involves intravenous hydration, supplementation of dopamine orally or intravenously and close monitoring. Physical measures such as cooling therapy are helpful.

CONCLUSION: Hyperpyrexia(>106.7F) should prompt evaluation for central causes of fever. The case illustrates the importance of home medication reconciliation upon hospitalization; not taking medications contributed to fever in this case

CEPHALOSPORIN-INDUCED HYPOPROTHOMBINEMIA VIA A WARFARIN-LIKE EFFECT

Vikas Gampa¹; Ariel Majidi¹; Jason Moran². ¹Cambridge Health Alliance, Somerville, MA; ²Beth Israel Deaconess Medical Center, Boston, MA. (Control ID #3183005)

LEARNING OBJECTIVE #1: Cephalosporins can lead to coagulopathy from inhibition of the enzyme inhibited by warfarin

LEARNING OBJECTIVE #2: Management of cephalosporin-induced coagulopathy is identical to that of warfarin toxicity

CASE: Ms. J is an 82 year-old woman who was diagnosed with a T2N0M0 squamous cell carcinoma of the tongue and was admitted to the hospital for planned surgical intervention including tracheostomy, right hemi-glossectomy, neck dissection, and skin graft. History was notable for decreased po intake. She received standard pre-operative antibiotic prophylaxis with cefazolin. Pre-operative labs were unremarkable. There were no intra-operative complications. She received cefazolin as per protocol after her surgery. On post-op day 3, she had excessive oozing at the incision sites. Labs were notable for decreased Hgb 11.1 → 8.1, platelets 125, an elevated PT (40.8) with INR 3.8, baseline normal PT 11.7 and INR 1.1. PTT was normal. Thrombin time was normal at 15.3 and fibrinogen was elevated to 432. Amidst bleeding and coagulopathy, 10mg IV vitamin K was urgently administered. On a subsequent lab draw, levels of Factors II, VII, IX, and X were 45, 26, 111, and 47, respectively, and a mixing study was inconclusive for presence of an inhibitor - these modestly reduced Factor levels and inconclusive mixing study were likely the result of administration of vitamin K with partial correction of her coagulopathy by the time they were drawn. She was treated with additional IV vitamin K, discontinuation of cefazolin, and avoidance of other cephalosporin antibiotics, with normalization of PT/INR and resolution of bleeding.

IMPACT/DISCUSSION: Antibiotics are often implicated as a cause of coagulopathy with prolongation of PT/INR and the mechanism is attributed to elimination of gut flora. Cephalosporins may pose a unique mechanism of inducing a coagulopathy via a warfarinoid effect. Certain cephalosporins contain side-chains that, released upon drug degradation, can directly inhibit Vitamin K epoxide reductase, impairing gamma-carboxylation and the

ability to activate the vitamin-K dependent factors II, VII, IX, and X. This particular case illustrates that patients with a prolonged duration of decreased PO intake with reduction of vitamin K stores are prone to the hypoprothrombinemic effect of certain cephalosporins. This case should raise caution in the use of cephalosporins in patients with poor nutritional status, or close monitoring of coagulation parameters.

CONCLUSION: Our patient underwent an uncomplicated surgical resection for SCC of the tongue, though she developed significant bleeding, likely in part due to a coagulopathy from cefazolin administration. Cephalosporins can cause hypoprothrombinemia and bleeding via a warfarin-like mechanism and may be more likely in patients who have decreased dietary intake of vitamin K. Treatment is vitamin K repletion and cessation of the offending antibiotic; if bleeding is severe, more urgent normalization of PT can be achieved with administration of vitamin-K dependent factors.

CERVICAL MYELOPATHY SECONDARY TO B12 DEFICIENCY FOLLOWING SLEEVE GASTRECTOMY SURGERY

Murali K. Duggirala. Mayo Clinic, Rochester, MN. (Control ID #3181431)

LEARNING OBJECTIVE #1: B 12 deficiency is common following a bariatric surgery; although rare, this deficiency can result in serious complications such as cervical myelopathy.

LEARNING OBJECTIVE #2: Patient education is crucial in preventing serious complications of bariatric surgery.

CASE: Patient is a 33-year-old woman presented for a 2nd opinion regarding an outside diagnosis of multiple sclerosis. She underwent a sleeve gastrectomy surgery approximately 3 years ago. She weighed 115 kg prior to surgery and was able to lose 50 kg. She was recommended B 12 injections monthly but she took only one after surgery. Later, she switched to oral B 12 supplementation. Two years after the surgery she had developed subacute onset of numbness affecting her fingertips bilaterally. Over the next several weeks her numbness had extended to both wrists and also experienced difficulty with walking. MRI imaging showed T2 hyperintensity restricted to the C3-4 region and CSF analysis was negative. Her B 12 levels were borderline at 153. She was started on glucocorticoids for suspected multiple sclerosis or clinically isolated syndrome. Her symptoms did not improve and a followup MRI scan demonstrated a longitudinally extensive T2 hyperintense lesion now extending from C1-C7. Her copper levels, NMO antibodies, paraneoplastic panel were negative. She was diagnosed with cervical myelopathy from B 12 deficiency and was started on vitamin B 12 injections. She received 1000 mcg of vitamin-B 12 intramuscularly once a day for 7 days then, once weekly for 4 weeks and then once monthly. At three month followup, her symptoms have completely resolved.

IMPACT/DISCUSSION: B 12 deficiency is very common following bariatric surgery and can occur in up to 64% of the patients. So, following the surgery replacement of B 12 is very important. Oral B 12 is not absorbed well in patients with bariatric surgery. Parenteral B 12 supplementation is commonly recommended. If sublingual B 12 is supplementation is chosen then periodic monitoring of blood B 12 level is recommended.

CONCLUSION: Cervical myelopathy can be a complication following a bariatric surgery. It is important to counsel patients about postoperative B 12 supplementation. With adequate supplementation of B 12 this serious complication can be prevented.

CHALLENGING THERAPEUTIC APPROACH FOR CENTRAL DIABETES INSIPIDUS

Maria del Mar Morales Hernandez¹; Marie A. Landicho¹; Ivan A. Serrano²; Kent Wehmeier¹. ¹University of Florida COM, Jacksonville, FL;

²University of Florida, Jacksonville, FL. (Control ID #3186355)

LEARNING OBJECTIVE #1: Diagnose central diabetes insipidus

LEARNING OBJECTIVE #2: Recognize limitations in the symptomatology treatment of central diabetes insipidus with desmopressin

CASE: A 34-year old female with history of hypertension, gastric bypass surgery, polycystic ovarian syndrome, and non-functional pituitary macroadenoma presented with chronic headaches for 3 years. Work-up showed 1.6 cm lesion within the rightward sella consistent with macroadenoma. Endocrine studies were consistent with non-functional adenoma. She underwent elective macroadenoma resection via transsphenoidal approach. Post operatory course complicated with increased urinary output of 8L within 24 hours. Morning cortisol and thyroid function studies were found within normal limits at that time. The patient was started on oral desmopressin(dDAVP) and adjusted to 400mcg three times daily without improvement of polyuria and polydipsia. Oral desmopressin was changed to 1mcg of subcutaneous form of dDAVP twice daily with improvement of polyuria. The urinary output improved from of 6.6 liters to 3 liters in 24 hours. She was eventually discharged home in stable condition on subcutaneous desmopressin with close follow up with Endocrinology with plans to try intranasal form as outpatient.

IMPACT/DISCUSSION: Central Diabetes Insipidus symptomatology can be efficiently managed with hormone replacement with Desmopressin. Data had showed increased morbidity and mortality involved with inadequate treatment of Central Diabetes Insipidus. Individualization of treatment should be provided based on patient severity of polyuria, absorption and baseline conditions. Patients who are unable to tolerate intranasal or oral desmopressin should be provided with subcutaneous form. The deficiency of the antidiuretic hormone, vasopressin (AVP) causes Central Diabetes Insipidus (CDI). AVP deficiency results in uncontrolled diuresis. Complete deficiency can lead to polyuria exceeding 10 liters in 24 hours. CDI is treated with desmopressin, an analogue of arginine vasopressin (AVP) without vasopressor activity. Desmopressin can be administer intranasally, in an oral tablet form or in a parenteral formulation. Oral route is preferred by patients for their ease of administration but only 5% is absorbed on the gut and its absorption can decrease up to 50% if taken with meals. Intranasal form is contraindicated in cases of rhinitis or nasal mucosa edema. When patients have inadequate response to intranasal or oral forms of dDAVP, it should be given subcutaneously and the dose should be adjusted accordingly. Treatment should be continued for as long patient has CDI. Patient should be educated and closely monitor about signs of symptoms of hyponatremia while on DDAVP.

CONCLUSION: Prompt recognition and adequate administration of desmopressin can efficiently control symptoms of CDI. Route of dDAVP administration should be decided based on patient profile and clinical response.

CHECK YOUR BIAS AT THE DOOR: A CASE OF ANCHORING BIAS IN REFRACTORY IMMUNE CHECKPOINT INHIBITOR-ASSOCIATED COLITIS.

Nathan C. Nowalk; Grant Pickett. Baylor College of Medicine, Houston, TX. (Control ID #3186250)

LEARNING OBJECTIVE #1: Appraise a clinically challenging case for cognitive errors, specifically, anchoring bias

LEARNING OBJECTIVE #2: Compose a diagnostic schema for inflammatory diarrhea in patients on immune checkpoint inhibitors

CASE: A 50 year-old female with high-grade urothelial carcinoma presented with two-week history of abdominal pain and diarrhea of small-volume hematochezia. One month prior to symptom-onset, the patient received her first doses of nivolumab and ipilimumab. A sigmoidoscopy with biopsies was performed showing neutrophilic crypt microabscesses consistent with diagnosis of immune checkpoint-inhibitor (ICI) associated-colitis. The patient received intravenous methylprednisolone and one dose of infliximab with improvement in symptoms. She was discharged on oral prednisone. Over the following four

weeks her prednisone was tapered down. Six weeks after initial presentation, she again presented with identical symptoms of abdominal pain and diarrhea of small-volume hematochezia. She was again started on intravenous methylprednisolone, but symptoms did not improve as they had before. Repeat sigmoidoscopy with biopsy showed mucosal ulcers with "owl's eye" inclusion bodies consistent with diagnosis of cytomegalovirus (CMV) colitis. She was started on intravenous ganciclovir, followed by oral valacyclovir with resolution in symptoms at two-week follow-up.

IMPACT/DISCUSSION: Due to prior success and growing indications, the use of ICIs in treating cancer continues to increase at a rapid rate. As expected, the frequency of immune-related adverse events from these agents has also increased. Prior studies have shown that combining ICIs can increase the risk of adverse events up to 55%. ICI associated-colitis remains the most commonly encountered severe adverse event and usually occurs within six weeks of initial dose. Diagnosis is established by endoscopy with biopsy. Management includes discontinuation of ICIs followed by immunosuppression. As is the case with other inflammatory bowel diseases, such as Crohn's disease, the exclusion of infectious diarrhea is paramount before initiating immunosuppression. CMV colitis is seen in these other inflammatory diarrheas but is only recently being recognized in ICI-associated diarrhea.

CONCLUSION: Anchoring bias is the cognitive error of retaining a single diagnosis based on a few case features and failing to integrate new information when appropriate. An extension of anchoring bias is diagnostic momentum, which describes the resistance to broaden a prior diagnosis made by an earlier provider. Both errors are unfortunately well-represented in our case. Our patient had an established diagnosis of ICI associated-colitis when she presented with her second inflammatory diarrhea in two months. Her recent decrease in steroids as an outpatient fortified the suspicion for recurrence of ICI associated-colitis. Unfortunate anchoring bias resulted in a therapeutic trial of steroids with no improvement in symptom severity.

CHECKING THE CHECKPOINTS: A CASE OF TYPE 1 DIABETES FOLLOWING PD-1 INHIBITION IN A PATIENT WITH HIV ON HAART

Michael S. Hughes¹; Sara Bedrose²; Madhuri M. Vasudevan²; Marco Marcelli². ¹Baylor College of Medicine, Houston, TX; ²Michael E. DeBakey VA Medical Center and Baylor College of Medicine, Houston, TX. (Control ID #3179491)

LEARNING OBJECTIVE #1: Recognize type 1 diabetes mellitus as a rare but important complication of immune checkpoint inhibition

LEARNING OBJECTIVE #2: Employ higher clinical suspicion for potential immune related adverse events in patients with HIV on checkpoint inhibitors

CASE: A 48-year-old man with HIV on HAART was diagnosed with Hodgkin's lymphoma and initiated the Programmed Death 1 (PD-1) immune checkpoint inhibitor, nivolumab. After 6 months, he reported polydipsia and polyuria. Labs revealed glucose 764 mg/dl and A1c 7.1%. Low C-peptide and elevated GAD-65 antibody levels confirmed type 1 diabetes mellitus (T1DM), and he started insulin therapy. Nivolumab was continued for 12 more months. Despite discontinuation of nivolumab, he remains on insulin therapy.

IMPACT/DISCUSSION: While A1c may reflect average glycemia, it alone cannot distinguish T2DM from T1DM progression. Tests for c-peptide and autoantibodies for T1DM must be included when evaluating patients on PD-1 inhibitors. T1DM is a known immune related adverse event (irAE) following treatment with PD-1 inhibitors with reported 0.9% incidence. However, little is known about such irAEs in individuals with HIV treated with PD-1 inhibitors. Patients with HIV have higher autoantibody titers in active disease states or following HAART initiation, as seen in immune reconstitution. Moreover, in vitro PD-1 inhibition elevates HIV cell proliferation and immune hyperactivity. The challenge in

patients with HIV on HAART and PD-1 inhibitors is unraveling whether autoantibody generation resulting in T1DM is potentiated by pre-existing HIV on HAART and/or provoked by immune response to PD-1 inhibition.

CONCLUSION: Clinicians treating patients with immune checkpoint inhibitors should maintain a high index of suspicion for development of autoimmune disorders. Literature on the use of PD-1 inhibitors in HIV patients is limited and warrants further investigation. To our knowledge, this is the first reported case of T1DM following PD-1 inhibition in a patient with HIV on HAART therapy. Such patients are predisposed to immune reconstitution, and response to PD-1 inhibition may potentiate risk for autoimmune complications. Therefore, higher clinical suspicion for irAEs is merited in patients with HIV on PD-1 inhibitors.

CHEST AND BACK PAIN WITHOUT ABDOMINAL PAIN AS AN INITIAL SYMPTOM OF ACUTE CHOLECYSTITIS

Risa Hirata; Masaki Tago; Hidetoshi Aihara; Motoshi Fujiwara; Shun Yamashita; Naoko E. Katsuki; Shu-ichi Yamashita. Saga University Hospital, Saga city, Japan. (Control ID #3147145)

LEARNING OBJECTIVE #1: Acute cholecystitis can develop only with chest pain at the site of sternal bone and back pain without abdominal pain

CASE: A 64-year-old man was transferred by ambulance to our hospital because of sudden-onset clamping chest pain in the lower half of his sternal bone, upper back pain, vomiting, and cold sweating at rest. On admission, he was alert and had a blood pressure of 127/81 mmHg, regular pulse rate of 70 beats/min, respiratory rate of 20 breaths/min, and SpO₂ of 94%. The only abnormality on physical examination was spontaneous and percussion pain in the lower half of the sternal bone; no other signs of acute cholecystitis were present, such as abdominal tenderness, muscular guarding, or Murphy's sign on his abdomen. Laboratory findings on admission including complete blood count and hepatobiliary enzyme were normal except for slightly elevated CRP of 1.08 mg/dL. Echocardiography and cardiac ultrasonography findings were normal. Abdominal ultrasonography only showed debris and slight thickening of the gallbladder wall. Abdominal computed tomography (CT) failed to reveal any abnormalities at that time. However, thoracic and abdominal CT was repeated 8 hours after admission because of persistent pain showing findings of acute cholecystitis such as thickness, a low-density area, and enhancement of the gallbladder wall. No abnormality of the common bile duct or intrahepatic biliary tract was found on magnetic resonance cholangiopancreatography. Although the patient's chest pain disappeared on the second hospital day, a fever and percussion tenderness on the liver appeared without Murphy's sign. The CRP level increased to 11.0 mg/dL. He was successfully treated by ampicillin/sulbactam and discharged from our hospital on the 10th hospital day.

IMPACT/DISCUSSION: What does this case add to the literature? This case suggests that acute cholecystitis can develop only with chest pain without typical abdominal signs or abnormalities on imaging studies in the early phase of the disease.

CONCLUSION: Acute cholecystitis presenting only as chest pain without epigastric or right hypochondrial pain is rare. Verdon et al. reported that only 1 of 672 patients who visited outpatient clinics for evaluation of chest pain had acute cholecystitis. The chest pain in our patient was likely to be referred pain. Pain from abdominal viscera is transmitted through the greater splanchnic nerve arising from T5 to T10, which could cause pain at the same dermatome level. Our patient complained of pain in the lower part of the sternal bone innervated by T5 to T7, which was compatible with referred pain from acute cholecystitis. In conclusion, acute cholecystitis can begin only with chest pain, which is likely to be referred pain, without typical abdominal signs or abnormalities on imaging studies in the early phase of the disease.

CHIKUNGUNYA "FEVER" IN AN AFEBRILLE TROPICAL TRAVELER WITH INTRACTABLE BACK PAIN

Kyle Macaulay; Ian Garrahy; Jesse Sengillo. Tower Health System, Wyomissing, PA. (Control ID #3186386)

LEARNING OBJECTIVE #1: Chikungunya fever can present in many ways which often leads to a missed or delayed diagnosis.

LEARNING OBJECTIVE #2: With the history of recent travel to a tropical island, Chikungunya fever should be considered as a diagnosis even with an atypical presentation.

CASE: Chikungunya fever is an arthropod-borne virus with prevalence up to 70% in some hyperendemic countries, and has recently spread to North America since its identification in Caribbean countries in late 2013. Diagnosis can be delayed or missed as the presentation varies from asymptomatic to typically severe arthralgias, high-grade fever, and maculopapular rash to chronic arthritis and death. A 57-year-old female presented to the emergency department with five days of flu-like symptoms, severe mid-thoracic back pain, and a transient urticarial-like rash after returning from Jamaica three weeks prior. She reported no sick contacts. The patient was afebrile with stable vital signs. She exhibited tenderness to palpation of the lumbar spine, and had no evidence of conjunctivitis or lymphadenopathy. Labs were significant for sodium of 123 mEq/L, lymphocytic-predominant leukocytosis of 16,200/uL with 17% atypical lymphocytes, and a mild transaminitis (AST 78 units/L, ALT 100 units/L). MRI of the lumbar and thoracic spine was unrevealing. Serology for chikungunya IgM antibody was unequivocally high with 1.54 IV (normal: <1.1 IV) and undetectable IgG antibodies. Titers were negative for CMV, HIV and dengue. Patients with non-classic presentations and recent travel to endemic areas should have Chikungunya fever considered as part of their differential. While most common presentations will include fever and debilitating joint pain, Chikungunya fever should be considered even in the absence of in-hospital fever when either peripheral or axial joints are involved.

IMPACT/DISCUSSION: Chikungunya fever most commonly presents with severe arthralgias, high-grade fever, and maculopapular rash. It should be considered even in those who are afebrile but who have joint pain and a tropical travel history.

CONCLUSION: Chikungunya fever is an arthropod-borne virus which has recently spread to North America since its identification in Caribbean countries in late 2013. Its increasing prevalence and varied presentations make it a diagnosis that should be considered when a traveler presents with joint pain.

CHRONIC ALCOHOL ABUSE: AN UNUSUAL PRESENTATION OF ANEMIA

Benjamin Yao¹; Kunal Patel^{2, 1}; Calen Frolkis^{2, 1}. ¹Case Western Reserve University, Cleveland, OH; ²MetroHealth Medical Center, Cleveland, OH. (Control ID #3185757)

LEARNING OBJECTIVE #1: Diagnose and manage complications of acute/chronic alcohol abuse

LEARNING OBJECTIVE #2: Recognize the classic triad of Zieve's syndrome

CASE: A 39-year-old female with a past medical history of chronic alcohol abuse, hyperlipidemia, and cirrhosis presents for readmission with swelling of the abdomen/lower extremities and worsening jaundice. She was admitted and discharged 2 weeks ago for jaundice and new acute anemia (Hgb 4.6g/dL, Hematocrit 13.3%) after consuming 4 drinks a night for 2 weeks; suspected to be decompensated cirrhosis secondary to alcohol abuse with alcoholic hepatitis and iron deficiency anemia. The patient received 4 units of packed RBCs and started on 4-week Prednisolone 40 mg daily regimen, vitamin repletion, and instruction for alcohol cessation. On readmission, the patient endorsed alcohol relapse and found

to have worsening anemia with no evidence of acute bleed (Hgb 6.0g/dL, Hematocrit 18.3%, MCV 110fL), thrombocytopenia (platelet 45K/uL), worsening liver disease (Total bilirubin 15.2mg/dL, Direct 5.8mg/dL), transaminitis (AST 127IU/L, ALT 48IU/L, alkaline phosphatase 87IU/L, albumin 2.8g/dL). She received 3 units of packed RBCs without expected incrementation. CT abdomen showed splenomegaly with significant perisplenic and splenorenal varices. Complete blood count showed elevated reticulocytes, elevated LDH, and low haptoglobin; coagulation panel showed prolonged PT 19.2 seconds, INR 1.68, and prolonged PTT 37 seconds. A peripheral blood smear showed schistocytes, Burr cells, and no toxic granulations. She was diagnosed with hemolytic anemia consistent with Zieve's syndrome.

IMPACT/DISCUSSION: This case illustrates the unique presentation of Zieve's syndrome which is a triad of hemolytic anemia, hyperlipidemia, and jaundice. The initial concern with this hospitalization was disseminated intravascular coagulation (DIC), given the presentation of schistocytes and recurrent, persistent anemia. The pathophysiology for DIC is based on the presence of increased thrombin formation in patients suffering from severe liver cirrhosis resulting in decreased clotting factors, hypofibrinogenemia and thrombocytopenia. The key finding was the presence of splenomegaly on CT abdomen. Zieve's syndrome is a special type of alcoholic hepatitis in which alcohol consumption causes hemolytic anemia and schistocytes from splenomegaly. Dr. Leslie Zieve originally proposed elevated circulating lipid levels resulted in alterations in erythrocyte membrane composition, leading to increased susceptibility to hemolysis. Patient treatment is focused on cessation of alcohol. Most patients recover within 4 to 6 weeks after alcohol withdrawal. For patients who continue to drink alcohol, it may aggravate the illness and potentially be fatal as this patient was readmitted again with worsening anemia unresponsive to transfusion and transferred to hospice care.

CONCLUSION: Establish unbiased differential diagnosis of alcoholic, liver, and blood related pathologies that may include Zieve's syndrome based on presentation

CLINICAL DILEMMA: MANAGING COMORBID CHRONIC PAIN, SUBSTANCE USE DISORDER, AND MENTAL ILLNESS

Joel Sawady^{1, 2}; Gina Stenhouse¹. ¹Cambridge Health Alliance, Cambridge, MA; ²Harvard Medical School, Boston, MA. (Control ID #3184727)

LEARNING OBJECTIVE #1: Formulate a long-term, patient-centered chronic pain management plan (including opioid tapering) for very high risk patients

LEARNING OBJECTIVE #2: Manage the clinical and professional dilemma of inheriting patients on high-risk opioid regimens

CASE: 52 yo male with history of OUD, MDD, and PTSD with recent suicide attempt, who transitioned to a new PCP. His chronic pain originated after an episode of vertebral osteomyelitis resulting in extensive surgery. At the time of meeting his new PCP, the patient was managed on 260 MME/day along with psychotropic medications including a benzodiazepine. The new primary care team, in collaboration with the patient and his mental health team, decided to pursue a gradual opioid taper. During the taper, the patient developed worsening anxiety and had difficulty managing psychosocial stressors. However, tapering also provided him GI relief and allowed him to become activated, goal-directed, and engaged in adaptive behaviors. The patient pursued neurosurgery reevaluation which led to revision of his spinal surgery. Unfortunately, despite pre-surgery coordination, the patient was discharged on an inappropriate opioid regimen. This was addressed and taper was resumed. Again, the patient experienced worsening psychological symptoms including poor sleep. Despite this, the patient continued to display improved affect compared to initial presentation and exercised more self-efficacy. At this point, two years into the taper, the patient does not have increased thoughts of illicit opioid use, but this is a continuing concern. We are discussing with the patient transitioning to buprenorphine for OUD and chronic pain.

IMPACT/DISCUSSION: Current guidelines recommend against starting high-dose opioids, particularly in high-risk patients. However, they offer little guidance on how to care for patients already on these regimens. Tapering may result in destabilization and poor outcomes. This case will complement the guidelines and provide clinicians with tools to manage these complex patients. Discussion points include: 1. The literature on concurrent OUD and chronic pain, including the role of buprenorphine 2. The evidence base for tapering opioids 3. Psychiatric symptoms that may emerge during opioid tapering, particularly in the presence of mental illness 4. Practices used to build a collaborative, patient-centered care plan 5. Ethical dilemmas in a situation in which all options (continue prescribing, fast taper, and slow taper) present risks

CONCLUSION: Prior to tapering opioids in any patient, including those with history of OUD, the risks of an expedited taper should be reviewed and consideration should be given to a gradual, patient-centered tapering plan. Empathy and relationship-building are important at every step. A multidisciplinary approach is critical for patients with concurrent mental illness, substance use disorder, and chronic pain. This is particularly important when tapering opioids, as psychiatric symptoms may be unmasked.

CLOSTRIDIUM DIFFICILE LIVER ABSCESS: AN UNUSUAL PRESENTATION

Pramod Acharya¹; Pinky Jha³; Aravind Seetharaman²; Mirza Baig¹; Sanjay Bhandari². ¹Medical College of Wisconsin, Pewaukee, WI; ²Medical College of Wisconsin, Milwaukee, WI; ³medical college of wisconsin, Milwaukee, WI. (Control ID #3178480)

LEARNING OBJECTIVE #1: To report/recognize a case of Clostridium liver abscess in a patient without history of C. difficile colitis.

LEARNING OBJECTIVE #2: To review the diagnosis and management of C. difficile liver abscess.

CASE: An 83-year-old woman with history of appendicitis, renal stones, and cholecystitis (with previous cholecystectomy) presented to an outside hospital for right upper quadrant pain 4 months ago and was found to have a 6.7 cm liver abscess on imaging. Biopsy and culture confirmed liver abscess with only C. difficile grown on the anaerobic culture. She denied previous history of C. difficile colitis. She was treated with 7 weeks of oral metronidazole, with much difficulty taking the medication. She reported 17 pounds weight loss. About 2-3 months ago she began to develop pleuritic chest pain and cough. Imaging showed pleural effusion and possible empyema. Pleural biopsy showed organizing pneumonia with negative special stains. She was admitted to our hospital with 3 weeks of right chest pain and cough with yellow sputum. Upon presentation vitals were stable. Physical Exam showed decreased breath sounds at posterior right base. Admission lab results were unremarkable except for Right lower lobe consolidation and possible empyema. ID was consulted, and patient was treated with IV vancomycin. Cardiothoracic surgery was consulted for empyema. Pleuropulmonary complication was secondary to needle manipulation during transpleural approach of liver biopsy.

IMPACT/DISCUSSION: In contrast to typical C. difficile infection (CDI), extra-intestinal manifestation of CDI has been rarely reported. The frequency of extra-intestinal CDI comprises approximately 0.17% to 0.6% of all CDI. Long-term metronidazole therapy (6-8 weeks) is considered to be effective because of excellent penetration to the liver and susceptibility of isolated *C difficile* strains. CDIs are becoming more frequent worldwide, however, the precise trend of extra-intestinal CDI is unclear. Our case is unique as the patient does not report history of C. difficile infection. This case further warns the treating physician of the possible risk of seeding of infection elsewhere on needle aspiration.

CONCLUSION: A greater accumulation of extra-intestinal CDI cases is necessary to determine its epidemiology for the proper treatment of extra-intestinal CDI, including recurrent C. difficile bacteremia and liver abscess. Needle track seeding may complicate liver abscess especially when the location of the abscess requires transpleural route of aspiration and increase morbidity.

CLOZAPINE: AN UNDER-RECOGNIZED CULPRIT

Deeva Berera¹; Peter Ting¹; Benjamin Bier². ¹Icahn School of Medicine at Mount Sinai Hospital, New York, NY; ²Mount Sinai Hospital, New York, NY. (Control ID #3186660)

LEARNING OBJECTIVE #1: Recognize the clinical features of clozapine cardiotoxicity.

LEARNING OBJECTIVE #2: Manage suspected clozapine cardiotoxicity.

CASE: 68 YOF with PMH of schizophrenia who was involuntarily admitted to inpatient psychiatry for worsening psychosis, unresponsive to titration of her outpatient medication regimen. She was started on clozapine for treatment of refractory schizophrenia with significant improvement. PMH: Obesity, osteoarthritis, schizophrenia PSH: None; Meds: Haldol 10mg BID, benztropine 1mg BID, clonazepam 1mg QHS SH: Lives with husband and son, no EtOH, tobacco, or illicit drug use. Employed as a part time supermarket clerk. On day 21 of admission, she was febrile to 103.1 F, other VS stable. She denied cough, rhinorrhea, N/V/D. CBC WNL. Infectious work-up including blood and urine cultures, and viral respiratory panel were negative. On day 22, she developed chest pain and shortness of breath. EKG was normal, however troponin 1.34. CXR showed mediastinal widening, follow-up CTA showed bilateral ground glass opacities concerning for pulmonary edema. She became acutely hypoxemic requiring HFNC and was transferred to medicine for management of suspected NSTEMI. Medicine course was complicated by worsening mental status and intubation for hypoxemic respiratory failure. She became acutely hypotensive during intubation requiring vasopressor support. A bedside echo showed poor LV function and severe mitral regurgitation. Her ScvO₂ was 30% consistent with cardiogenic shock. Follow-up TEE post dobutamine initiation was negative for endocarditis and showed normal LV function with moderate MR. Psychiatry and cardiology collectively determined her acute decompensation was most likely secondary to clozapine induced cardiotoxicity.

IMPACT/DISCUSSION: Clozapine induced cardiotoxicity is a well known phenomenon in the psychiatric community, often limiting its use. However, data is limited to case reports and there are few systematic reviews or guidelines for clinicians on how to recognize and manage clozapine induced toxicities. In retrospect, this case was classic for clozapine toxicity, which usually occurs at a median of 3 to 8 weeks from drug initiation. Cardiotoxicities (ranging from myocarditis to cardiogenic shock) are thought to be secondary to up regulation of IL-2 and TNF mediated pathways causing a systemic inflammatory response. Clinicians should have a high suspicion for clozapine cardiotoxicity in patients with acute cardiac decompensation without any other risk factors and a low threshold for performing urgent echocardiograms. Clozapine should be discontinued and cases should be reported to expand the existing body of literature.

CONCLUSION: -Clinical features of clozapine toxicity include fevers, tachypnea, and acute cardiac decompensation within 3 - 8 weeks of drug initiation. -The mainstay of treatment of clozapine-induced cardiotoxicity is cessation of clozapine, early echocardiography, and appropriate medical management of the resultant toxicity.

COCAINE AND ALCOHOL MISUSE INDUCED Rhabdomyolysis

Claire Huang Lucas²; Geeta Varghese¹; Paul El Tomb²; Joshua Berookhim². Mount Sinai Beth Israel, New York, NY; ²Mount Sinai Saint Luke's-Roosevelt, New York, NY. (Control ID #3175204)

LEARNING OBJECTIVE #1: Diagnose and distinguish cocaine and alcohol use as common differentials of rhabdomyolysis

CASE: 60 yo male with history of chronic alcohol misuse (1 pint of vodka 3-4 times per week), daily cocaine inhalation, DM2, hyperlipidemia, presented with fatigue and proximal muscle weakness of all extremities for 4

weeks. His medication list was noteworthy for daily Atorvastatin 40 mg, ASA 81 mg, Lisinopril 40 mg and Metformin 1,000 bid. He denied trauma, infection, strenuous exertion, prolonged immobilization, LOC and seizure. Physical exam revealed 4/5 strength in all extremities and no skin rash. Labs showed CPK > 35,000, transaminitis (AST 4,555, ALT 447), and normal BMP, TSH, ESR, CRP. UA positive for protein 1+, blood 2+, and no RBC. The patient was then directed to the ER and received IV and PO hydration and underwent muscle biopsy. Statins were ceased and a progressive steroid taper was started. At hospital discharge, CPK trended down to 6,000 with clinical improvement, however after resuming cocaine and alcohol use, CPK rose to 11,000 while on steroids. Muscle biopsy showed moderate myophagocytosis with no inflammatory infiltrate. Serology was negative for ANA, anti RNP, anti Smith, anti Jo, anti SSA, anti SSB, anti MSA. Final diagnosis was drug induced rhabdomyolysis.

IMPACT/DISCUSSION: Cocaine and alcohol abuse is a public health issue encountered in our daily practice. These patients are at greater risk of developing severe conditions, such as cardiovascular, CNS and liver diseases. Cocaine and alcohol use are rarely perceived as common differentials of rhabdomyolysis unless they are associated with a history of syncope, seizure, fall or focal muscle pain, none of which was reported by our patient. These rhabdomyolysis differentials are often overshadowed by statin use and extreme exertion. Cocaine and alcohol nefarious health effects are well documented. Specifically, cocaine has been reported to induce rhabdomyolysis in multiple case reports and one study on eel found a correlation between cocaine exposure and muscle swelling-breakdown. Alcohol misuse, acute or chronic, leads to pathological changes in the muscle, called alcohol-induced myopathy, found in over half of the alcohol abusers. Clinically, rhabdomyolysis is difficult to diagnose, half of biologically-proven rhabdomyolysis had no muscle related complaints and cocaine-induced rhabdomyolysis has been shown to poorly correlate with symptomatic muscle related complaints.

CONCLUSION: Given the significant potential complications induced by rhabdomyolysis, such as renal insufficiency, and electrolytes disturbances with risk of fatal cardiac arrhythmia and death, it is vital to learn to diagnose and distinguish cocaine and alcohol use as common differentials of rhabdomyolysis. Such cocaine and alcohol use should trigger a specific inquiry about any complaints of fatigue and muscle discomfort, and warrant a lower threshold to order CPK as part of the lab workup.

COLITIS ON THE CAPE - RECOGNIZING RESISTANCE PATTERNS IN SHIGELLA ENTEROCOLITIS

Timothy M. Bober¹; Furkan Ertem²; Amar Kohli³. ¹UPMC Presbyterian-Shadyside, Pittsburgh, PA; ²University of Pittsburgh Medical Center, Pittsburgh, PA; ³UPMC, Mars, PA. (Control ID #3186230)

LEARNING OBJECTIVE #1: Emphasize antibiotic treatment in Shigella enterocolitis

LEARNING OBJECTIVE #2: Recognize resistance patterns among Shigella infections among men who have sex with men

CASE: Case: This was a 54 year-old male with history of HIV with undetectable viral load on HAART, diverticulosis, Hepatitis C, and chronic inflammatory sensory polyneuropathy who presented with 5 days of large loose bowel movements with small clots and neurological symptoms. He had traveled to Cape Cod, where he explored marshes and ate "bad tasting" lobster. He had unprotected receptive anal intercourse with two male partners. Patient denied fever/chills, excessive NSAID use, recent antibiotic treatment, or family history of inflammatory bowel disease. Review of systems was notable for 4 pound weight loss and neurologic complaints including headache, diplopia, and patchy numbness. The patient was afebrile (36.8°C) and normotensive at 112/72 with a heart rate of 72 beats per minute. Abdominal exam showed a soft, non-tender, non-distended abdomen with right lower quadrant tenderness, normal liver span, no splenomegaly, and hyperactive bowel sounds. The differential included bacterial, viral, fungal, and parasitic etiologies.

Preliminary stool studies were negative but stool culture revealed Shigella species resistant to ampicillin-sulbactam and Bactrim. CT Abdomen/Pelvis with contrast demonstrated severe pan-colitis with trace pelvic fluid. Patient was treated with one day of ciprofloxacin and metronidazole and supportive treatment. He was then discharged to home.

IMPACT/DISCUSSION: This case highlights growing resistance patterns among Shigella species in the United States - especially among men who have sex with men. Shigella species cause 500,000 diarrheal illnesses annually in the US¹ with growing resistance to ciprofloxacin, azithromycin, and bactrim.² Empiric treatment for diarrhea is not generally advised, but Shigella infections merit treatment with 7-10 days Bactrim (7-10 days) or azithromycin (5 days).^{3,4}

CONCLUSION: References: 1. Scallan, E., et. al. (2011). Foodborne illness acquired in the United States—major pathogens. *Emerging infectious diseases*, 17(1), 7. 2. Heiman, K. E., et. al. (2014). COMPASSIONATE USE OF A NEW INVESTIGATIONAL PATENT FORAMEN OVALE CLOSURE DEVICE FOR PLATYPNEA-ORTHODEOXIA SYNDROME

Bilal Saqi. Cleveland Clinic Foundation, Cleveland, OH. (Control ID #3186329)

LEARNING OBJECTIVE #1: To recognize role of Patent foramen ovale (PFO) closure devices not just for cryptogenic strokes, but for the treatment of hypoxic conditions.

LEARNING OBJECTIVE #2: Managing a patient with an investigational PFO closure device on basis of compassionate use

CASE: 69 year old male with history of squamous cell carcinoma of the right lung status post pneumonectomy, mid-tracheal recurrence, pulmonary aspergillosis complicated by recurrent pleural effusions, rectal adenocarcinoma, COPD, transient ischemic attack (TIA) and left lower lobe subsegmental pulmonary embolus presented for a surveillance bronchoscopy. Upon arrival, he was hypoxic and found to have platypnea-orthodeoxia syndrome. Echo with agitated saline revealed a PFO. Ejection fraction was 55% with mild right ventricular (RV) dilation with low normal systolic RV function. In the setting of large intracardiac shunt with hypoxia as well as history of prior TIA, we elected to close the PFO. His transesophageal echo images suggested a large defect with PFO diameter of 21mm and a very mobile/aneurysmal septum and borderline aortic rims anteriorly, therefore we favored the Gore Cardioform 30mm device over an Amplatzer septal occluder (ASO) device to minimize long term risk of erosion. During the procedure, the device was seen to dislodge from the septum and migrate into the left atrial cavity. Unfortunately, the defect was too large and this procedure was unsuccessful, and the devices were retrieved. He was not deemed to be a surgical candidate due to multiple comorbidities, but we were able to get Gore's investigational Cardioform device on compassionate use (currently only available in clinical trials, for which patient would not be a candidate). Patient was approved and successful PFO closure with a 44mm Cardioform device was performed with marked improvement in oxygen saturation.

IMPACT/DISCUSSION: Patent foramen ovale (PFO) closure devices for cryptogenic strokes have been well debated leading to FDA approval, but they also have a role in treating hypoxic conditions. This was a unique example of using a new investigational device that the patient would not otherwise qualify for, but asking for its use under compassionate basis. In

the end, patients improvement in oxygen saturation was remarkable. This case shows the impact new PFO closure devices can play in Platypnea-Orthodeoxia Syndrome patients as well.

CONCLUSION: Use of the new Cardioform closure device for patients with PFO and hypoxia due to right to left shunt and anatomy leading to failure of older closure devices leads to functional improvement.

CONCURRENT PRESENTATION OF ALL 3-STAGES OF LYME DISEASE

Sona Franklin; Manisha Naik. St Mary Medical Center, Langhorne, PA. (Control ID #3186215)

LEARNING OBJECTIVE #1: Recognize 3-stages of Lyme disease may present concurrently

CASE: A 57-year-old Caucasian male, with no reported past medical history, presented to the Emergency Department complaining of intermittent subjective fevers for three-weeks and drenching night sweats, associated with an erythematous "splotchy" rash over his abdomen and legs, joint pain, swelling, and muscle aches. He also had diplopia two days prior to arrival with no improvement. He did not recall tick, mosquito or animal bites and denied previous episodes of similar symptoms. He had recently traveled to Florida and had spiking fevers prior to that trip. He admitted to outdoor garden work and denied sick contacts. The rash initially presented on his left ankle with swelling and minimal pain, but no pruritus. Family history was significant for father with rheumatoid arthritis and daughter with Celiac disease. Initial vital signs were blood pressure:144/94, pulse:77, respiratory rate:16, temperature:36.7 centigrade, oxygen saturation of 98% on room air. Physical exam was significant for left eye lateral gaze palsy, rightward gaze nystagmus, circular rash with central clearing on the abdomen, and erythematous rashes without central clearing on left lower back and bilateral thighs. Neurological exam revealed slight left eye droop but was otherwise unremarkable. Chest radiograph, magnetic resonance imaging and magnetic resonance angiogram of the brain, were all unremarkable. Swab for influenza A and B was negative, and urinalysis was negative for infection. Complete blood count revealed a leukocyte count of 12.1K/UL with 81% neutrophils. C-reactive protein was 45.30mg/L. He was started on intravenous ceftriaxone awaiting Lyme serology analysis. Cerebrospinal fluid array was negative. Lyme panel revealed a positive Lyme IgG and IgM, Western Blot was positive for six IgG antibodies, and reactive for three IgM antibodies. He was subsequently discharged home to complete a 28-day course of intravenous ceftriaxone and methylprednisolone.

IMPACT/DISCUSSION: Lyme disease is prevalent in Bucks County, Pennsylvania, and is caused by *Borrelia* species, with *B. burgdorferi* as the primary agent in the United States. Stages of Lyme disease occur in three phases: early localized, early disseminated and late disease. Most often the phases occur in succession. Overlap may occur, with later stages of Lyme as the initial presentation. There are case reports of simultaneous presentation of two stages,^{1,2} but no published cases of all three stages presenting concurrently. We present a unique case where all three stages of Lyme disease present simultaneously.

CONCLUSION: Our case is an unusual presentation of all three stages of Lyme disease presenting concurrently in a patient located in a region with a high prevalence of Lyme. It is imperative to bring light to this unique phenomenon of Lyme disease, as unawareness of this presentation may lead to misdiagnosis. Greater attention will help ensure prompt and appropriate treatment of these patients.

CONGENITAL HERNIA MAY NOT BE CONGENITAL ANYMORE

Ravi K. Thimmisetty¹; Kiran Chintam²; Venu Madhav Chirunomula²; Matthew Shoemaker². ¹Nephrology Associates, Cape Girardeau, MO; ²Southeast hospital, Cape Girardeau, MO. (Control ID #3186369)

LEARNING OBJECTIVE #1: Diagnosis and treatment of rare presentation of congenital hernia

LEARNING OBJECTIVE #2: Assessing the complications of Morgagni hernia

CASE: 53 year old healthy Caucasian male transferred from outside facility with hypoxic respiratory failure. He was complaining of progressive shortness of breath over 8 months before admission. Admission vitals were temperature of 98.2 f, blood pressure of 122/79 mm of Hg, heart rate of 79 beats per minute, respiratory rate of 27 per minute, 96% oxygen saturation on BiPAP 14/8. Physical examination revealed mild to moderate acute distress, with decreased breath sounds on right side. Rest of the exam is within normal. Laboratory results revealed pH of 7.173, pCO₂ is 108, pO₂ is 98.7 and bicarbonate of 39, serum sodium of 139, potassium of 5.0, bicarbonate 34, rest of laboratory results were acceptable range. CT scan of chest demonstrated diaphragmatic hernia suggestive of foramen of Morgagni hernia and right hemithorax is filled with abdominal contents including small, large bowel and omentum, pushing the heart into left side of chest, pneumonia vs pneumonitis. Empiric antibiotics was started (Azithromycin and piperacillin/tazobactum) after drawing blood cultures. Patient got intubated for severe respiratory acidosis. Patient underwent emergent explorative laparotomy and repaired diaphragm with prolene mesh patch. Fiberoptic bronchoscopy showed thick white mucus in right bronchus intermedius which was aspirated. Chest tube was placed in right 6th intercostal space. Patient underwent thoracotomy and decortication of right lower and middle lobes. Blood and sputum cultures were inconclusive. Subsequently patient was hemodynamically improved after finishing the antibiotics (both piperacillin/tazobactum and azithromycin). He got extubated and chest tube was removed once drainage was minimal.

IMPACT/DISCUSSION: Our case illustrates the rare presentation of congenital hernia. Patient was asymptomatic since birth and presented to the hospital with respiratory failure. Morgagni hernia is an anatomical defect in the anterior diaphragm that allow herniation of abdominal organs into the thorax. These hernia's were the rarest of the congenital diaphragmatic defects with a reported frequency of 1% to 5.1%. Chest radiograph can show homogenous masses in the thorax with air fluid levels suggestive of hernia. CT scan is the investigation of choice for diagnosis of Morgagni's hernia. This case illustrates the need to act quickly when a potential diagnosis of a Morgagni's hernia is made. A missed diagnosis can lead to complications such as hemorrhage, obstruction, or strangulation. Assessing the hernia in a timely manner and acting appropriately will minimize the complications of Morgagni hernia and by doing so, we were able to save the patient

CONCLUSION: All health care professionals not limited to internists should be aware of this rare presentation and can prevent devastating complications by suspecting diagnosis by clinical, physical examination and imaging studies

CONGESTIVE HEART FAILURE OR COULD IT BE SOMETHING ELSE?

Saketh Parsi¹; Lakshmi Priyanka Mahali². ¹Montefiore Medical centre, Bronx, NY; ²Montefiore Medical Center, Bronx, NY. (Control ID #3185224)

LEARNING OBJECTIVE #1: Diagnosis of Right Atrial myxoma should be suspected in patients with symptoms mimicking congestive heart failure associated with weight loss.

LEARNING OBJECTIVE #2: Right atrial myxoma can create pro-thrombotic environment and lead to clot formation causing pulmonary embolism.

CASE: A 71 year-old woman with hypertension presented with progressive ascending bilateral leg swelling for one week. She also reported chronic dry cough, wheeze and dyspnea on exertion since over one month and unintentional weight loss of 40 pounds since over a year. She was hemodynamically stable. Physical exam revealed a diastolic murmur on

the left sternal border. Diagnosis of heart failure was suspected and Transthoracic Echocardiography (TTE) was done, which surprisingly revealed severe right atrial dilatation and a pedunculated, mobile mass with multiple stalks (3.1 x 1.9 cm in longest dimensions) attached to interatrial septum, consistent with an atrial myxoma. Computed tomography (CT) of chest revealed bilateral extensive pulmonary embolisms (PE), with right heart strain, pulmonary arterial hypertension, and irregular filling defect within the right atrium (RA) corresponding with the myxoma. Anti-coagulation (AC) was started with lovenox and patient was discharged on apixaban with cardiothoracic clinic follow up.

IMPACT/DISCUSSION: Approximately 80 percent of myxomas are found in the left atrium; the remainders are in the RA. RA myxomas grow into the lumen and obstruct flow, producing hemodynamic changes that are similar to tricuspid stenosis. RA myxomas typically present with signs and symptoms of right heart failure (peripheral edema, hepatomegaly, and ascites) and cause diastolic murmurs. Constitutional symptoms like malaise, anorexia, fever, arthralgia, weight loss are more common in cases of cardiac myxomas due to the release of cytokine interleukin-6 (IL-6). In addition, tumor fragments may be released into the pulmonary circulation causing symptoms consistent with pulmonary embolism, as seen in our patient. Presence of an atrial septal defect results in shunting of venous blood into the systemic circulation causing hypoxemia or systemic emboli. Provoked PE is temporarily managed with AC and permanently managed by treating the cause. RA myxomas require prompt resection to prevent further embolization or cardiovascular complications, including sudden death.

CONCLUSION: In patient with heart failure symptoms, PE and associated significant weight loss other diagnoses like right heart myxoma, malignant pericardial effusion should be considered. Patients with right atrial myxomas should be managed with AC, if no medical contraindications. However ultimate management is tumor resection.

CORONARY ARTERY DISSECTION IN MULIPAROUS POST-PARTUM PATIENT

Kuroush Nezafati. Methodist Dallas Hospital, Arlington, TX. (Control ID #3185805)

LEARNING OBJECTIVE #1: Recognize spontaneous coronary artery dissection (SCAD) as an important and rare etiology of chest pain, especially in younger women with a history of recent emotional or physical stressor such as in peripartum/postpartum women.

LEARNING OBJECTIVE #2: Recognize the range of management for SCAD depending on the severity of dissection and associated mortality with SCAD.

CASE: A 29-year-old G5P5 female with past medical history of pre-eclampsia during her 3rd pregnancy presented to the Emergency Department (ED) with substernal chest pain 18 days postpartum. Pain was pressure like, non exertional and radiated into bilateral upper extremities; she initially attributed her symptoms to anxiety, but with a 3rd episode of pain and her measured systolic blood pressure of 180 mmHg at home, she sought medical attention. Evaluation in the ED showed normal chest radiograph, electrocardiogram (ECG) with ST segment depression in precordial leads concerning for subendocardial ischemia. Initial troponin was 0.739 ng/mL. Troponin was 4.27 ng/mL six hours later for which patient had an angiogram which showed multiple dissections in left anterior descending (LAD) & left circumflex with anteroapical hypokinesis but preserved ejection fraction. The most significant of these dissections was within the left anterior descending coronary which had extensive anterograde and retrograde involvement. Two long stents were placed in the LAD, one proximally extending up to left main coronary and one distally up to the distal third of the left anterior descending coronary. The left circumflex dissection showed no intimal flap and good wall integrity. Vessel branches off of the marginal branch also showed area of dissection with no wall compromise. The patient was placed on dual antiplatelet therapy along with a statin and beta blocker and recovered well.

IMPACT/DISCUSSION: Spontaneous coronary artery dissection (SCAD) is an important and rare cause of acute coronary syndrome (ACS). This case demonstrates the importance of thorough workup of chest pain in patients with few to no comorbidities with abnormal ECG, elevated troponin levels, and recent stressor. Literature demonstrates SCAD carries with it significantly increased in-hospital mortality above other non-SCAD acute myocardial infarction causes. Patients with SCAD should at the least have long term medical management including hypertension management and use of a beta blocker, to avoid recurrence of dissection. This case also highlights the range of management depending on severity of dissection.

CONCLUSION: SCAD is an important and rare cause of ACS more commonly found in younger women who generally carry fewer comorbidities than other ACS patients. Yet, SCAD is associated with significantly increased mortality above other ACS causes. Depending on findings during angiogram, SCAD management can vary from conservative management (especially hypertension control and beta blocker use) to interventions including coronary stenting.

CREATIVE SELF-EXPRESSION: ONE PRONG IN A MULTIMODAL TREATMENT PLAN FOR ADDICTION

Colleen Farrell¹; Katie Grogan². ¹NYU Langone, New York, NY; ²NYU School of Medicine, New York, NY. (Control ID #3181441)

LEARNING OBJECTIVE #1: Recognize the therapeutic benefit of creative self-expression in the treatment of addiction

CASE: Ms. D is a 37-year-old woman with history of opioid use disorder (using intravenous heroin), who presented to our hospital with severe neck pain. She was diagnosed with C-spine osteomyelitis and initiated on IV antibiotic therapy. Her course was complicated by cardiac arrest from heroin overdose (provided by a personal visitor). During her hospitalization, she was initiated on buprenorphine and met regularly with an art therapist. She created drawings and small sculptures that depicted her years-long struggle with heroin use, as well as emotional traumas that contributed to her use. Prior to discharge, she shared her artwork with her medical team, eloquently articulating how creating art helped her process her trauma and make a commitment to recovery.

IMPACT/DISCUSSION: Addictions are an increasingly pressing national health concern. Many elements of Ms. D's case—her early childhood trauma, her life-threatening medical complications—will likely be familiar to internists who care for patients with substance use disorders. This presentation will focus on a promising and understudied aspect of addiction treatment: creative self-expression. Creative self-expression can be joyful, relaxing, and distracting from other difficulties. It also empowers patients to create their own narratives of self, recognizes patients' subjective experiences, and provides means of communicating difficult experiences with the clinical team and others. There is a strong theoretical foundation for the use of self-expression as a means for improved wellbeing in the medical setting and in trauma recovery (1,2). Current empirical data are encouraging but limited by small sample size, lack of objective metrics, and heterogeneity of art therapy modalities (3,4). This presentation will introduce conference participants to the robust theoretical basis of creative self-expression in healing and recovery. This theoretical basis will then be applied to a discussion of Ms. D's case. The presentation will include photographs of Ms. D's artwork, for which she has provided her consent. 1. Frank AW. Just Listening: Narrative and Deep Illness. Fam Syst Heal. 1998;16(3):197-212. 2. Larkin M and Griffiths M. Experiences of Addiction and Recovery: the Case for Subjective Accounts. Addiction Research & Theory. 2009;10: 281-311. 3. Uttley L et al. The clinical and cost effectiveness of group art therapy for people with non-psychotic mental health disorders: a systematic review and cost-effectiveness analysis. BMC Psychiatry. 2015;15:151. 4. Schouten KA et al. The Effectiveness of Art Therapy in the Treatment

of Traumatized Adults: A Systematic Review on Art Therapy and Trauma. Trauma Violence Abuse. 2015;16(2):220-228.

CONCLUSION: This case demonstrates the therapeutic potential of creative self-expression as part of a multi-modal treatment strategy for addiction.

CUTANEOUS CRYPTOCOCCUS NEOFORMANS: A FATAL WARNING SIGN.

Tania M. Kohal; Ahmad D. Duder; Gillian Grafton. Henry Ford Hospital, Detroit, MI. (Control ID #3162884)

LEARNING OBJECTIVE #1: Understand the incidence of cutaneous manifestations of cryptococcal infections and its relation to systemic cryptococcal infection.

LEARNING OBJECTIVE #2: Identify cryptococcal skin lesions.

CASE: An 81 year old woman presented to the medical intensive care unit as an outside transfer for escalation of care. Two months prior to this hospitalization the patient was fully independent and lived alone; however, she had a recent admission for renal failure which revealed an ANCA-positive vasculitis with myeloperoxidase antibody elevation and crescentic pauci-immune glomerulonephritis on renal biopsy. She was discharged on a maintenance dose of prednisone, but began to clinically deteriorate shortly thereafter at home with decline in mental status and renal function. The patient was transferred from an outside hospital to our facility with acute encephalopathy and cellulitis. On arrival, physical exam revealed skin lesions on the bilateral upper extremities and right lower extremity that were violaceous and purpuritic as well as areas of induration and necrosis. Blood cultures revealed a gram positive bacteremia. Dermatology was consulted with the request of a skin biopsy given the patient's prior history. On the day of the skin biopsy the patient had further clinical deterioration with progressive hypoxia requiring intubation as well as renal failure and severe lactic acidosis. She was treated with broad spectrum antibiotics as well as anti-fungals; however her clinical status continued to deteriorate and eventually she expired within 48 hours of admission. Her skin biopsy revealed disseminated encapsulated yeast consistent with *Cryptococcus neoformans*.

IMPACT/DISCUSSION: *Cryptococcus neoformans* is a dimorphic fungus that is ubiquitous in the environment, found in soil, dust, wild and domesticated birds as well as a skin contaminant. Clinically, its primary manifestation is pulmonary infection; however, 10-15% of clinical manifestations are cutaneous. Cutaneous manifestations can be diverse including plaques, crusts, nodules, or microhemorrhages. When presented with an individual with cutaneous manifestations, the patient should be assumed to have systemic infection unless proven otherwise, and this case demonstrates that delay in treatment can become fatal. The diagnostic challenge in this case was identifying a patient with known immunocompromised status presenting with no other objective data of cryptococcal meningitis or pulmonary infection. The patient was started on antifungals; however, not with enough alacrity to become effective.

CONCLUSION: Cryptococcosis can be encountered around the world and the majority of its clinical manifestations will be elucidated via the common infectious routes; however, there are opportunities to diagnose cryptococcosis and treat patient faster in an attempt to reduce morbidity and mortality from this infection. One of these opportunities is assessment of new dermatological manifestations of unknown origin in at risk patients.

CUTANEOUS NECROSIS: A CASE OF CONCOMITANT ECTHYMA GANGRENOsum AND CALCIPHYLAXIS

Neha Agarwal¹; Sarah Schoenbrun¹; Esteves Hernandez². ¹UCLA Ronald Reagan, Los Angeles, CA; ²David Geffen UCLA School of Medicine, Los Angeles, CA. (Control ID #3179543)

LEARNING OBJECTIVE #1: Recognize the clinical features of ecthyma gangrenosum and calciphylaxis

LEARNING OBJECTIVE #2: Manage ulcers due to calciphylaxis

CASE: An 89 year-old female with a history of multiple myeloma (MM) not on therapy, chronic kidney disease stage IV, and diabetes presented to the emergency room with confusion and left lower extremity allodynia. Home medications included cholecalciferol, patiromer, and nephrovite. Physical exam was notable for temperature of 38°C, suprapubic tenderness, and left lower extremity edema, allodynia, and an inability to bear weight. Labs demonstrated creatinine 3.08 mg/dL (near baseline), white blood cell count 50.0 k/uL, and normal calcium, phosphorus and parathyroid hormone (PTH). Urinalysis was significant for >100 white blood cells cells/uL and leg X-rays were unremarkable. Urine cultures grew resistant *Klebsiella pneumoniae* which was treated with 5 days of ertapenem. On hospital day 7, the patient developed a 12x6cm stellate-shaped purpuric plaque with an overlying tense bulla over the medial ankle. Pathology from two punch biopsies was consistent with ecthyma gangrenosum and *Klebsiella pneumonia* grew on wound cultures. Ertapenem was continued, but the ulcer developed central necrosis with undefined borders and persistent allodynia. A CT of the leg showed extensive subcutaneous edema with vascular calcifications. Given lack of clinical improvement and progressive necrosis, a repeat biopsy was performed on hospital day 12, which noted vessel thrombosis and calcification consistent with calciphylaxis. The patient was started on bi-weekly sodium thiosulfate and hyperbaric oxygen therapy.

IMPACT/DISCUSSION: Cutaneous necrosis is associated with high rates of morbidity and mortality, necessitating early recognition and diagnosis. Among the various etiologies are ecthyma gangrenosum and calciphylaxis. Ecthyma gangrenosum, typically associated with *Pseudomonas* infections in immunocompromised bacteremic patients, has been increasingly reported in association with *E. coli* and *Klebsiella* in the absence of bacteremia. As in this case, it can predispose to calciphylaxis in at-risk patients. Calciphylaxis typically develops in patients with advanced renal disease, hyperparathyroidism and elevated calcium-phosphate product. It has also been reported in patients with MM due to an acquired protein S deficiency. Treatment is typically multimodal and includes sodium thiosulfate, which is associated with clinical improvement but lacks conclusive evidence demonstrating efficacy, treatment of hyperphosphatemia, and wound care. Hyperbaric oxygen has been used as an adjunctive therapy to facilitate wound healing. This case highlights the diagnostic challenge with a necrotic ulcer, and cautions against premature diagnostic closure.

CONCLUSION: The differential for acute cutaneous necrosis includes ecthyma gangrenosum and calciphylaxis. Calciphylaxis has been described in patients with MM due to an acquired hypercoagulability state. Hyperbaric oxygen therapy improves healing and morbidity in calciphylaxis.

CYBERCHONDRIASIS-RELATED HYPERVITAMINOSIS D

Sally Namoodiri; Clifford D. Packer. Cleveland VAMC, Cleveland, OH. (Control ID #3163956)

LEARNING OBJECTIVE #1: Recognize the internet's influence on patients with illness anxiety disorders

LEARNING OBJECTIVE #2: Review the symptoms and management of hypervitaminosis D

CASE: A 50-year-old white male presented with two weeks of constipation and anorexia. His past medical history included chronic kidney disease (baseline creatinine 1.6 mg/dl), family history of Huntington's disease and an untreated anxiety disorder. He took numerous vitamin supplements. His physical exam was unremarkable. Labs showed creatinine 3.7 mg/dl (0.5-1.2), calcium 12.5 mg/dl (8.5-10.1), Vitamin D 258 ng/ml (30-45), and PTH < 7 pg/ml (15-72). Abdominal computerized tomography showed multiple nonobstructive renal calculi. When asked about his vitamin usage, he said that he took 100,000 international units (IUs) of Ergocalciferol daily for many weeks. He was convinced that he had Huntington's disease due to symptoms of hand tremors and brain fog.

Based on information from the internet, he compulsively took supplements and varied his diet to improve his symptoms. When asked for specific sources, he cited a physician on YouTube with secondary progressive multiple sclerosis who failed multiple medications. After searching the internet for answers, she cured her disease with high doses of vitamin D and other supplements along with a special diet. The patient was admitted with acute kidney injury and hypercalcemia from hypervitaminosis D. With intravenous (IV) hydration and withholding of Ergocalciferol, his creatinine improved to 1.8 mg/dl and calcium to 9.7 mg/dl. Despite his subsequently negative genetic testing for Huntington's disease, he remained convinced that he had a serious illness which could only be controlled with high doses of supplements and special diets.

IMPACT/DISCUSSION: Hypervitaminosis D is a rare phenomenon that is most often due to prescription or medication formulation errors. Intoxication has been reported when doses exceed 50,000 IUs per day. Hypercalcemia occurs due to increased gut absorption of calcium, with resultant anorexia and constipation. Vitamin D's direct effect on renal vasoconstriction can lead to acute kidney injury. Chronic hypervitaminosis D causes kidney stones due to increased urinary calcium excretion. Calcitriol (1,25 OH Vitamin D)-induced hypercalcemia is easily treated with IV fluids and withholding Vitamin D due calcitriol's short half-life. In contrast to most cases of hypervitaminosis D, this patient's illness anxiety disorder led him to intentionally consume high doses of Vitamin D, a supplement whose health benefits are touted on the internet based on little scientific evidence. Treatment options for illness anxiety disorder, or "cyberchondriasis" in this patient's case, include cognitive-behavioral therapy and antidepressants.

CONCLUSION: Our patient's deliberate ingestion of high doses of Vitamin D led to hypercalcemia, acute kidney injury and nephrolithiasis. Inquiring about vitamin usage can unmask illness anxiety disorders which, if untreated, can lead to self-harm under the influence of the internet.

D-MYSTIFYING HYPERCALCEMIA

Theresa Wong; Katherine Julian. UCSF, San Francisco, CA. (Control ID #3181407)

LEARNING OBJECTIVE #1: Summarize the evaluation of new hypercalcemia (hyperCa)

LEARNING OBJECTIVE #2: Describe the risk factors for hypervitaminosis D

CASE: ES is an 80 year old woman with hypertension and chronic tobacco use who presented for an annual checkup. She had no complaints except for a buttock rash. Review of systems was normal except for a 15 lb weight loss over the last 1.5 years due to poor appetite. Her medications included HCTZ, duloxetine, and multiple vitamin supplements. Her vital signs were normal. On physical exam, she was thin and frail with a shallow sacral pressure ulcer. The rest of the exam was normal. A screening low-dose CT scan showed several pulmonary nodules 2-15mm in size that were unchanged from prior CT. A routine BMP revealed a serum calcium of 13.5, Cr 1.36 and albumin 4.4. Her previous labs showed a calcium of 10.9 and a baseline Cr of 0.9. She was sent to the ED where further workup showed 25-hydroxy vitamin D (25(OH)D) elevated to 115 and low PTH. TSH, free T4, PTHrP, and 1-25 dihydroxy vitamin D (1-25(OH)2D) were normal. She revealed she was taking calcium and vitamin D (vit D) supplements not noted in her medication list. She was discharged home after her Cr and Ca downtrended with fluids, and she discontinued her HCTZ, Ca, and vit D.

IMPACT/DISCUSSION: Hyperparathyroidism (hyperPTH) and malignancy are the most common causes of hyperCa, making up more than 90% of the cases. The first step of diagnosis is whether the hyperCa is PTH or non-PTH mediated. An elevated PTH is diagnostic of primary hyperPTH. A low PTH prompts further testing with PTHrP, vit D metabolites, SPEP, serum free light chains, TSH, free T4. PTHrP can be elevated in malignancy. 1-25(OH)2D can be elevated in lymphoma and granulomatous diseases. Drug-mediated effects are most commonly due

to thiazides and calcium and vit D supplements. Miscellaneous causes of hyperCa include immobilization and dehydration. The tolerable upper intake level of vit D as defined by the Institute of Medicine is 4000 IU daily. Published cases of hypervitaminosis D have involved intake of >40,000 IU daily. The serum concentration of 25(OH)D that results in hyperCa is undefined, though experts have estimated vit D intoxication as >150 ng/ml. Cases of toxicity have been reported in those taking megadoses of vit D as part of a fad diet or as replacement therapy in conditions such as malabsorption, renal osteodystrophy, osteoporosis, or psoriasis. In our case, the patient was taking 1000 IU of D3 daily. Though her dose and serum levels were not expected to cause toxicity and hyperCa, multiple other factors likely increased her serum Ca, including Ca supplementation, thiazide use, dehydration, and immobility.

CONCLUSION: The etiology of hyperCa can be quickly determined with history, medicine reconciliation, and a limited set of laboratory tests. Vit D toxicity has been reported with intake of >40,000 IU per day and 25(OH)D levels >150, but hyperCa can occur at lower levels with multiple seemingly benign contributing factors.

DEVELOPMENT OF SEVERE RED RASH DUE TO VITAMIN DEFICIENCY YEARS FOLLOWING GASTRIC BYPASS SURGERY.

Robert Case¹; Jared Freitas²; Sean P. Bliven². ¹University of Florida, Gainesville, FL; ²University of Florida School of Medicine, Gainesville, FL. (Control ID #3183336)

LEARNING OBJECTIVE #1: Recognize vitamin deficiencies of zinc and B6 as causes of red rash after gastric bypass surgery.

CASE: A 39-year-old female presented with red, painful rash, confusion and severe dehydration. Her past medical history included alcohol abuse, CHF, and untreated hep B and hep C infections. Her surgical history included gastric bypass surgery (Roux en-Y) 6 years prior to admission and both mitral and aortic valve replacement due to endocarditis. Her rash was bright red, blanchable and exquisitely tender with areas of blisters and active wheeping of fluid. The rash involved the lower half of the trunk, acrum and upper thighs. She also had angular chelitis, glossitis and pain within her mouth. She denied recent initiation of new prescription medications or supplements. Her labs revealed multi organ system dysfunction as exhibited by acute on chronic liver injury, acute kidney injury and early signs of DIC. She became increasingly confused with worsening hypotension leading to transfer to the ICU. Her rash was biopsied and returned suggestive of a vitamin deficiency. Her labs further supported this result with critical deficiencies in vitamin B6 and zinc. After repletion of these vitamins, the rash progressively improved over the course of several weeks.

IMPACT/DISCUSSION: This case represents an unusual presentation of vitamin deficiency after gastric bypass surgery. Both dermatology and infectious disease consultants felt her presentation was concerning for toxic shock syndrome on initial evaluation. Staphylococcal toxic shock syndrome was supported as a possibility based on the presence of the erythematous rash, hypotension and multiple organ damage. However, biopsy definitively ruled this condition out. Both zinc and vitamin B6 deficiencies are common after bariatric surgery. One paper found 75% of women to have zinc deficiency after this surgery. Notably, alcohol abuse is known to exacerbate zinc deficiency by increasing bodily losses. The distribution of her rash resembled that of a diaper rash of an infant spreading to the trunk is notably consistent with a distribution due to these mineral deficiencies. The presence of angular chelitis and glossitis is also consistent with low zinc and B6 levels. While her rash may be well-explained by the vitamin deficiency, her acute presentation and sudden onset of the rash were surprising and left this diagnosis in doubt initially. This case demonstrates the variability with which these vitamin deficiencies may present clinically. Clinicians who encounter similar cases should have a low threshold to test for vitamin deficiencies and initiate treatment promptly if levels are low.

CONCLUSION: -Patients who previously underwent bariatric surgery presenting with a diffuse, red rash should be tested for vitamin deficiencies, especially vitamin B6 and zinc. -The rash associated with zinc and B6 deficiency may resemble toxic shock syndrome -Onset of a systemic rash may occur years after bariatric surgery and progress rapidly without clear provoking cause.

DEVIC'S DISEASE AND TRANSVERSE MYELITIS: AN IMPORTANT PRESENTATION OF AN UNCOMMON DISEASE

Samuel Shapiro; Benjamin Hayes. gwinnett medical center, Lawrenceville, GA. (Control ID #3162774)

LEARNING OBJECTIVE #1: Evaluate a patient with transverse myelitis

LEARNING OBJECTIVE #2: Diagnose neuromyelitis optica (NMO) in a patient with transverse myelitis

CASE: A 55-year-old African American female with a past medical history of polymyositis presented to the emergency room with progressive ascending paresthesia of the lower extremities to the mid abdomen for 3 days. Review of systems was positive for bowel incontinence and negative for bladder incontinence, motor weakness, dysphagia, dyspnea, fever or chills. Her only medication was prednisone 5mg daily. Otherwise she did not have a significant family, surgical or social history. On physical exam, her vitals and major organ systems were normal except for the neurologic exam. She had loss of sensation to light touch and temperature distal to T5 and decreased vibratory sense of the feet. Otherwise motor, cognitive and cerebellar functions were intact. MRI of the brain and spine were significant for signal abnormality of the central gray matter from T4 to T8. The patient was diagnosed with transverse myelitis and started on high dose steroids. Serologic work up was positive for aquaporin-4 (AQP4) antibody specific for NMO or Devic's disease. Her symptoms improved and follow up MRI 3 months later showed significant improvement in the lesion.

IMPACT/DISCUSSION: Acute TM is a rare inflammatory disorder that can affect any portion of the spinal cord and cause major morbidity. It is considered a neurologic emergency and can present with motor, sensory and/or autonomic dysfunction. The differential is broad and includes spinal artery infarcts, metabolic abnormalities (vitamin B12, copper), infection, neoplasm, neurodegenerative (multiple sclerosis (MS), neuromyelitis optica), and autoimmune (SLE, sarcoidosis, Sjogren's) disorders. The location of lesion(s) is an important early indicator of the possible etiologies. For instance, our patient had a central thoracic lesion more commonly seen with NMO or autoimmune disease as opposed to an anterior lesion from an anterior spinal artery infarct. MRI of the entire spinal cord is essential to evaluate extent of disease as multiple lesions can be seen with either MS or NMO. High dose steroids are the mainstay of treatment for neurodegenerative and autoimmune etiologies and should be started promptly. Our patient improved but for those with refractory diseases plasma exchange is another option. Previously thought to be a form of MS, NMO differentiates itself by its necrosis and cavitations of both white and gray matter. Optic nerve involvement is also common but was absent in our patient. Anti-AQP4 antibody is pivotal in the diagnosis of NMO attributed to its high sensitivity and specificity.

CONCLUSION: TM has a broad differential that internists should be able to recognize early to initiate the appropriate treatment as it is paramount in reversing the neurologic deficits.

DIABETIC AMYOTROPHY: A DISTINCT AND DISABLING NEUROPATHY

Cindy Fang; David Rhee. NYU, Flushing, NY. (Control ID #3139144)

LEARNING OBJECTIVE #1: Understand diabetic neuropathy does not only include distal polyneuropathy

LEARNING OBJECTIVE #2: Recognize the clinical features of diabetic amyotrophy

CASE: An 80-year-old man with a history of Type 2 diabetes and chronic lumbar radiculopathy presented to the emergency room after four days of left thigh pain radiating from the groin and progressive left leg weakness, now needing a wheelchair. On exam, he had decreased strength in hip flexion and knee extension, decreased sensation to touch along his medial calf, and a muted patellar reflex. He also had decreased vibrational sense in the toes bilaterally. Labs revealed a hemoglobin A1C of 9.8%. An MRI showed diffuse, extensive degenerative disease in the lumbar-sacral spine but no focal structural lesions such as epidural abscess or osteomyelitis. Electromyography showed evidence for diabetic amyotrophy as well as moderate polyneuropathy. After two months of strict glycemic control and physical therapy, the patient recovered some function and was ambulatory with a cane.

IMPACT/DISCUSSION: Diabetic amyotrophy is also known as diabetic femoral neuropathy, diabetic proximal neuropathy, diabetic lumbosacral radiculoplexopathy, and Bruns-Gardland syndrome. Patients with this entity typically present with acute or subacute, severe unilateral pain and weakness in the proximal lower extremity, and may often have muscle wasting. While distal polyneuropathy is the most common type of diabetes-induced neuropathy that can affect more than 20% of all diabetic patients, diabetic amyotrophy is much rarer and affect less than 1% of patients. Because of its low prevalence, it is often misdiagnosed as lumbosacral radiculopathy. In this case, our patient's neurologic symptoms were initially assumed to be due to known lumbar radiculopathy, but a thorough exam localized the lesion to the left femoral nerve, which did not correlate with the imaging finding. The diagnosis of diabetic amyotrophy depended on a high level of suspicion, recognition of poorly controlled diabetes, and confirmatory testing with electromyography. Treatment mainly consists of pain management and glycemic control, but studies on steroids and immunoglobulin are on-going. The majority of patients spontaneously improve over months.

CONCLUSION: Diabetic amyotrophy is a rare yet debilitating complication of diabetes. Because diagnosis rely heavily on clinical recognition, it is important for internist to keep a high level of suspicion when diabetic patients present with asymmetric proximal neuropathy.

DIABETIC MUSCLE INFARCTION: A CASE OF MISTAKEN IDENTITY

Kirsten Salline; Lily Belfi; David Pisapia; Sydney Katz. Weill Cornell Medicine, New York, NY. (Control ID #3181712)

LEARNING OBJECTIVE #1: Review common etiologies of muscle pain and edema in diabetic patients.

LEARNING OBJECTIVE #2: Discuss the presentation, diagnosis, treatment, and prognosis of diabetic muscle infarctions.

CASE: A 47-year-old woman with poorly controlled T1DM (HbA1c 12-14%) presented to the ER for the third time in two weeks with persistent right thigh pain and swelling despite a seven-day course of cephalaxin for presumed cellulitis. She denied lacerations, trauma, fevers, or recent immobilization. On exam, she was afebrile and the right thigh was edematous and indurated without erythema. Labs were notable for WBC 9.9/uL, CRP 9.3 mg/dL, ESR >130 mm/hr, and CK 771 U/L. A thigh ultrasound showed soft tissue edema without drainable fluid collection or DVT. She was treated with IV vancomycin and piperacillin/tazobactam for a working diagnosis of pyomyositis. A right knee effusion was noted on hospital day three which raised concern for septic arthritis in the setting of adjacent pyomyositis. Synovial fluid revealed no organisms, a normal nucleated cell count, and negative cultures. MRI of the right knee and thigh showed increased T2 signal of the quadriceps musculature. Blood cultures drawn on admission were sterile. Despite imaging suggestive of pyomyositis, the patient did not improve clinically with broad-spectrum antibiotics. A muscle biopsy was performed. Biopsy revealed diffuse myonecrosis consistent with diabetic muscle infarction (DMI). Muscle tissue cultures were sterile. Antibiotics were stopped and aspirin was started.

IMPACT/DISCUSSION: DMI is a rare and morbid complication of poorly controlled diabetes. Diagnosis can be delayed due to its rarity and similar presentation to soft tissue infections and VTE. DMI is an infrequent complication of diabetes that presents with acute pain and swelling of large muscle groups without constitutional symptoms, prior trauma, or simultaneous infection. Patients often have complications of poorly controlled diabetes at diagnosis. Diabetic microangiopathy or ischemia-reperfusion injury is thought to cause the muscle infarction. Associated knee effusions have been described a handful of times in cases of DMI. Diagnosis is made via imaging in association with clinical context. Routine labs are nonspecific, though ESR and CRP are often elevated. MRI is the imaging modality of choice, and on T2-weighted images infarcted muscle appears heterogeneous and hyperintense. Definitive diagnosis is made with muscle biopsy; however, this has been associated with increased recovery time. Antiplatelet agents have been associated with a shorter recovery time and lower recurrence rate compared to surgery. Recurrent infarcts and increased mortality make for an overall poor prognosis.

CONCLUSION: DMI is an under-recognized and often misdiagnosed cause of muscle pain and edema in poorly controlled diabetic patients. Prognosis of DMI is poor and treatment is largely supportive, though antiplatelet agents are associated with better outcomes.

DIAGNOSING A RARE CASE OF METFORMIN INDUCED LACTIC ACIDOSIS

Evan R. Gordon-Wollin¹; Minho Yu^{1, 2}; Ilho Kang^{1, 2}. ¹Loma Linda Medical Center, Rancho Cucamonga, CA; ²Riverside University Health System, Moreno Valley, CA. (Control ID #3168756)

LEARNING OBJECTIVE #1: Recognize the features of Metformin Induced Lactic Acidosis (MILA).

LEARNING OBJECTIVE #2: Treat MILA promptly and aggressively to improve patient outcomes.

CASE: This is a 65-year-old female with a history of hypertension and well-controlled diabetes mellitus type 2 on Metformin, who presented with non-bloody diarrhea 2-3 times per day, poor oral intake, and no urine output for 3-4 days. She denied any abdominal pain or fever. Despite not producing any urine for days, she continued to take her Metformin daily. Social, family, and surgical history were negative. Her other medications included Furosemide, Simvastatin, and Lisinopril. On physical exam she was afebrile with stable vital signs. The patient was in no acute distress, her abdominal exam was benign, and the rest of the physical exam was normal. Laboratory studies revealed a leukocytosis of 13.5, lactate 13.3 mmol/L, procyclitom 0.6 ng/mL, creatinine 10.6 mg/dL, bicarbonate 5 mmol/L, anion gap 35, and a pH of 6.85. Glucose was 56 mg/dL, lipase 1,043 U/L, and beta-hydroxybutyrate 5.2 mmol/L. Point of care ultrasound suggested that the patient was not in distributive shock. The most likely explanation for the severe lactic acidosis was a Type B lactic acidosis due to toxic Metformin accumulation in the setting of acute renal failure precipitated by a pre-renal state. No severe infection was identified, and other causes of a Type B lactic acidosis were ruled out. The patient was admitted to the ICU not on antibiotics, not on vasopressors, and immediately underwent emergent hemodialysis. There was a rapid reduction of lactate to 1.6, and a return of renal function by the end of hospital day two. The patient was discharged home four days later.

IMPACT/DISCUSSION: While a Type A lactic acidosis due to systemic hypoperfusion is often at the top of the differential, one must consider a Type B lactic acidosis when the clinical picture and objective data do not fit. Although controversial, rare, and without standard diagnostic criteria, a severe lactic acidosis in the setting of Metformin use and renal failure should prompt consideration of MILA. In a large cohort study of 258,539 patients on Metformin, Eppenga et al. (Diabetes Care, 2014) found a six-fold increase in lactic acidosis with eGFR <60 mL/min/1.73m², and Lazarus et. al. (JAMA, 2018) found among 75, 413 patients a two-fold

increase with eGFR less than 30 mL/min/1.73m². As seen with our patient, given the dialyzable nature of Metformin, rapid identification and treatment of MILA can have a good outcome. Although the mortality rate can still be high, Friesenecker et al. (Critical Care, 2010) demonstrated that when compared to a similarly severe lactic acidosis of other origin, MILA has a significantly better prognosis.

CONCLUSION: It is important to evaluate all potential etiologies of lactic acidosis before deciding on management. Consider MILA when a patient presents with renal failure and severe lactic acidosis, and treat aggressively with emergent dialysis as indicated.

DIAGNOSING EHLERS-DANLOS SYNDROME IN THE AGE OF IN-HOME GENETIC TESTING

Cameron Bell; Lucy Guerra; Asa Oxner. University of South Florida, Tampa, FL. (Control ID #3184484)

LEARNING OBJECTIVE #1: Assess patients for Ehlers-Danlos Syndrome using the Beighton Scoring System.

LEARNING OBJECTIVE #2: Recognize the existence of in-home genetic testing, its role in patient care, and its limitations in diagnosing disease.

CASE: A 47 year old female with no past medical history presented for evaluation of joint hypermobility. During yoga she noted a dislocation of her right shoulder and was concerned about a possible diagnosis of Ehlers-Danlos syndrome. She recalled joint hypermobility since birth as well as diagnosis of a cardiac murmur in her 20s. She also reported frequent bruising of her legs which led to her being removed from her home at age 9 over concerns of abuse. She reported similar symptoms in 3 out of 4 of her children. On physical exam, patient scored a 7/9 on the Beighton hypermobility score but was otherwise unremarkable. In home genetic testing showed collagen mutations. She was referred to a geneticist and rheumatology for further workup.

IMPACT/DISCUSSION: This case highlights the importance of considering Ehlers-Danlos syndrome and the use of the Beighton hypermobility scale in the differential diagnosis of patients with joint hypermobility and dislocations not expected by the level of activity. Patients are also increasingly turning to in-home genetic testing which has unproven benefit for clinical practice, causing providers to navigate discussion of results. Patients presenting with joint hypermobility, skin hyperextensibility and atypical joint dislocations should be evaluated for a diagnosis of Ehlers-Danlos Syndrome. Bowen et. al discuss the Beighton hypermobility score which examines hand, elbow, knee and spine mobility as a tool to evaluate patients for joint hypermobility with a score of 5/9 or greater suggestive of the diagnosis. Patients suspected of having Ehlers-Danlos based on the hypermobility score and clinical symptoms should be referred for confirmatory genetic testing, as well as a multidisciplinary team consisting of a Rheumatologist and Sport's Medicine physician. In today's healthcare environment, in home genetic testing is increasingly prevalent which provides unique challenges in the physician patient relationship. In an editorial by Burke et. al in 2016, it was suggested that among patients who discussed their results at appointments, many patients were unsatisfied with the interaction, 1/5 saying they were not satisfied at all. These tests should be used to assist with diagnosis but should not replace formal evaluation by a geneticist or clinical judgement.

CONCLUSION: The Beighton hypermobility score is a valuable clinical tool for evaluating joint hypermobility in the diagnosis of Ehlers-Danlos Syndrome. Internists should also be aware of patients' increased use of in-home genetic testing and work with patients to navigate their results.

DIAGNOSING MYASTHENIA GRAVIS FROM ISOLATED RESPIRATORY FAILURE

Anthony Higinbotham; Hongyang Pi; Kaveh Moghboli. University of Pittsburgh Medical Center, Pittsburgh, PA. (Control ID #3185767)

LEARNING OBJECTIVE #1: Recognize respiratory failure as a potential manifestation of neuromuscular disease.

CASE: 78 year old female with a history of hypertension on atenolol who presented initially to an outside hospital for ptosis and respiratory insufficiency requiring intubation prior to transfer. Stroke workup was unrevealing. Initial labs on arrival to our hospital were notable for a normal comprehensive metabolic panel, a troponin-I elevation of 1.25 (peak 3.65) and lactate 6.5 mmol/L. EKG and chest radiograph did not show any abnormalities. Patient was quickly weaned off sedation and was noted to follow commands. Physical examination was normal except for 4/5 strength of her upper extremities and bilateral hip flexors. Family added that patient was recently diagnosed with polymyalgia rheumatica for progressive muscle weakness and had received a short course of steroids. She passed a spontaneous breathing trial, met all criteria for extubation, and was subsequently extubated. Within 30 minutes of her initial extubation, she was noted to be hypertensive and tachycardia, an episode of apnea was noted, and she became hypoxemic, ultimately requiring emergent re-intubation. Forty eight hours later, she again passed a spontaneous breathing trial via T-piece and met all criteria for extubation. She was extubated. A few hours later, she was noted to have minimal respiratory effort, neck weakness with inability to lift her head against gravity, and a depressed mental status. Blood work confirmed hypopneic respiratory failure requiring re-intubation. Point of care ultrasound revealed an akinetic left hemidiaphragm. A neuromuscular serologies and EMG confirmed a diagnosis of myasthenia gravis. Patient underwent treatment with IVIG and was able to be extubated successfully.

IMPACT/DISCUSSION: Myasthenia gravis (MG) is the most common neuromuscular disorder characterized primarily by weakness and fatigability of ocular, bulbar, limb and respiratory muscles. These symptoms are due to autoimmune inhibition or destruction of the muscle fiber nicotinic acetylcholine receptor at the neuromuscular junction by autoantibodies. Certain medications may precipitate or exacerbate an episode of MG crisis: in this patient's case - atenolol, magnesium, and, as a possible paradoxical effect, corticosteroids. Involvement of the respiratory muscles is the most serious form of a MG crisis and can be life-threatening. In many patients, manifestations in the early stages of respiratory insufficiency could be transient and remit spontaneously. However the symptoms typically get worse and more persistent without treatment. In intubated patients, evaluation of diaphragmatic function can provide helpful information with regards to the appropriateness of extubation.

CONCLUSION: Respiratory failure could be a potential manifestation of neuromuscular disease. Avoid the medications that could exacerbate myasthenia gravis crisis.

DIAGNOSTIC APPROACH TO ACUTE RHEUMATIC FEVER PRESENTING AS POLYARTHRITIS

Julien Feghaly; Ariana Mooradian. St. Louis University Hospital, St. Louis, MO. (Control ID #3162790)

LEARNING OBJECTIVE #1: Diagnose acute rheumatic fever using the Jones criteria.

LEARNING OBJECTIVE #2: Review the utility of throat culture, rapid streptococcal antigen test and streptococcal antibody titers in the diagnosis of ARF.

CASE: A 52-year-old male with a previous medical history significant for gout, hypertension, hyperlipidemia and alcohol abuse, presented with 9-day history of gradually worsening polyarthritis. He was treated with indomethacin & colchicine for a possible gout flare, with no improvement. Additionally, receiving vancomycin for concern of septic arthritis, having had an elevated temperature of 101.9 °F and an elevated ESR & CRP. The patient went on to report history of recent illness following contact with relative having Group-A Streptococcus pharyngitis. Further investigation revealed an elevated ASO titer & normal anti-DNase B titer. A diagnosis of acute rheumatic fever was made, as the patient fulfilled the

Jones criteria with 1 major feature (Polyarthritis) and 2 minor features (documented fever and an elevated ESR & CRP). He was started on a 10-day course of oral penicillin V. Transthoracic echocardiography was performed showing no abnormalities nor any signs of carditis.

IMPACT/DISCUSSION: The diagnosis of acute rheumatic fever is guided by the modified Jones criteria. The criteria require the presence of a preceding GAS infection, in addition to the presence of two major criteria or one major with two minor criteria. Further, supported by evidence of a GAS infection by throat culture, rapid streptococcal antigen test, or elevated or rising streptococcal antibody titers. Throat culture & rapid antigen testing tend to be inconclusive as they do not differentiate between chronic pharyngeal colonization and ARF, thus serologic evidence of elevated or rising anti-streptolysin O (ASO) and anti-DNase B titers is needed. ASO has been the most widely used antibody test for GAS, detected in more than 80% of patient with GAS pharyngitis, having a sensitivity of 72.7% & specificity of 93.2% in post-streptococcal disease phase. Comparatively, anti-DNase B titer measurements had a lower sensitivity of 70.5 % & a similar specificity to ASO of 93.2%. Yet, the greatest advantage of antibody testing has been the combined measurement of ASO and anti-DNase B titers which exhibits a higher sensitivity of 95.5% in identifying post-streptococcal disease; at the cost of a lower specificity 88.6%. Once the diagnosis has been confirmed, further diagnostic testing is required to rule out carditis. This promptly performed by clinical examination, auscultating for new murmurs, and echocardiography, assessing for mitral or aortic regurgitation.

CONCLUSION: ARF may have varying presentation and needs to be considered when assessing polyarthritis. The combined measurement of ASO & anti-DNase B titers demonstrates the highest sensitivity in the diagnosis of GAS. Cardiac examination followed by echocardiography is highly recommended in ARF.

DIAGNOSTIC BIAS IN ACUTE KIDNEY INJURY: A CASE OF MPO-ANCA VASCULITIS ASSOCIATED WITH MULTIPLE MYELOMA

Jammie Law; Eugeniya Golub; Bibi Ayesha. Montefiore Medical Center, Bronx, NY. (Control ID #3185768)

LEARNING OBJECTIVE #1: Recognize diagnostic bias when working up worsening kidney injury in patients with multiple myeloma.

LEARNING OBJECTIVE #2: Illustrate an uncommon renal manifestation of multiple myeloma associated with MPO-ANCA vasculitis.

CASE: A 70 year old female presented with acute kidney injury (AKI). She had a past medical history significant for hypertension and multiple myeloma. Two months prior, urine protein/creatinine was significant for 1.2 grams of protein with a serum creatinine of 1.3 mg/dL. Labs showed a normocytic anemia, thrombocytosis, and elevated ESR. SPEP notable for monoclonal protein detected in gamma region-IgM Kappa M. Urine microscopy was notable for 2 RBC casts. On follow-up, patient had a serum creatinine of 2.1 mg/dL. Further laboratory workup was significant for a MPO-ANCA (>8 AI) and low C4. Given unclear diagnosis of AKI secondary to multiple myeloma versus MPO-ANCA vasculitis, renal biopsy was obtained. Renal biopsy showed pauci-immune focal segmental glomerulosclerosis consistent with ANCA-associated glomerulonephritis without evidence of plasma cell disease or granulomas. HIV, hepatitis, cryoglobulin, and abdominal fat pad biopsy for amyloid workup was negative. Given underlying hematologic malignancy, patient was determined to have an ANCA-vasculitis associated with multiple myeloma.

IMPACT/DISCUSSION: It is important for general internists to recognize diagnostic bias when working up worsening AKI in patients with multiple myeloma.

CONCLUSION: Multiple myeloma is a malignant clonal plasma cell proliferation commonly diagnosed in elderly adults. It classically presents with bone pain and lytic lesions, hypercalcemia, anemia, elevated serum protein usually IgG or IgA, and renal involvement due to free light chain

excretion (Bence Jones Protein). While renal complications of multiple myeloma are well known, the significance of red blood cell casts in this patient's earlier presentation should have prompted a full workup for suspected glomerulonephritis. An accurate diagnosis with renal biopsy and serologic testing is especially important to prevent worsening kidney injury, which can progress to ESRD within months. Serologic workup includes complement levels, ANCA, anti-GBM, ANA, anti-dsDNA, hepatitis, and SPEP. Interestingly, our patient had a positive MPO-ANCA and subsequent renal biopsy was consistent with a MPO-ANCA vasculitis. There is a possible immunogenic relationship that has been observed in serum between monoclonal gammopathies and ANCA. The presence of monoclonal immunoglobulins, through possible neutrophil activity, may be causal in the pathogenesis of vasculitis. However, there are few reports of ANCA-vasculitis coexisting with multiple myeloma and is unlikely to be encountered by the general internist. Thus, we present a case that demonstrates the importance of recognizing diagnostic bias and looking for disconfirmatory evidence in patients with multiple myeloma and worsening kidney injury.

DIAGNOSTIC MIS-CU(E): A MISSED DIAGNOSIS OF COPPER DEFICIENCY

Kayla Correia-Staudt¹; Deepa R. Nandiwada². ¹Hospital of the University of Pennsylvania, Philadelphia, PA; ²University of Pennsylvania, Ardmore, PA. (Control ID #3185681)

LEARNING OBJECTIVE #1: Identify clinical manifestations of copper deficiency and highlight its place in a differential for neurologic and hematologic abnormalities.

LEARNING OBJECTIVE #2: Recognize the importance of a thorough review of non-prescribed supplements and hygiene products a patient is using.

CASE: A 55 year-old woman with recently diagnosed myelodysplastic syndrome (MDS) on azacitidine presented to our hospital with pancytopenia, paresthesias, and gait dysfunction. Prior to this presentation, she was admitted to another hospital for similar symptoms where MRI revealed a thoracic dorsal cord lesion, felt to be congenital. She was given intravenous immunoglobulin (IVIG) and discharged. Following, her gait dysfunction progressed, prompting presentation to our hospital. Her exam was notable for impaired proprioception and sensation of the lower extremities, which was felt to represent a posterior cord syndrome. Laboratory studies revealed stable pancytopenia; normal vitamin B12, folate, and vitamin E levels; negative HIV testing and undetectable rapid plasma reagins titers. Further testing revealed serum copper <10 ug/dL and elevated zinc levels (181 ug/dL, normal 60-120). On further history, the patient endorsed years use of a high-zinc "immune-boosting" supplement and several months use of a zinc-containing dental paste for a loose crown. She was diagnosed with copper deficiency due to excessive zinc intake. Zinc products were stopped and she was started on copper supplementation with improvement in pancytopenia and neurologic symptoms.

IMPACT/DISCUSSION: Clinical manifestations of copper deficiency are somewhat similar to those of B12 deficiency. It most commonly presents as anemia and leukopenia with neurologic manifestations, including dorsal column myelopathy (sensory ataxia) and sensory peripheral neuropathy (with associated paresthesia). However, as in this patient, copper deficiency can mimic MDS, with pancytopenia, clonal abnormalities, and ringed sideroblasts on bone marrow biopsy. It is caused by malabsorption (most commonly post-gastric bypass) or excessive zinc intake (which inhibits intestinal absorption), and though rare, it is increasingly recognized following gastric bypass in those without adequate supplementation. In this case, the diagnosis was initially missed likely in part due to clinician unfamiliarity with this rare syndrome and potentially due to unidentified use of zinc-containing products which were only discovered with direct questioning. This case highlights the importance of a thorough supplement and dental product review, and also illustrates the need to question whether new diagnoses have alternative explanations.

CONCLUSION: -Copper deficiency should be considered in the differential diagnosis for cytopenias and neurologic symptoms, particularly in those at risk for malabsorption or with high zinc intake. -Supplements and dental products should be considered in a differential for unexplained symptoms, and a medication reconciliation should include these substances.

DIALYSIS DEPENDENT RENAL FAILURE AFTER HEALTH MOTIVATED DIETARY CHANGE IN A PATIENT WITH REMOTE BARIATRIC SURGERY

Karl Gubler²; Michael Odom²; Elena Lebduska³; Sandipani M. Sandilya¹.

¹United States Air Force, North Las Vegas, NV; ²United States Air Force, Nellis AFB, NV; ³University of Pittsburgh Medical Center, Denver, CO. (Control ID #3181385)

LEARNING OBJECTIVE #1: Assess the bariatric patient for nutritional needs and facilitate adherence to postoperative recommendations.

LEARNING OBJECTIVE #2: Recognize potential complications of dietary nonadherence following bariatric surgery

CASE: An 81 year old female with hypertensive chronic kidney disease stage 3b (baseline creatinine 1.4 mg/dL) developed acute kidney injury (AKI) with creatinine 3.2 one week after starting losartan. She had undergone uncomplicated Roux en Y gastric bypass (RYGB) sixteen years prior. She reported several days of darker urine and loose green stool. Examination was unremarkable. Her BMI was 23. She had moderate proteinuria and a bland urinary sediment. Laboratory studies were otherwise unremarkable. Renal ultrasound showed structurally normal kidneys. Renal function declined despite hydration and she required three sessions of dialysis. Biopsy showed acute tubular necrosis secondary to oxalate nephropathy. Further history revealed recently increased consumption of oxalate rich vegetables like spinach and okra in an attempt to improve her diet. The patient was started on oral calcium carbonate and potassium citrate to promote dissolution of oxalate crystals. She also received dietary education on avoidance of oxalate rich foods. Her renal function recovered to baseline within three months.

IMPACT/DISCUSSION: Consumption of oxalate rich foods, high doses of vitamin C, and RYGB increase the risk of oxalate nephropathy. RYGB causes enteric hyperoxaluria via increased absorption, increased endogenous oxalate synthesis, concentrated urine, and altered gut flora. Treatment includes dietary modification to decrease exogenous oxalate, oral calcium to reduce enteric absorption, hydration to dilute and citrate supplements to alkalinize the urine. RYGB reversal has been reported to reverse hyperoxaluria and kidney failure refractory to medical management. There has been research on oxalate degrading bacteria in rat models as a potential future treatment. Our case demonstrates that significant complications can arise even years after bariatric surgery, ironically from changes most patients would expect to promote health. It also shows that complete recovery may occur with diet and medication.

CONCLUSION: The primary care provider (PCP) should be aware of the risks of both deficiencies and toxicities after bariatric surgery, as these can occur many years later when patients are no longer seen in bariatric clinics. The PCP should reinforce the need for dietary adherence, and follow guidelines on monitoring vitamin and mineral levels to provide thorough care for this ever growing population.

DIFFUSE CORONARY ARTERY ECTASIA: AN UNUSUAL CAUSE OF ST-ELEVATION MYOCARDIAL INFARCTION

Ann Wang; Vikram Brahmanandam. Montefiore Medical Center, Bronx, NY. (Control ID #3186244)

LEARNING OBJECTIVE #1: Recognize a relatively uncommon cardiac anatomy which increases the risk of myocardial infarction

LEARNING OBJECTIVE #2: Recognize the challenges in management of coronary artery ectasia

CASE: A 58 year old male with no significant medical history presented to the emergency department (ED) with acute onset substernal chest pain. An electrocardiogram (ECG) showed inferior ST-segment depressions, and cardiac troponins peaked at 1.05 ng/mL (normal 0.00-0.10 ng/mL). Cardiac catheterization revealed diffuse coronary artery ectasia (CAE), with marked dilation of the right coronary artery (RCA), left anterior descending (LAD), and left circumflex arteries. The ectatic vessels, especially the distal RCA, demonstrated slow flow. He otherwise had mild coronary artery disease. A transthoracic echocardiogram (TTE) showed normal function without wall motion abnormalities. The patient was started on warfarin and aspirin, as well as a beta blocker and high dose statin. Three months after discharge, he again felt severe substernal chest pain while walking and presented to the ED. ECG showed an inferior ST-segment myocardial infarction. Of note, his international normalized ratio (INR) was subtherapeutic. Cardiac catheterization again showed slow flow in the ectatic RCA without an intervenable lesion. He was then placed on triple therapy with clopidogrel, aspirin, and warfarin. He has remained on triple therapy and without further cardiac symptoms, now ten months after his initial presentation.

IMPACT/DISCUSSION: CAE is characterized by dilation of diffuse segment(s) of the coronary arteries to at least 1.5 times the normal diameter. CAE is typically asymptomatic and incidentally discovered during cardiac catheterization or other imaging, and the incidence has been reported to be between 0.3%-5%. The RCA is most commonly affected, followed by the LAD. The etiology is likely multifactorial. CAE is strongly associated with atherosclerotic disease, hypertension, and dyslipidemia. Connective tissue diseases, vasculitis, and iatrogenic vessel injury have also been implicated. Patients with CAE have a higher incidence of major adverse cardiac events (MACE), likely due to increased turbulent flow, stasis, and endothelial dysfunction in the ectatic vessels. In one study, patients who presented with myocardial infarction and were found to have CAE had a 3.25 fold greater risk of recurrent MACE after 49 months, compared to similar patients without CAE. Evidence to guide management of CAE is still scarce. One retrospective study has found that warfarin monotherapy significantly decreased adverse cardiac events in CAE patients compared to no anticoagulation. Another study showed that dual antiplatelet therapy halved the incidence of cardiac events in patients with CAE, compared to no anticoagulation.

CONCLUSION: Coronary artery ectasia is relatively uncommon. Patients with CAE are at greater risk for MACE and will likely benefit from anti-coagulation; however, further studies are needed to determine the optimal anticoagulation strategy.

DISSECTING A CASE OF CHEST PAIN

Deep Sangani; Aaron W. Sweeney. Tulane University School of Medicine, New Orleans, LA. (Control ID #3184095)

LEARNING OBJECTIVE #1: Recognize the clinical presentation of spontaneous coronary artery dissection

LEARNING OBJECTIVE #2: Review management of spontaneous coronary artery dissection

CASE: A 57-year-old woman presented with sudden onset, sharp chest pain across her entire chest with radiated down both arms. There was associated nausea, vomiting, and palpitations. She did not have any prior cardiac history. Her 36-year-old son had a myocardial infarction the previous year. Two-millimeter ST elevations were identified in multiple leads on the EKG and the patient was taken for cardiac catheterization. Coronary angiography did not reveal any evidence of obstructive coronary disease, though a dissection of the middle left anterior descending coronary artery was noted. Echocardiogram returned with an ejection fraction of 30-35% along with moderate septal hypokinesis. Approximately four hours into her hospital course, chest pain recurred with dynamic EKG changes and she underwent coronary artery bypass grafting.

IMPACT/DISCUSSION: Spontaneous coronary artery dissection (SCAD) is epicardial coronary artery dissection that is not associated with atherosclerosis, trauma, or iatrogenic causes. The primary mechanism that leads to myocardial injury is coronary artery obstruction secondary to a spontaneous formation of an intramural hematoma following disruption of the vessel wall or spontaneous hemorrhage arising from the vasa vasorum within the vessel wall. Middle aged women account for up to 95% of SCAD cases. For young women presenting with acute coronary syndrome, including those with pregnancy-related myocardial infarction, the prevalence of SCAD is 24%-35%. Additional risk factors for SCAD include fibromuscular dysplasia (FMD), connective tissue disorders, systemic inflammatory disorders, pregnancy, hormonal therapy, intense valsalva, and intracranial aneurysms. Presentation of SCAD mimics ACS with chest pain that radiates to the arms or neck, nausea, vomiting, and troponin elevation. Patients with SCAD are at risk of being incorrectly diagnosed due to their young age or lack of atherosclerotic risk factors. If SCAD is suspected, then coronary angiography should be performed to evaluate atherosclerotic lesions that could require intervention. There is a high rate of technical failure with PCI and lack of protective effect against future dissection events. Beta-blockers should be considered for patients who have LV dysfunction, arrhythmias, or hypertension. ACE inhibitors and ARBs are recommended. However, statins are not recommended unless the patient has guideline-based indications for primary prevention of atherosclerosis. Experts are divided about the use of anti-platelet and anti-coagulants.

CONCLUSION: SCAD should be considered in the differential diagnosis of acute chest pain, especially in a young female patient who lacks traditional atherosclerosis risk factors. It is important to distinguish SCAD from ACS as clinical management differs.

DISSECTING THE CAUSE OF ATRIAL FIBRILLATION: AN ATYPICAL PRESENTATION OF SPONTANEOUS CORONARY ARTERY DISSECTION

Pedro Covas¹; Talal S. Alzahrani². ¹George Washington University, Washington, DC; ²The George Washington University, Arlington, VA. (Control ID #3159762)

LEARNING OBJECTIVE #1: Recognizing atrial fibrillation as an uncommon presenting symptom of a spontaneous coronary artery dissection.

CASE: A 46-year-old woman with a history of hypertension presented with acute substernal chest pain and an episode of emesis. EKG done by paramedics demonstrated atrial fibrillation with a rapid ventricular response and aberrancy (EKG difficult to interpret as limb lead reversal is possible), which spontaneously resolved. Troponin upon arrival was 0.10 ng/ml, which was presumed to be secondary to her atrial fibrillation. However, her repeated troponin was peaked at 10.5 ng/ml. Serial EKGs showed normal sinus rhythm with prolonged QTc and few fusion beats without ST-segment changes. Echocardiogram showed anterolateral and apical wall motion abnormalities, and cardiac catheterization revealed spontaneous coronary artery dissection (SCAD). Renal ultrasound showed normal kidneys without any evidence of renal artery stenosis, a sign of fibromuscular dysplasia. The patient was discharged with optimal medical therapy.

IMPACT/DISCUSSION: SCAD is a form of non-atherosclerotic myocardial infarction, that commonly affects young women. Chest pain, sudden cardiac death (SCD), STEMI, NSTEMI with or without EKG changes are common presentations of SCAD, but arrhythmias are relatively uncommon and sparsely noted in the literature. Although ACS can cause arrhythmias leading to SCD, atrial fibrillation has never been reported in young women with SCAD. Treatment involves optimized medical therapy, but PCI has been performed for persistent symptoms. SCAD is highly associated with fibromuscular dysplasia and connective tissue disorders, and proper screening should be performed.

CONCLUSION: This case highlights the importance of early recognition of atypical presentations of SCAD, especially atrial fibrillation, as this can lead to immediate medical therapy and interventions.

DISSEMINATED BLASTOMYCOSIS IN AN IMMUNOCOMPETENT PATIENT

Anjeanette Mendez¹; Kristen Corrao¹; Joyce Okendo¹; Mirza Baig¹; Pinky Jha²; Sanjay Bhandari¹. ¹Medical College of Wisconsin, Milwaukee, WI; ²medical college of wisconsin, Milwaukee, WI. (Control ID #3186117)

LEARNING OBJECTIVE #1: Recognize an interesting and unusual case of disseminated blastomycosis in an immunocompetent male patient.

LEARNING OBJECTIVE #2: Review the diagnosis and management of disseminated blastomycosis.

CASE: A 27 year-old incarcerated male presented with a 2-month duration of hemoptysis and cough. He denied any symptoms of weight loss, night sweats or fatigue. He denied any sick contact and any travel prior to incarceration. He also complained of bilateral headache and neck pain along with light sensitivity. Physical examination was significant for cutaneous lesions on his forehead, left ear, bilateral cheeks and right forearm. He was initially started on intravenous vancomycin and ceftriaxone for possible pneumonia. Due to concern for pulmonary tuberculosis (TB), patient was placed in isolation until further work-up could be done. Infectious disease and Dermatology were consulted. Computed tomography (CT) of the chest was obtained along with lumbar puncture, sputum cultures and skin biopsy. CT chest revealed a right lower lobe consolidative opacity with areas of cavitation as well as bilateral diffuse centrilobular nodules. TB was ruled out with negative sputum cultures x 3 and *QuantiFERON-TB Gold test*. HIV test was negative. Urine was positive for presence of Blastomyces antigen and sputum cultures were positive for Blastomyces. CSF studies showed high protein (170 mg/dL), low glucose (21 mg/dL), and elevated leucocyte count (371/microL) consistent with central nervous system (CNS) involvement. Skin sample under direct microscopy revealed broad based budding yeast. Tissue punch biopsy from left ear lesion was positive for round yeast forms consistent with *Blastomyces dermatitidis*. Antibiotics were discontinued, and he was started on Amphotericin B intravenously to complete a 4-week course followed by a 12-month course of voriconazole.

IMPACT/DISCUSSION: Blastomycosis is treated with an oral azole in mild to moderate disease or Amphotericin B in more severe presentations. In our patient who not only had pulmonary and cutaneous but also possible CNS involvement, the treatment of choice is Amphotericin B. He was initially on antibiotics which were discontinued once the appropriate diagnosis was made and was started on Amphotericin B. This case describes a rare presentation of disseminated blastomycosis in an immunocompetent patient and can help increase its awareness among clinicians.

CONCLUSION: Disseminated blastomycosis is an uncommon fungal infection especially in immunocompetent hosts. Our case highlights the need for a high index of suspicion for the diagnosis of blastomycosis regardless of the immunological status of a patient, and the importance of prompt diagnosis and treatment with the appropriate antifungal.

DISSEMINATED CRYPTOCOCCUS IN MYASTHENIA GRAVIS

Neil Evans; Amitabh Singh; Soumya Chatterjee. Saint Louis University, Saint Louis, MO. (Control ID #3186140)

LEARNING OBJECTIVE #1: Delineate risk factors for Cryptococcus neoformans

LEARNING OBJECTIVE #2: Diagnosis Cryptococcus neoformans

CASE: 70 year old male farmer from Illinois with a past medical history of myasthenia gravis treated with 15 milligrams of prednisone daily and Cellcept 500 milligrams twice daily. He was transferred to the hospital

after recent biopsy of necrotic skin lesion revealed Cryptococcus neoformans. Notably, he also presented with fatigue and new productive cough and dyspnea in addition to the skin lesion. Serum Cryptococcal antigen titer was 1:10. Subsequent lumbar puncture was negative for cryptococcal antigen and CT head was also negative. Due to persistent dyspnea and cough, a CT chest was obtained. CT revealed a new 2 x 2 cm nodule. Concerned for disseminated Cryptococcal infection in the setting of chronic immunosuppression, he was treated with flucytosine and amphotericin B for 3 weeks. After treatment, the skin lesion resolved and repeat CT chest showed decreased size of the pulmonary lesion to 1.2 x 1.5 cm. He was transitioned to oral fluconazole 400 mg for 8 weeks followed by fluconazole 200 mg for at least a year.

IMPACT/DISCUSSION: Cryptococcus neoformans has worldwide distribution. Cryptococcus neoformans is an invasive fungal infection that is prevalent in immunocompromised patients and represents an important cause of morbidity and mortality in this population. It's most common presentation is cryptococcal meningitis (15% of all AIDS-related deaths globally). It can also present as pulmonary disease, skin, lymph node, and bone disease. Patients at risk include: AIDS with CD4 counts < 200 cells/ μ L, patients on 20 milligrams of prednisone for at least 2 weeks, history of organ transplantation, malignancy, and liver disease. Screening for cryptococcal antigen should be driven by symptoms in the context of chronic immunosuppression. For patients with respiratory symptoms, cryptococcal antigen is a good first test. Symptoms concerning for meningitis like neurological deficits, severe headaches, or neck stiffness should also prompt a lumbar puncture. Also, if a high serum cryptococcal antigen titer (>1:512) is found, the high infection burden increases the risk for extrapulmonary spread and seeding of the central nervous system and also requires a lumbar puncture. Look for high opening pressure, positive culture, or elevated cryptococcal antigen titer.

CONCLUSION: Cryptococcus neoformans infection can present in several different ways, and is an important pathogen to consider in at risk populations (chronic immunosuppressed state). Notably, patients can present with more than one manifestation of cryptococcal disease. Cryptococcal disease, if progresses to meningitis, is uniformly fatal, but shows good response to treatment with the appropriate induction regimen of amphotericin and flucytosine, and maintenance therapy with fluconazole.

DISSEMINATED HISTOPLASMOSIS AS AN IMPORTANT DIFFERENTIAL TO CONSIDER IN PATIENTS PRESENTING WITH HYPERCALCEMIA

Jacob Burch; Lawrenshey Charles; Emir Kurtovic; Jason Liu; Sonya Gupta. Sparrow Hospital, Lansing, MI. (Control ID #3185825)

LEARNING OBJECTIVE #1: Recognize uncommon presentations of disseminated histoplasmosis

LEARNING OBJECTIVE #2: Distinguish various etiologies of hypercalcemia

CASE: JM is a 62-year-old female with history of rheumatoid arthritis, on etanercept and methotrexate, who presented to the hospital for persistent RLL pneumonia, confusion, weight loss, and weakness. Examination showed jaundice, dry mucosal membranes, and generalized abdominal pain. She was found to have hypercalcemia with corrected value of 17.8, vitamin D 1,25 elevated at 157, PTH 13.4, PTHrp 0.5, pancytopenia, elevated transaminases, and AKI with Cr of 2.58. CT revealed mild mediastinal lymphadenopathy and persistent infiltrates in RLL. Patient was admitted and worked up for possible infectious versus malignant etiology. She was started on broad-spectrum antibiotics, later discontinued with negative cultures. ACE level elevated at 170. SPEP, direct coombs, IFE and bence jones protein were negative. Hypercalcemia improved following IV fluids, furosemide, calcitonin, and pamidronate. Bone marrow biopsy was performed due to concern for possible lymphoma and demonstrated disseminated histoplasmosis. Fungal studies resulted with fungal Ab negative, urine histoplasma Ag positive, and fungal precipitins

positive for histoplasma. Patient was started on oral itraconazole. Following improvement in clinical status, she was discharged to a long-term acute care facility with plans for close follow-up.

IMPACT/DISCUSSION: Histoplasmosis is the most common endemic mycosis to cause hospitalization in the US. It is prevalent along the Ohio and Mississippi River Valleys. It can have dramatic clinical manifestations, including flu-like illness to severe and progressive disseminated infections. Individuals at high risk of infection include the immunocompromised, those at extremes of age, or patients with unusually heavy exposure. Infections can involve multiple organ systems resulting in adrenal insufficiency, hepatosplenomegaly, pancytopenia, GI tract ulcers, skin and CNS lesions, and lung pathology. Radiographic studies typically show patchy or nodular focal infiltrates and mediastinal or hilar lymphadenopathy. Disseminated histoplasmosis presenting with hypercalcemia has been described in the literature, but is considered a rare manifestation. If left untreated mortality is as high as 80%, reduced to 25% with treatment. As evident in our case, Histoplasmosis is often initially mistaken as other infection, inflammatory disease, or malignancy. Atypical presentations can delay diagnosis and lead to poor outcome. Our case demonstrates the importance of keeping a broad differential in patients presenting with hypercalcemia.

CONCLUSION: Disseminated histoplasmosis can present with many features similar to malignancy. Physicians should have a high index of suspicion for granulomatous disease, such as histoplasmosis, when encountering patients with hypercalcemia. Unusual pathogens should be suspected in immunocompromised patients.

DISSEMINATED INTRAVASCULAR COAGULATION AS INITIAL PRESENTATION OF METASTATIC PROSTATE CANCER

Kavita Agrawal; Nirav Agrawal. Overlook Medical Center, Summit, NJ. (Control ID #3162850)

LEARNING OBJECTIVE #1: Diagnose disseminated intravascular coagulation (DIC) based on laboratory findings.

LEARNING OBJECTIVE #2: Understand pathophysiology of DIC in prostate cancer. Treatment of prostate cancer induced DIC

CASE: A 70-year-old male presented with hematuria and bruising of arms and legs for 3 days. He complained of 40 pounds weight loss over the last 4 months. Initial blood tests showed prothrombin time of 25.1 seconds, INR 2.5, partial thromboplastin time 43.9 seconds, fibrinogen 60 mg/dL, fibrin degradation products >20 ug/ml and platelets 88000/nL. The results were consistent with DIC. Patient was seen on the outpatient basis for complaints of urinary frequency and hesitancy 6 months prior to this admission. During this time, prostate specific antigen (PSA) was found to be elevated at 241 ug/dL. However, patient was lost to follow up. On this admission, he had worsening PSA of 942 ug/L. Computed tomography of abdomen pelvis showed enlarged prostate with mass effect on the bladder base, left side hydronephrosis and numerous enlarged pelvic lymph nodes. Bone scan of the whole body showed increased sclerosis of L3 vertebral body suggestive of osseous lesions. There was a concern for metastatic prostate cancer inducing DIC. He received fresh frozen plasma and cryoglobulin. He was started on Bicalutamide and leuprolide as inpatient pending pathologic diagnosis. Patient responded well to the therapy and labs were improving. The patient refused prostate biopsy. So, bone marrow biopsy was performed which revealed metastatic prostate adenocarcinoma. Our case highlights DIC as an initial manifestation of prostate cancer which is unusual.

IMPACT/DISCUSSION: DIC is a pathological systemic condition which occurs due to widespread activation of clotting factors causing bleeding and thrombosis. DIC does not occur in isolation. It is crucial to search for underlying secondary causes propagating DIC. This includes sepsis, trauma, pre-eclampsia, malignancies, acute hemolytic transfusion reaction and others. It is important to search for malignancies when there is no apparent underlying cause. Among malignancies, DIC is more commonly associated with acute promyelocytic leukemia, brain tumor

and mucinous tumors such as ovarian, pancreatic and gastric. Our patient had prostate cancer induced DIC. The pathophysiology involves release of polyphosphate containing protasomes from prostate gland which activates Factor XII leading to DIC. Management should focus on supportive measures to correct the coagulopathy and treatment of underlying cause. Our patient received anti-androgen therapy bicalutamide and leuprolide with improvement in PSA and DIC.

CONCLUSION: DIC can be an initial manifestation of underlying prostate cancer. It is important to monitor the patients with metastatic prostate cancer for signs and symptoms of development of DIC such as bleeding or low platelet counts. The management of DIC must be to control coagulopathy with supportive measures (such as platelet transfusion, cryoglobulin) and treatment of underlying cause.

DISTINGUISHING BETWEEN ERYTHEMA MULTIFORME MAJOR AND SEVENS JOHNSON SYNDROME: A DIAGNOSTIC CHALLENGE

Amali Gunawardana^{1, 2}; Ribka Ayama¹; Mary Maiberger¹. ¹Washington DC VA Medical Center, Washington DC, DC; ²George Washington University Hospital, Washington, DC. (Control ID #3184120)

LEARNING OBJECTIVE #1: Recognize the clinical distinction between Erythema Multiforme Major (EMM) and Stevens-Johnson Syndrome (SJS)

LEARNING OBJECTIVE #2: Recognize the difference in morbidity and mortality associated with EMM vs. SJS

CASE: A 62-year-old hospitalized male complained of a burning, tender blister on his upper lip. Three days prior, he was started on vancomycin and ertapenem for urinary tract infection and osteomyelitis though after, ertapenem was changed to meropenem for persistent fevers. Acyclovir was started for suspected herpes infection, but his lesions progressed. Dermatology evaluated the patient and noted multiple superficial ulcerations and erosions involving the upper and lower lips, buccal mucosa as well as thin fissuring of the lower lip. Oral examination revealed grayish-white mucosal desquamation of the hard palate. In addition, he had focal erythematous, dusty plaques scattered over several digits on both hands. There was no ocular or genital involvement. Patient declined a skin biopsy. A clinical diagnosis of EMM was made, and vancomycin and meropenem were discontinued. Lesions slowly resolved and patient completed treatment course with clindamycin and aztreonam.

IMPACT/DISCUSSION: First, drug-induced EMM is an uncommon variant. Second, to our knowledge, there exist no cases of vancomycin or carbapenem induced EMM reported in the literature. Lastly, in early stages, severe EMM and SJS can be confused, though early clinical distinction is critical as management strategies vary, and SJS is associated with a higher morbidity and mortality.

CONCLUSION: EMM is a mucocutaneous eruption characterized by targetoid lesions in an acral and mucosal distribution, categorized into two subtypes (major and minor) based on the severity and number of mucosal sites involved. Most commonly caused by infections, such as herpes simplex virus infection and mycoplasma pneumoniae, it is less commonly triggered by medications such as sulfonamides, NSAIDs, and anticonvulsants. EMM is a distinct clinical syndrome from SJS/toxic epidermal necrolysis (TEN) which are more severe desquamating mucocutaneous drug reactions. SJS and TEN are often drug induced reactions. The degree of mucosal involvement is typically limited to 1-2% of body surface area in EMM, up to 10% in SJS and greater than 30% in TEN. SJS is more likely associated with lesions starting on trunk and spreading distally in contrast to EMM, and lesions appear more like atypical targetoid macules or purpuric papules. SJS/ TEN patients are more likely to have fever, skin detachment, and ocular manifestations and require treatment with immunosuppressive. EMM is a clinical diagnosis, although biopsy can support clinical findings and help exclude other causes. EMM is usually self-limited and resolves in 3-5 weeks, though can reoccur.

DOCTOR! MY EYES?

Nooraldin Merza¹; Assad Mohammedzein¹; Nibras Talib-mamury¹; James ". Walker²; Karen Cutts¹. ¹Texas Tech University Health Science Center, Amarillo, TX; ²Texas Tech, Amarillo, TX. (Control ID #3147541)

LEARNING OBJECTIVE #1: Recognize Miller Fisher Syndrome (MFS) as a variant of Guillain-Barre (GBS)

LEARNING OBJECTIVE #2: Maintain low threshold to perform lumbar puncture in a young patient with unusual neurological presentation

CASE: A 49-year-old male with no significant medical history presented with sudden onset drooping of the left eyelid and diplopia looking into the right. He was recently treated for sinusitis with antibiotic. He was seen a week prior with upper and lower extremity numbness and unsteady gait, CT head was unremarkable, his symptoms improved but he was still using a cane for support. He denied any focal weakness or incontinence. He is married, works in foundation repair, and denies recent travel or tick bite. Vital signs were normal. He had left partial ptosis. Left eye was directed downward and outward and unable to adduct. Left eye pupillary reflex was intact. Other cranial nerves were normal. Had normal power and sensation, no cerebellar signs, absent deep tendon reflexes and slightly unsteady gait with inability to perform tiptoe walk. Romberg sign was negative. Laboratory workup was unremarkable. MRI showed no demyelinating lesion. Lumbar puncture showed normal cell count with total protein of 157 mg/dl (Ref. Range 15-45). MFS was suspected, the patient was started on intravenous immunoglobulin for 4 consecutive days, with remarkable improvement in eye movement noted by the time of discharge.

IMPACT/DISCUSSION: MFS is a variant of GBS, characterized by the triad of ophthalmoplegia, ataxia and areflexia. Incomplete forms with 2 out of the three features do exist. CSF is often diagnostic with the characteristic cytoalbuminologic dissociation. Antibodies against GQ1b (a ganglioside component of nerve) are present in 85 to 90 % of patients. Most of the patients do recover, with a mean recovery onset at 10 weeks. Immunomodulatory treatment has been used to hasten recovery. Intravenous immunoglobulin, as used in our patient, have proved equally effective to plasma exchange. The initial presentation of our patient was a bit challenging, especially with normal motor function and reflexes. Gait instability and recent upper respiratory symptoms may have misled to vestibular neuritis as a probable cause. MFS as the likely diagnosis was not apparent until after he was readmitted with partial third nerve palsy and areflexia.

CONCLUSION: This case illustrates how important the clinical judgment in assessing someone who presents with complex neurological complaints. In young patients like ours, it helps to maintain a low threshold to perform lumbar puncture and CSF analysis whenever there is uncertainty about the diagnosis.

DON'T FORGET THE STEROIDS! MANAGEMENT OF A RARE ETIOLOGY OF PERICARDIAL EFFUSION

Christopher Lee¹; Henry Bergquist¹; Stefan Nguyen¹; Sumit Patel¹; Harveen Bergquist²; Enrique Ostrzega¹. ¹University of Southern California, La Crescenta, CA; ²University of Southern California, Los Angeles, CA. (Control ID #3183748)

LEARNING OBJECTIVE #1: Recognize a rare etiology of pericardial effusions and possible treatment modalities

CASE: A 65-year-old male with a history of hypertension presented with 2 weeks of shortness of breath and dyspnea on exertion along with orthopnea and a dry cough. He denied any chest pain, weight loss, fevers, or night sweats. On examination, vital signs were stable and he was saturating well on room air. He had jugular venous distension, distant heart sounds, and lower extremity edema. Laboratory values were within normal with the exception of alkaline phosphatase 558 U/L, AST 137 U/L, ALT 88 U/L, T Bili 1.4 mg/dL, D Bili 0.7 mg/dL, and a mildly elevated pro-BNP to 804 pg/ml. HIV and hepatitis panel was negative.

Electrocardiogram revealed normal sinus rhythm with low voltages on the limb leads and chest x-ray showed cardiomegaly without evidence of pulmonary edema. Transthoracic echocardiogram showed a large circumferential pericardial effusion measuring 3.3 cm with early tamponade physiology. Right heart catheterization revealed elevated right and left-sided pressures (right atrial mean 17, right ventricular pressure 43/13, right ventricular end-diastolic pressure 17, pulmonary artery pressure 42/23, pulmonary capillary wedge pressure 22) with a pericardial pressure of 13 mmHg. Pericardiocentesis was performed with removal of 700 cc of serous fluid, resulting in improvement of filling pressures. Fluid analysis showed an exudative effusion with 2,035 nucleated cells with a 58% lymphocytic predominance and adenosine deaminase elevated to 118.1 U/L (normal less than 9.2 U/L). He was empirically treated with a four-drug anti-tuberculous regimen and subsequent pericardial fluid and induced-sputum cultures grew *Mycobacterium tuberculosis*. He was continued on anti-tuberculous antibiotics but unfortunately, eventually succumbed to his disease 9 months later.

IMPACT/DISCUSSION: Although a more common diagnosis in developing countries, tuberculous pericardial effusions are rare in developed countries and are usually limited to immunocompromised individuals. Treatment involves anti-tuberculous antibiotic therapy with possible adjunctive glucocorticoid use. Pericardiocentesis may also be performed. Studies regarding adjunctive glucocorticoid use have yielded mixed results but data from meta-analyses have shown that corticosteroids may reduce death from all causes in HIV-negative patients, which usually result from complications of pericardial constriction. However regardless of treatment, mortality rates remain high.

CONCLUSION: This case demonstrates the importance of having a broad differential when working up pericardial effusions. Although tuberculosis is a rare etiology of pericardial effusions, rapid recognition and intervention with antibiotics and corticosteroids are important in management.

DON'T MIND THE GAP

Yuliana Noah¹; Justine Phifer²; Sarah W. Baron². ¹Albert Einstein College of Medicine, Bronx, NY; ²Montefiore Medical Center, Bronx, NY. (Control ID #3159904)

LEARNING OBJECTIVE #1: Recognize various etiologies of an elevated globulin gap.

LEARNING OBJECTIVE #2: Assess appropriateness of SPEP (serum protein electrophoresis) and avoid unnecessary testing.

CASE: A 56-year-old woman with type 1 diabetes presented with altered mental status in diabetic ketoacidosis. On admission, her total protein was 12.1 g/dL with an elevated globulin gap of 8 g/dL (albumin level 4.1 g/dL), hemoglobin 13.5 g/dL and calcium 9.8 mg/dL. HIV and HCV tests were negative. Serum protein electrophoresis (SPEP) revealed an elevated M-Spike of 2.7 g/dL, IgG of 5860 mg/dL, and free light chain ratio of 232. Skeletal survey was negative for bony lesions. Subsequent labs demonstrated protein gap closure after DKA resolution. She was followed for a presumptive diagnosis of monoclonal gammopathy of undetermined significance.

IMPACT/DISCUSSION: The globulin gap is the calculated difference between total protein and albumin level. It accounts for serum proteins besides albumin, notably immunoglobulins. Etiologies of an elevated globulin gap include polyclonal gammopathies from liver disease, connective tissue disease, and chronic infection, and monoclonal gammopathies from plasma cell dyscrasias, like monoclonal gammopathy of undetermined significance (MGUS) and multiple myeloma. There are many etiologies of a globulin gap, not just malignancy, as evidenced by the closure of our patient's gap after resolution of her DKA. Ordering SPEP following any elevation of globulin gap is inefficient and expensive. At one institution, only 3% and 1% of 7,090 SPEP ordered resulted in diagnoses of MGUS and malignancies, respectively. A clinical decision rule was developed to increase the abnormal SPEP yield: 5 points for globulin gap >4.1 g/dL, 3 points for age 60, 2 points each for hemoglobin

<12 g/dL and male sex, and 1 point for eGFR <60 mL/min/1.73m². A score of 11+ corresponds to a specificity of >90% for abnormal SPEP, while a score of 0-5 had a negative predictive value of ~97%. Using this tool, our patient scored 6, making her borderline for whether SPEP was warranted. Monoclonal Gammopathy of Undetermined Significance (MGUS) is a premalignant condition with ~1% potential for progression. The clinical significance of MGUS diagnosis has come into question as disease progression is rarely recognized prior to serious complications despite close monitoring. One study found that a majority of malignant transformation identified were a result of symptomatic presentations outside of regularly scheduled follow-up. Thus, overtesting is not only expensive but also may lead to ineffective management.

CONCLUSION: • Clinical decision rules should be utilized to determine appropriateness of SPEP testing. • Overtesting leads to unnecessary diagnosis and follow-up of MGUS.

DOUBLE TROUBLE: SIMULTANEOUS CUTANEOUS LYMPHOMAS IN AN AIDS PATIENT

Albert Jang; Lucy Huo; Mahmoud Gaballa; Martha Mims. Baylor College of Medicine, Houston, TX. (Control ID #3139823)

LEARNING OBJECTIVE #1: Understand that patients with HIV may develop more than one type of lymphoma.

LEARNING OBJECTIVE #2: Recognize the need to biopsy a new or worsening cutaneous lesion in the setting of a diagnosed cutaneous malignancy.

CASE: A 41-year-old woman with AIDS (on HAART, CD4 count 154/mm³ with an undetectable viral load) and plasmablastic lymphoma (on EPOCH chemotherapy) presented following syncope. Two weeks ago, she noticed a new annular lesion with an ulcerating, necrotic center and an erythematous-violaceous border on her right thigh, similar to other lymphoma lesions on her legs. On admission, she reported four days of fever and increasing right thigh pain. Physical exam was notable for an overall cachectic and tearful appearance, with no hepatosplenomegaly and no palpable lymphadenopathy, and skin exam was significant for several scattered large patches of cutaneous lesions with granulation tissue and thick yellow exudate but no purulent drainage along the legs bilaterally. A CT scan showed an abscess underlying her new right thigh lesion. The patient underwent bilateral thigh wound incision and drainage, irrigation, and debridement, with biopsies taken. While waiting on pathology, the patient's chemotherapy regimen was changed to bortezomib followed by ICE regimen, presuming progression of the original plasmablastic lymphoma. Biopsy results revealed the new lesion was an extranodal NK/T-cell lymphoma, nasal type. Comparison to the original biopsy demonstrated a completely different immunohistochemical profile.

IMPACT/DISCUSSION: Patients with HIV have more than a 60-fold risk of developing non-Hodgkin's lymphoma. The increased risk is related to transforming properties of the retrovirus, immunosuppression, cytokine dysregulation, and opportunistic infections from lymphotrophic herpesviruses. Plasmablastic lymphoma, a rare and aggressive subtype of diffuse large B-cell lymphoma, comprises 2% of all HIV-related lymphomas. NK/T-cell lymphoma is a destructive and necrotic lymphoma, most commonly presenting in the nasal cavity but can manifest on the skin. Epstein-Barr virus plays a role in the pathogenesis of both lymphomas. No standard chemotherapy regimens exist for either lymphoma, and outcomes are often poor for both. In this case, bortezomib with ICE to treat the progressing plasmablastic lymphoma coincidentally became an option to treat the NK/T cell lymphoma, which is sensitive to platinum agents. When an HIV patient with lymphoma develops new lesions during treatment, it is important to biopsy the new lesion. Not only does an immunocompromised state place a patient with HIV at increased risk of infection and malignancy, chemotherapy may induce a new malignancy or transformation of the original malignancy.

CONCLUSION: Treating two separate but concurrent aggressive malignancies, each with no standardized regimen, is extremely difficult. Physicians should maintain a high index of suspicion when a new lesion appears different from the others, and obtaining a new biopsy if possible should be done quickly.

DRY GANGRENE AND ULCERS IN MULTIPLE DIGITS IN A PATIENT WITH TOBACCO USE

Anu Kurl¹; Robin Klein². ¹Emory University School of Medicine, Hampton, GA; ²Emory, Atlanta, GA. (Control ID #3185362)

LEARNING OBJECTIVE #1: Recognize the clinical presentation of thromboangiitis obliterans.

LEARNING OBJECTIVE #2: Discuss diagnosis of thromboangiitis obliterans and how to differentiate from other causes of digital ulcers

CASE: A 61 year-old female presents with three months of pain and discoloration of her left thumb. Three months ago, she injured the tip of her thumb after which it became progressively swollen, painful, discolored and ulcerated. She also noted ulceration of multiple other digits, which she attributed to prior injuries. Past medical history was notable for arthritis, tobacco use and cocaine use. Exam revealed dry gangrene of the left thumb, and digital ulcers on the left index finger, right fourth digit and fifth digit. Laboratory studies revealed a positive ANA and P-ANCA. Drug screen was positive for cocaine. MRI of her hand showed acroosteolysis with soft tissue swelling, necrosis, and diffuse swelling of the first digit with flexion contracture. LUE arteriogram was performed which showed digital corkscrewing consistent with thromboangiitis obliterans. She underwent amputation of her left first digit, was started on amlodipine, and underwent counseling to avoid cocaine and nicotine containing products. At one month follow up she described no new symptoms.

IMPACT/DISCUSSION: We present a case which illustrates the classic presentation of thromboangiitis obliterans including digit ulceration, smoking history and characteristic imaging findings. It is important to consider this complication of smoking in patients presenting with such findings. While initial presentation for distal necrosis can be broad and can include different types of vasculitis or infection, using different modes of diagnosis can be helpful. Our patient had a positive ANA which can be present in multiple rheumatologic conditions, but given her smoking history and other diagnostic modalities such as the arteriogram the diagnosis of thromboangiitis obliterans was more likely. Thromboangiitis obliterans (also known as Buerger's disease) is a segmental inflammatory disease that is usually seen in small to medium sized arteries and veins. In this condition there is inflammatory intraluminal thrombus formation with sparing of the vessel wall. It is classically seen in patients who use tobacco products. Patients may present with dry gangrene and digit ulceration as seen in our case. Other presentations may include claudication or Raynaud's phenomena. Diagnosis is difficult and often requires evaluation for and exclusion of other etiologies such as connective tissue disease or embolus. Certain angiogram patterns are diagnostic of thromboangiitis obliterans including a 'corkscrew' appearance of arteries and 'tree root' appearance from collateral vessels

CONCLUSION: Thromboangiitis obliterans is an inflammatory vessel disease that affects patients with a history of tobacco abuse. In this case, the tobacco history combined with digit ulceration and classic imaging findings aided the diagnosis of thromboangiitis obliterans.

DYSKERATOSIS CONGENITA MANIFESTING AS PULMONARY FIBROSIS: AN UNUSUAL PRESENTATION

Sehar Zulfiqar; Joshua Allgaier; Osama Kandalaft. Baystate Medical Center, Springfield, MA. (Control ID #3184535)

LEARNING OBJECTIVE #1: Describe the presentation and clinical course of isolated pulmonary fibrosis as a manifestation of Dyskeratosis Congenita.

CASE: We present a case of a 45-year-old female from Puerto Rico who presented to the pulmonology clinic for a 3- year history of chronic cough. She had a prior diagnosis of Dyskeratosis Congenita (DC) and her sister had recently passed away from pulmonary complications related to DC. A CT scan revealed subpleural septal thickening and honeycombing with mild traction bronchiectasis. A Video-assisted thoracoscopic surgery (VATS) biopsy revealed patchy interstitial fibrosis with mild to moderate chronic inflammation suggestive of usual interstitial pneumonia. Over the next few months, she had an extensive workup, yielding a positive ANA with speckled pattern, anti-Ro antibodies, and MI-2 on a myositis panel. Her pulmonary disorder was attributed to antisynthetase-related interstitial lung disease and she was started on daily prednisone. While her symptoms improved, her PFTs showed a rapid decline with FVC decreasing from 2.30L (64% predicted) to 1.85L (47% predicted) over seven months. Further workup was conducted with a bone marrow biopsy negative for major abnormalities and telomere length testing significant for short telomere length in lymphocytes and granulocytes indicating a primary telomere disorder. The conclusion was made that she had progressive pulmonary fibrosis due to DC, though without bone marrow involvement. She was evaluated for lung transplant, but unfortunately passed away prior to this occurring.

IMPACT/DISCUSSION: DC is a genetic multisystem disorder characterized by short telomeres for age with a highly variable phenotype defined by a triad of nail dysplasia, mucosal leukoplakia and patchy skin hyperpigmentation. A recent review of data from the DC registry demonstrated that idiopathic pulmonary fibrosis develops in about 20% of the patients with DC¹ and is characterized by cough, dyspnea, impaired gas exchange, and reduced lung volume as demonstrated by a reduced DLCO and/or restrictive pattern. The onset and progression of the manifestations of DC vary, with bone marrow failure thought to precede the development of pulmonary fibrosis. Pulmonary complications are the second most common cause of mortality in patients with DC after aplastic anemia but idiopathic pulmonary fibrosis in the absence of bone marrow failure is rare which makes this a unique but lethal presentation.

CONCLUSION: It is important to recognize the protean manifestations of Dyskeratosis Congenita and that Pulmonary fibrosis although an uncommon entity, can still occur and is life threatening. Early recognition is important as these individuals will require a comprehensive healthcare program including smoking abstinence/cessation, monitoring of disease progression with regular PFTs and early evaluation for lung transplantation as no other therapy has shown to be of benefit.

DYSPEPSIA ON DOAC? THINK DILI!

Rachel Solomon; Laurie Edelman; Aparna Sarin. Mount Sinai Medical Center, New York, NY. (Control ID #3184611)

LEARNING OBJECTIVE #1: Recognize that direct oral anticoagulants (DOAC) confer risk of liver injury.

LEARNING OBJECTIVE #2: Identify patients who may benefit from hepatic monitoring on DOAC therapy.

CASE: A 68 year-old female with hyperlipidemia on statin was hospitalized and started on rivaroxaban for bilateral, submassive pulmonary emboli. Two weeks post-discharge she e-mailed her PCP complaining of two days of intermittent abdominal pain, nausea, and vomiting after eating chicken salad. Symptoms were improving and were attributed to gastroenteritis. Several days later, she reported resolution of nausea and vomiting, but persistent burning pain, waxing and waning, with occasional radiation to back. The symptoms felt similar to her prior dyspepsia; seltzer helped. An H2 blocker was started. A week later, she called with recurrent vomiting for one day, abdominal discomfort unchanged on ranitidine, and nausea worsened after taking rivaroxaban each day. In clinic, exam was notable for epigastric tenderness. Labs revealed significant transaminitis: ALT 609, AST 332, Alkaline Phosphatase 575. Liver sonogram and hepatitis serologies were unremarkable. Rivaroxaban was

stopped immediately. The patient was transitioned to LMWH and warfarin. Within a month, labs normalized and symptoms resolved.

IMPACT/DISCUSSION: As DOACs gain traction, providers must be aware of adverse effects, including liver injury, increasingly described in the postmarketing literature. DOACs, used for treatment and prevention of venous thromboembolism and stroke prevention in non-valvular atrial fibrillation, carry similar overall bleeding risk to vitamin K antagonists, but offer advantages like fixed dosing, and freedom from laboratory monitoring and dietary restrictions. While early studies focused mainly on bleeding outcomes, rarer side effects - like drug-induced liver injury (DILI) - have since been supported by pharmacovigilance and case reports and statistical analyses. Risk factors may include underlying liver disease and concomitant use of other potential hepatotoxins (e.g. alcohol, statins). Rivaroxaban seems to carry the highest risk, though no clear mechanism has been described. Manifestations of DILI related to DOACs range from asymptomatic transaminitis to liver failure. Symptoms like those seen in our patient – nausea, anorexia, abdominal pain - should prompt immediate evaluation. Early identification and withdrawal of the offending drug may prevent progression to cirrhosis or liver failure and is generally followed by recovery and normalization of transaminases.

CONCLUSION: Evolving evidence of DOAC-related DILIs should prompt caution in prescribing and management. Patients with liver disease or who consume other potential hepatotoxins may be at higher risk. Given risk of asymptomatic presentation, monitoring liver function in all patients initiated on DOAC therapy may be warranted.

DYSPHAGIA LUSORIA: A RARE PATHOLOGY FOR A COMMON AND CONCERNING PRESENTATION

Megan Kosirog²; Farhad Ghamsari¹; Victoria Behrend²; Kelley Wachsberg². ¹Feinberg School of Medicine, Chicago, IL; ²Northwestern University, Chicago, IL. (Control ID #3186109)

LEARNING OBJECTIVE #1: Recognize this congenital anomaly as a potential cause of dysphagia in an otherwise nonspecific presentation.

CASE: A 69 year-old man with controlled HIV, COPD and significant smoking history presented to the ED complaining of sore throat and solid-food dysphagia without discrete odynophagia, along with a 30-pound weight loss over 3 months. Physical exam, routine labs, and CXR were unrevealing. Last CD4 count 1 month prior was 964. Given the patient's risk factors and presentation, diagnostics focused around esophageal pathologies. An initial barium swallow demonstrated esophageal dysmotility approximately one-third of the way down the esophagus. No discrete ulcers or strictures were visualized. A subsequent esophagogastroduodenoscopy (EGD) corroborated the existence of a pulsatile vessel along the posterior esophageal wall resulting in mild esophageal compression without significant luminal narrowing. EGD was otherwise unremarkable. A CT chest was obtained to evaluate for extrinsic mass effect which revealed an aberrant right subclavian vessel coursing posterior to the esophagus. A Videofluoroscopic Swallow Study was conducted to further evaluate the degree of esophageal narrowing and functional effect on swallowing, both of which were reported as minimal. A conservative management approach was advised with the patient instructed to chew well, eat slower and utilize smaller bites. Nutritional supplements were also begun. At 1 month follow up the patient reported resolution of symptoms and a 5 pound weight gain was noted.

IMPACT/DISCUSSION: An aberrant right subclavian artery, also known as arteria lusoria, is a congenital abnormality of the aortic arch wherein the right subclavian artery originates distal to the left subclavian artery. Arising from the distal aortic arch, the aberrant subclavian typically passes behind the esophagus and back across the midline to perfuse the right arm. General population prevalence is between 0.5-1.8% with 70-80% of patients being asymptomatic. When symptomatic, 91% experience dysphagia; termed dysphagia lusoria. Cough, chest pain, and Horner's syndrome have also been reported. While the exact mechanism

of associated dysphagia is unknown, direct esophageal compression and/or motility changes are suspected. Dysphagia lusoria is most often diagnosed via barium swallow study showing a diagonal defect between the third and fourth vertebrae, followed by CT scan and upper endoscopy to help both confirm diagnosis and exclude alternate pathology.

CONCLUSION: This case illustrates a rare congenital anomaly that is typically only discovered incidentally, but when symptomatic, most often presents with dysphagia. Recognition of this pathology and screening for extrinsic mass effect is important given the non-specific presentation. Further, endoscopy is generally insensitive and can result in diagnostic delay. If symptoms fail to respond to conservative management, treatment of an aberrant right subclavian artery typically involves correction with vascular surgery.

DYSPNEA IN DISGUISE: A PANCREATIC DILEMMA

Pooja Magavi; Emily Kim; Duc T. Do. Scripps Clinic/Scripps Green Hospital, La Jolla, CA. (Control ID #3186103)

LEARNING OBJECTIVE #1: Identify risk factors for pancreatic fistulas and the basic underlying pathophysiology.

LEARNING OBJECTIVE #2: Recognize the general clinical features of pancreatic fistulas.

CASE: A 72-year-old female with a history of alcoholic pancreatitis and recent perforated diverticulitis requiring emergent sigmoid colectomy with colostomy presented to urgent care with progressive shortness of breath and associated lower extremity swelling. She was initially afebrile with a blood pressure of 91/51, heart rate of 108, respiratory rate of 20 and oxygen saturation of 91% on room air. She was ill appearing with increased work of breathing, crackles throughout her lung fields and pitting edema up to her shins bilaterally. Chest X-ray showed a moderate right-sided pleural effusion. Lower extremity Doppler ultrasound showed acute proximal deep vein thromboses bilaterally. She was admitted to the ICU and started on a heparin drip for presumed pulmonary embolism. Thoracentesis revealed an exudative effusion with a significantly elevated amylase level. A chest tube was placed for continuous drainage and octreotide was started. ERCP identified a pancreatic-pleural fistula. The patient's pancreatic duct was stented. Her chest tube output gradually decreased and further imaging showed stabilization of the pleural fluid, allowing discontinuation of octreotide and removal of the chest tube. She was ultimately discharged on day 27 of her hospitalization.

IMPACT/DISCUSSION: Pancreatic fistulas can develop when the pancreatic duct is disrupted because of pancreatic disease, surgery or trauma, with subsequent leakage of secretions into the adjacent space. The pancreatic duct may communicate with the pleural or peritoneal cavity or other viscera, forming an internal fistula, or with the skin, forming an external fistula. Internal pancreatic fistulas are most commonly associated with chronic alcohol-induced pancreatitis, as in our patient. Pancreatic-pleural fistulas are rare, with an estimated incidence of 0.4%. This case illustrates the potential complexity of an uncommon condition that can present in a routine fashion. The diagnosis can be made based on evidence of pancreatic duct disruption on MRCP/ERCP, with high levels of amylase in the extravasated pancreatic fluid. Management involves supportive care and endoscopic therapy, if needed. Pancreatic fistulas can lead to sepsis, malnutrition and other complications, such as skin excoriation. Our case serves as a reminder to constantly reassess care plans to address changes in an individual's clinical picture and to include pancreatic fistula in the differential diagnosis for patients with prior pancreatic injury.

CONCLUSION: A pancreatic-pleural fistula may initially manifest as a pleural effusion on chest X-ray. The differential diagnosis for any patient with a history of pancreatic injury who presents with new or unusual symptoms and fluid collections or drainage should include pancreatic fistula.

EBV IN AIDS: WHEN THE LAMB BECOMES THE LION

Alexandra J. Chastant; Phillip S. Bell; Shanti Rao. Tulane University School of Medicine, New Orleans, LA. (Control ID #3184422)

LEARNING OBJECTIVE #1: Recognize the risk of lymphoma in HIV infected patients.

LEARNING OBJECTIVE #2: Utilize EBV DNA quantification in the workup of localized lymphadenopathy in the AIDS population.

CASE: A 44-year-old Caucasian man with HIV presented with new severe upper back pain. Six weeks prior to presentation, he visited an urgent care for a right submandibular mass. He was given one week of prednisone and Augmentin without resolution of the mass. Three weeks prior to presentation, he noticed progressively enlarging masses on his neck, scalp, axilla, back and groin. He endorsed a nonproductive cough, headache, night sweats and 6lb weight loss. He denied any fevers, sick contacts, or substance abuse. He was diagnosed with HIV 24 years ago but had not been on ART for two years. He was afebrile on presentation. Physical exam was remarkable for diffuse, palpable, non-tender lymphadenopathy. Labs on presentation were remarkable for a CD4 count of 41. Imaging revealed numerous soft tissue nodules throughout the chest, abdomen and pelvis measuring up to 7.7x4.5cm, as well as multiple pleural lesions. ID was consulted and ART was initiated. Excisional lymph node biopsy was performed. Further workup revealed an EBV DNA: 78,000 copies/mL. Pathology resulted as diffuse large B-cell lymphoma, activated B-cell type. Oncology was consulted and chemotherapy was started with DA-EPOCH and intrathecal methotrexate.

IMPACT/DISCUSSION: Internists frequently encounter HIV-infected patients. Given that 25-40% of HIV-positive patients will develop a malignancy in their lifetime, a heightened suspicion for malignancy is critical. Compared to the general population, HIV infection significantly increases the risk for non-Hodgkin's Lymphoma (NHL). This increased risk becomes striking in the AIDS population where highly aggressive NHL accounts for the vast majority of lymphomas. The relative risk is 400-fold higher compared to the general population. Unexplained localized lymphadenopathy can be reasonably managed with one month follow up in the immunocompetent patient. This same presentation in the AIDS patient, however, requires strong consideration of lymphoma given the propensity for highly aggressive malignancy. No guideline exists for how to manage this clinical scenario. Evaluation may be limited as further imaging or excisional biopsy can be costly and difficult to arrange in a timely fashion. EBV DNA quantification is routinely performed in certain post-transplant patients to monitor for PTLD; additional studies have shown a significant association with EBV and HIV-associated lymphomas. Further, studies show that EBV DNA from plasma correlates with active EBV disease.

CONCLUSION: Given the risk for NHL in HIV-infected patients, EBV DNA PCR may be a critical diagnostic tool in the evaluation of unexplained localized lymphadenopathy in AIDS and HIV.

ECULIZUMAB: A LIFE SAVER IN POSTPARTUM ATYPICAL HEMOLYTIC UREMIC SYNDROME

Mais Abdou¹; Muath Alsharif⁴; Sameer Prakash²; Tarek Naguib³; Manish Patel¹. ¹TTUHSC, Amarillo, Amarillo, TX; ²Texas Tech University Health Sciences Center Amarillo, Amarillo, TX; ³Texas Tech University Health Sciences Center - Amarillo, Amarillo, TX; ⁴Texas Tech University Health Science Center, Amarillo, TX. (Control ID #3184566)

LEARNING OBJECTIVE #1: Recognize postpartum atypical hemolytic uremic syndrome (P-aHUS) as a rare but potentially fatal disease. Consider Eculizumab for P-aHUS treatment.

CASE: A 20 year-old 3rd week postpartum female with uncomplicated pregnancy presented with nausea, vomiting and few episodes of watery diarrhea since delivery. Vitals were normal. Physical exam was notable for trace pitting edema in the lower extremities. Laboratory studies showed Hb 8.5, platelets 137, creatinine 21.8 mg/dl (normal baseline), BUN 128 mg/dl, and albumin of 3 mg/dl. Urinalysis showed 2+ protein and 3+ blood. LDH was 916 U/L. Haptoglobin and fibrinogen were low with elevated D-dimer. Next day, the patient developed severe pulmonary edema. She was

transferred to ICU and intubated for 9 days. Acute glomerulopathy was suspected and she was started on hemodialysis. Peripheral blood smear and kidney biopsy showed evidence of thrombotic microangiopathy. Complement C3 level was low and ADAMTS13 activity was 65%. Atypical hemolytic uremic syndrome (aHUS) was diagnosed. Complement gene panel showed complement factor H (CFH) gene and plasminogen (BLG) gene mutations. Daily plasmapheresis was initiated with hematological improvement and normalization of platelet counts. However, this was not matched by concomitant renal improvement. After discussion with the patient about the limited but promising data of Eculizumab, she agreed to proceed. She was started on 900 mg IV weekly for 4 weeks followed by 1200 mg every second week thereafter. She significantly recovered and became dialysis independent within few weeks.

IMPACT/DISCUSSION: P-aHUS remains an under-recognized disease with life-threatening complications. It is caused by dysregulation of the alternative complement pathway due to gene mutations. It offers particular challenges in postpartum period given the broad differential. Many other conditions manifest as thrombotic microangiopathy causing delay in initiating appropriate treatment. Plasma exchange (PE) was the treatment of choice. However, with increased understanding of the complement pathway activation role, the monoclonal antibody C5-inhibitor Eculizumab is being used recently. It showed considerable success and improved outcomes compared to PE. In our case, Eculizumab was highly effective and well tolerated. It resulted in remission and full recovery of kidney function.

CONCLUSION: Postpartum atypical hemolytic uremic syndrome (P-aHUS) is a rare but potentially fatal disease that physicians should be aware of in the setting of acute kidney injury in postpartum period. Recently, Eculizumab is relatively new but promising treatment in P-aHUS. Early diagnosis and treatment can be lifesaving.

ECZEMA HERPETICUM: A RARE MEDICAL EMERGENCY

Leena Pathikonda; Preetivi Ellis. Methodist Dallas Medical Center, Dallas, TX. (Control ID #3159470)

LEARNING OBJECTIVE #1: Recognizing eczema herpticum so treatment with Acyclovir will be started quickly to prevent morbidity and mortality

CASE: A 23-year-old woman with a history of eczema and asthma presented to the emergency department with fever and painful rash on her right chest that began three days prior to hospitalization. The day prior to the rash she spilled jalapeno juice on her chest and reported having diarrhea she attributed to food poisoning. A physical exam revealed a vesiculopustular rash on an erythematous base with draining serous fluid on the chest and extending down the right arm and abdomen. The rash did not follow a dermatomal pattern. A clinical diagnosis of irritant contact dermatitis with a superimposed bacterial infection was made. She was empirically treated with intravenous vancomycin and cefepime. Despite antibiotics, her condition worsened and the rash spread to her lips and eyelids. Due to rapid skin sloughing and mucosal involvement, there was concern for Stephen Johnson syndrome, toxic epidermal necrolysis, or necrotizing fasciitis. Dermatology was consulted on day two of hospitalization. The diagnosis of eczema herpticum was made clinically based on widespread vesicles and her history of eczema. A Tzanck smear, varicella zoster PCR, herpes simplex PCR, and biopsies were obtained. While results were pending, intravenous acyclovir was initiated. The patient clinically improved after only twelve hours on appropriate therapy. After two days on intravenous acyclovir, she had rapid improvement of her skin lesions. HSV-1 PCR came back positive, and the pathology showed extensive ulceration and underlying acute and chronic inflammation with focal smudgy nuclear inclusions in ulcer base with associated immunoreactivity for HSV. This was consistent with a diagnosis of eczema herpticum. She was discharged on oral acyclovir.

IMPACT/DISCUSSION: Eczema herpeticum, also known as Kaposi varicelliform eruption, is a generalized vesiculopustular rash caused by herpes simplex virus and is usually diagnosed in children. The clinical presentation can mimic other diseases making eczema herpeticum a difficult diagnosis, but an important one, because of the high morbidity and mortality without treatment.

CONCLUSION: Eczema herpeticum presents with symptoms similar to other pathologies, and usually presents in children, it is rarely diagnosed in adults. It is even more difficult to distinguish in patients with poorly controlled eczema as in our patient. The delay in treatment can be life threatening, since the virus spreads quickly. This case illustrates the importance of quickly recognizing the presentation of eczema herpeticum to prevent delays in treatment with acyclovir.

ELEVATED VITAMIN B12 IN A CASE OF PERNICIOUS ANEMIA

Marcella Tschautscher; Ryan Giddings-Connolly. Mayo Clinic, Rochester, MN. (Control ID #3164820)

LEARNING OBJECTIVE #1: Diagnose pernicious anemia as a cause of macrocytic anemia in an adult with elevated vitamin B12 levels

LEARNING OBJECTIVE #2: Recognize that anti-intrinsic factor antibodies can lead to false elevations in serum vitamin B12 levels

CASE: A 59 year old woman with a history of chronic venous insufficiency, hypothyroidism, attention deficit hyperactivity disorder, nicotine use disorder, and traumatic brain injury presented to her outpatient visit for evaluation of a new, right>left lower extremity lace-like, non-pruritic rash and paresthesias. She denied new or worsening lower extremity pain, fevers, fatigue, urinary or abdominal symptoms. Medications included dextromethorphan and levothyroxine. Physical exam was notable for livedo reticularis involving the lower extremities that was blanchable and improved with elevation. Lab work consisting of complete blood counts, blood smear, coagulation studies, ferritin, liver function tests, creatinine, creatine kinase, thyroid function studies, vitamin B12, ANA, and ANCA was notable for hemoglobin 6.9 g/dL, MCV 124.7 FL, macrocytic red blood cells platelet count 114x10⁹/L, and vitamin B12>1,400 ng/dL. A methylmalonic acid (MMA) level was obtained and returned elevated at 50 nm/mL (ref<0.4 nm/mL) consistent with vitamin B12 deficiency. She was started on intramuscular vitamin B12 1000 mcg/mL monthly. Three months into treatment additional blood work was performed and notable of a positive for anti-intrinsic factor antibody and anti-parietal cell antibody (59.6 U (ref:<20 U)). Her hemoglobin had improved to 12.1 g/dL with resolution of livedo reticularis.

IMPACT/DISCUSSION: Although this patient demonstrated vitamin B12 deficiency as demonstrated by elevation of her MMA level, it is intriguing that her vitamin B12 level was not only elevated, but above the upper limit of normal. Standard practice sways us to rely on the competitive-binding luminescence assay (CBLA) for quantitative cobalamin measurements. This specific assay has been shown to report false normal levels of vitamin B12 in a state of deficiency, and more specifically-in pernicious anemia. This inaccuracy is due to the assay's inability to inactivate the anti-intrinsic factor antibody which can pose as cobalamin. This finding was studied from stored serum in patients with B12 deficiency with all false normal cobalamin levels only occurring among those who tested positive for anti-intrinsic factor antibody. This case highlights the importance of measuring an MMA level when evaluating for vitamin B12 deficiency and the limitations in using the CBLA in quantifying cobalamin levels especially in the setting of pernicious anemia.

CONCLUSION: The MMA level remains essential in evaluating for vitamin B12 deficiency and should be used in routine clinical practice. The CBLA has its limitations in quantifying cobalamin levels and should be recognized for its capability of reporting false normal values in the setting of pernicious anemia.

ELSBERG SYNDROME: AN UNDER-RECOGNIZED CAUSE OF CAUDA EQUINA SYNDROME

Joel Burnett¹; Christopher P. Terndrup². ¹Oregon Health & Science University, Portland, OR; ²Oregon Health and Sciences University, Portland, OR. (Control ID #3186102)

LEARNING OBJECTIVE #1: Identify compressive and non-compressive causes of cauda equina syndrome.

LEARNING OBJECTIVE #2: Recognize Elsberg syndrome - an atypical presentation of herpes genitalis.

CASE: A 62-year-old woman with chronic left lower extremity radiculopathy, chronic kidney disease, hypertension, and remote invasive ductal carcinoma in remission presented to urgent care with one week of chills, vaginal pain, dysuria, urinary retention, and constipation. She had a new sexual partner of 4 months. They did not use condoms. On exam, vitals were within normal limits. Genitourinary exam revealed vaginal erythema and multiple, bilateral ulcerative lesions of the labia. Urinalysis was unremarkable. Tests for *Neisseria gonorrhoea* and *Chlamydia trachomatis* were negative. HSV culture of a genital lesion was positive. She was prescribed acyclovir and advised to follow up in one week. A week later she represented with improvement in the genital lesions and new complaints of perineal numbness and fecal and urinary incontinence. A detailed neurologic exam was not documented. CT abdomen and pelvis with contrast revealed anterolisthesis of L3-L4 causing narrowing of the thecal sac. She was referred to neurosurgery but failed to schedule an appointment. After 6 weeks, she presented to her primary care physician (PCP), reporting persistent but improved fecal incontinence and perineal paresthesia. Exam was notable for normal gait, 5/5 lower extremity strength, decreased perineal sensation, and flaccid rectal tone. She was sent to the emergency department for urgent MRI and surgical evaluation. MRI spine without contrast redemonstrated L3-L4 anterolisthesis with moderate canal stenosis. She was evaluated by orthopedic surgeons who concluded that "her degree of stenosis [did] not explain her incontinence symptoms. Other causes should be investigated" thus she was discharged. After 3 weeks, she saw her PCP and reported continued improvement in fecal incontinence and paresthesia. After careful review of primary data and consideration of etiologies of CES, she was diagnosed with Elsberg syndrome - a self-limited cause of CES due to genital HSV infection - and was continued on acyclovir.

IMPACT/DISCUSSION: In this case, a woman with chronic spinal stenosis developed subacute CES after acute HSV infection, underwent spinal imaging and surgical evaluation, and was judged to have insufficient spinal stenosis to account for CES. Over time she experienced spontaneous symptom improvement. This presentation is best explained by Elsberg syndrome, a manifestation of a primary infection or reactivation of HSV-2 consisting of acute/subacute sacral radiculitis. The syndrome presents with CES of acute/subacute onset and recent or coexisting HSV infection in the absence of alternative CES causes. The syndrome is likely under-recognized. Epidemiological data is scarce.

CONCLUSION: While managing patients with acute or chronic genital HSV, physicians should be aware that cauda equina syndrome can present as severe manifestation of HSV infection.

EMOTIONAL STRESS INDUCED SPONTANEOUS CORONARY ARTERY DISSECTION

Victoria Gonzalez¹; Mulham Shikh Hamdon²; Vesna Tegeltija¹. ¹Wayne State University, Rochester Hills, MI; ²Wayne State University, Shelby Twp, MI. (Control ID #3185229)

LEARNING OBJECTIVE #1: Spontaneous coronary artery dissection (SCAD) is an important yet often forgotten cause of ACS, especially in women presenting with acute myocardial infarction. Frequently associated with varying precipitating risk factors, we are presenting a case in which intense emotional stress alone led to dissection in the absence of other identifiable underlying predisposing risk factors.

CASE: A 47-year-old woman with history of asthma and eczema and no cardiovascular risk factors is admitted for acute STEMI. She reported no home medications including hormonal therapy and denies smoking or illicit drug use. The night prior to her arrival, she had an emotionally intense argument with her boyfriend which she described as very stressful. The following morning, she was awoken by a severe substernal chest pain which radiated to the left chest and had 2 episodes of non-bloody emesis. EKG showed ST elevation in V1, V2, and V3 with no reciprocal changes and echocardiogram showed EF 50% with apical hypokinesis. Immediate angiography then revealed SCAD of the proximal left anterior descending artery with TIMI 3 flow of the coronary tree. There was complete resolution of ST-segment elevation without intervention. The patient was treated with dual antiplatelet therapy and discharged with follow-up CT-angiography in 3 months.

IMPACT/DISCUSSION: This case is a unique example of non-atherosclerotic SCAD presenting in a patient without predisposing risk factors, solely precipitated by emotional stress. Once believed to be a very rare condition, SCAD, has become an important identifiable cause of MI in women ages 43-52. The underlying etiology of SCAD is multifactorial, yet, up to 20% of cases are considered idiopathic. Typically, patients have an identifiable predisposing arteriopathy; fibromuscular dysplasia (FMD) being the most common. Others include postpartum status, multiparity, connective tissue disorders, systemic inflammatory conditions, and hormonal therapy. Most patients do not have conventional risk factors for CAD but often do have specific precipitating stressors which compound the underlying arteriopathy. Physical activity, heavy lifting, severe coughing or vomiting can cause cardio-circulatory stress through increased intrathoracic pressures and potential SCAD. Intense emotional stress can manifest differently through catecholamines acting on myocardial contractility or vasospasm and increased arterial shear stress leading to dissection. Interestingly, the patient presented in this case had no such arteriopathies. She was a null-parous non-smoker with no cardiac risk factors or significant family history. She used no medications, including hormonal therapy and denied illicit drug use. This patient lacked any history or evidence of other contributing causes.

CONCLUSION: A very emotional argument was the only indefinable precipitating stressor leading to SCAD in an otherwise healthy woman with no distinguishable arteriopathy.

EOSINOPHILIA IN PULMONARY ADENOCARCINOMA AS AN EXTREMELY RARE PARANEOPLASTIC MANIFESTATION

Muath Alsharif; Mohammad Islam; Mais Abdou; Thien Vo. Texas Tech University Health Science Center, Amarillo, TX. (Control ID #3184731)

LEARNING OBJECTIVE #1: Recognize eosinophilia as a rare finding with solid tumors. Diagnose lung cancer when eosinophilia is the main paraneoplastic feature.

CASE: A 67-year-old female with history of severe chronic obstructive pulmonary disease (COPD) presented with generalized weakness, malaise and dizziness for 1 month. She denied any history of hemoptysis, anorexia or weight loss. On physical examination, vitals were normal and respiratory system was notable for diminished breath sounds bilaterally with no overt crackles or rhonchi. No clubbing, cyanosis, or organomegaly appreciated. Laboratory investigations revealed white cell count of 17,200/ μ L with 34% eosinophils, hemoglobin 11.5 g/dL, blood urea nitrogen 33 mg/dL, creatinine 2 mg/dL. Computed tomography of thorax revealed 2 cm nodular like density along with the medial aspect of the right upper lobe abutting the mediastinum with multiple enlarged mediastinal and axillary lymph nodes. Metastatic lung carcinoma and lymphoma with paraneoplastic eosinophilia were the initial differentials. Fine needle aspiration of axillary lymph node was inconclusive for malignancy. Later, Mediastinoscopy with excisional biopsy was done and showed poorly differentiated pulmonary adenocarcinoma with metastatic carcinoma to lymph nodes. Acid fast, fungal smear and culture were all negative. Her

eosinophilia was thought to be secondary to the lung malignancy as no other overt cause was found including allergic, parasitic infection, vasculitis, drug reaction and hematological malignancy.

IMPACT/DISCUSSION: Paraneoplastic eosinophilia is an unusual manifestation that usually remains asymptomatic but it can be life threatening because of the multi organ involvement. It is found in less than 1% of all cancer population. The pathogenesis of tumor-associated eosinophilia is not well understood. Interleukin-5 (IL-5) is a cytokine that has been implicated in the development of eosinophilia in humans. However, there is little data associating IL-5 production with eosinophilia in the presence of tumor. In some case series, it was reported that removal of primary cancer, if possible, or combination of steroid and hydroxyurea are currently available options to address paraneoplastic eosinophilia. **CONCLUSION:** Our case reminds physician about the rare association of eosinophilia and pulmonary adenocarcinoma; a relationship which is not frequently reported in medical literature. Early recognition may play a crucial role in management plan and treatment outcome.

EOSINOPHILS AT WORK: CAVITARY LUNG LESIONS IN A YOUNG NURSE

Kajali Mishra; Shivani Sharma; Sarah Gorgis; Marcus Zervos. Henry Ford Hospital, Detroit, MI. (Control ID #3185976)

LEARNING OBJECTIVE #1: Develop a differential diagnosis for cavitary lung lesions

LEARNING OBJECTIVE #2: Diagnose and treat chronic eosinophilic pneumonia

CASE: A 35 year-old woman with recurrent sinusitis and development of asthma-like symptoms presented with two months of progressively worsening shortness of breath, wheezing and productive cough. She is an avid runner and noticed a significant decrease in her exercise capacity. She works as a CRNA in the bronchoscopy suite and her last PPD six months ago was negative. Vital signs were stable. Physical examination revealed bilateral wheezes. She had a leukocytosis of 13.3 K/uL with eosinophilia (absolute eosinophils 2.30 K/uL). Computed tomography (CT) thorax revealed pulmonary nodular densities with cavitations. A workup for infectious (tuberculosis, aspergillus, histoplasma, blastomycosis, coccidioides), vasculitis (p-ANCA, c-ANCA), and autoimmune (ANA, dsDNA, Anti-Smith, Anti-RNP) disease was negative. Pulmonary function tests (PFTs) showed FEV1 of 103% with FEV1/FVC ratio of 73%. The patient made symptomatic improvement on scheduled bronchodilators. Bronchoscopy revealed normal airways. Biopsy showed alveolar lung tissue with minimal inflammatory infiltrate, clusters of pigment-laden macrophages and minimally thickened alveolar septa. Bronchoalveolar lavage (BAL) was positive for 49% eosinophils and negative for infection. She was diagnosed with chronic eosinophilic pneumonia (CEP). The patient received inhaled corticosteroids and short acting beta agonists with symptomatic improvement. Repeat PFTs two weeks later showed improvement. CT thorax after 3 months showed improved ground glass opacities with stable pulmonary nodules. The patient endorsed complete resolution of symptoms at follow up and returned to her normal exercise capacity.

IMPACT/DISCUSSION: Chronic eosinophilic pneumonia is a rare disease which accounts for 2.5% of interstitial lung disease. It is an idiopathic disorder described by abnormal accumulation of eosinophils in the interstitium and alveolar spaces of the lung. Patients typically have a history of atopy, prolonged asthma-like symptoms, and exercise intolerance. IgE levels, peripheral eosinophilia, and elevation in inflammatory markers are nonspecific, but common. Bronchoalveolar lavage is essential to the diagnosis, as it can rule out infection and reveal alveolar eosinophilia. The BAL eosinophil count is almost always > 25%, with more than 80% of patients having a BAL eosinophil count > 40%. Glucocorticoids are the mainstay of management and patients often require long term systemic steroids. However, our patient made significant symptomatic improvement on inhaled steroids.

CONCLUSION: CEP often presents with nonspecific respiratory symptoms which leads to delays in diagnosis. Early clinical suspicion upon recognition of marked peripheral eosinophilia can lead to timely imaging and procedures (BAL) that are required to make the diagnosis.

EPICARDIAL FAT NECROSIS- AN UNCOMMON CAUSE OF PLEURITIC CHEST PAIN

Dimple Shah; Bijan Zisman. Donald and Barbara Zucker School of Medicine at Hofstra/Northwell, Manhasset, NY. (Control ID #3184492)

LEARNING OBJECTIVE #1: 1. Recognize epicardial fat necrosis as a cause of acute onset chest pain.

CASE: A 59-year-old male with a medical history of Type 1 muscular dystrophy presented to the emergency room with acute onset of chest which began in the morning. He reports 10/10 left sided chest pain, sharp and pleuritic in nature. On admission, the patient's vital signs were within normal limits. His physical exam was significant for rhonchi in the left lower lobe, and upper and lower extremity weakness, with distal weakness greater than proximal. His EKG showed sinus rhythm with an incomplete right bundle branch block, unchanged from an EKG eight years prior. Cardiac enzymes, troponin T, CK and CKMB, were <.01, 30 and 1.0 respectively. His chest x-ray revealed a left lower lobe opacity. Given an unrevealing EKG and negative cardiac enzymes, acute coronary syndrome was lower on the differential diagnosis, and patient underwent a CT angiogram of the chest. The CT showed fat stranding in the pericardial space concerning for epicardial fat necrosis, and a small left sided pleural effusion; no pulmonary emboli were identified. The cardiothoracic surgery team was consulted for further evaluation of the fat necrosis, who advised to treat conservatively with NSAIDs. The patient's pain markedly improved on hospital day two and resolved by day three. His hospital course was complicated by aspiration pneumonia with development of a loculated pleural effusion requiring a video assisted thoracoscopy. A repeat CT scan of the chest four weeks later showed resolution of the epicardial fat necrosis.

IMPACT/DISCUSSION: Epicardial fat necrosis (EPFN) is a rare inflammatory disorder that causes acute onset pleuritic chest pain, lasting from hours to days. It can often be mistaken as a life-threatening disorder such as pulmonary embolism, pericarditis or myocardial infarction. Chest x-rays can be clear or may demonstrate an opacity at the cardio-phrenic angle. A chest CT is the imaging modality of choice, which usually reveals a mass with fat attenuation, often encapsulated, adjacent to the pericardium with surrounding inflammatory changes. The pathophysiology is poorly understood, although it has been hypothesized it may be secondary to vascular pedicle torsion or pre-existing structural abnormalities. In the past, the diagnosis of EPFN required tissue diagnosis, but recent literature suggests a CT is enough to make the diagnosis. Although EPFN is an uncommon disease, it is especially relevant in the hospital setting where patients often present with acute chest pain. The treatment of EPFN is conservative and targeted towards pain control with NSAIDs. Resolution can be determined with a follow up CT scan.

CONCLUSION: EPFN is an uncommon cause of chest pain. It often presents as acute onset pleuritic chest pain, and should be included on the differential diagnosis of acute chest pain in patients who have been ruled out for life-threatening etiologies such as myocardial infarction or pulmonary embolism.

ESOPHAGEAL NECROSIS: A RARE COMPLICATION OF DIABETIC KETOACIDOSIS

Ricky A. Buckshaw¹; Ethan Stern¹; Robert Andrews¹; Frederic A. Stelzer^{1,2}. Lehigh Valley Health Network, Allentown, PA; ²Eastern Penn Gastroenterology, Allentown, PA. (Control ID #3155128)

LEARNING OBJECTIVE #1: To be able to identify a high mortality complication of a fairly common medical problem.

CASE: A 50 year old male with past medical history of DM type I, gastroparesis, chronic pancreatitis, and Barrett's esophagus presented with non-radiating epigastric abdominal pain, coffee ground emesis, and nausea. He was vomiting frequently with severe pain for approximately two days. He denied any new medications, sick contacts, alcohol intake or intentional ingestions at the time. Arriving vitals were systolic BP 60's - 70's, HR 98, GCS 12. Dried blood was present around the patient's mouth and tenderness in the epigastric area was present. He was given IV normal saline for volume resuscitation as well as emergent blood transfusions. He was started on empiric treatment for a GI bleed along with Zofran for persistent nausea. Initial lab work revealed hemoglobin 9.9, blood pH 7.34, lactate 3.7, glucose >1000, positive serum ketones, bicarbonate 14, and anion gap 39. CT scan of his abdomen and pelvis revealed esophageal wall thickening, gastric distention with dilated fluid-filled esophagus, fatty liver, and chronic pancreatitis. He was later admitted to the MICU due to his critical clinical status. A diagnosis of diabetic ketoacidosis was made and DKA treatment protocol with insulin infusion, electrolyte replacement and frequent labs was started. Gastroenterology consult with EGD revealed the distal 2/3 of the esophagus having black, necrotic appearing mucosa with abrupt transition at the GE junction. No biopsies were taken due to the nature of the patient's presentation and risk of perforation. The patient was subsequently started on IV PPI and Carafate with gradual improvement of his symptoms.

IMPACT/DISCUSSION: Diabetic ketoacidosis (DKA) is a common complication of uncontrolled diabetes mellitus. Rarely, DKA can be complicated by acute esophageal necrosis (AEN) with the hallmark finding of circumferential black distal esophageal mucosa seen with endoscopy. Common presentation of AEN includes upper GI bleeding, nausea, vomiting, dysphagia, and syncope. Most commonly AEN is associated with hemodynamic compromise and low flow states, like what is encountered with the profound dehydration in patients with DKA. Those considered at greatest risk for developing AEN are men over age 50 with comorbid conditions such as DM, malignancy, hypertension, alcohol abuse, and CAD.

CONCLUSION: AEN is a rare complication of DKA and was discovered in this patient. Typical management involves fluid resuscitation, treatment of the underlying DKA, PPI, Carafate, and keeping the patient NPO. Although uncommon, AEN is an important condition to recognize as it is associated with mortality rates ranging from 15% - 36%. Also, 15% of survivors develop long term complications such as esophageal strictures or stenosis. Many of the symptoms of AEN are common presenting symptoms of DKA so clinical suspicion and evaluation in the correct context could prevent morbidity and mortality.

EVEN THE ELDERLY CAN CONTRACT MENINGOCOCCAL MENINGITIS - A CASE REPORT

Yuriko Terada¹; Takafumi Kubota³; Suguru Matsuzaka⁴; Ivor Cammack². ¹Teine Keijinkai Hospital, Sapporo-shi, Japan; ²Keijinkai, Yoichi, Japan; ³Teine Keijinkai Hospital, Sapporo, Japan; ⁴Teine Keijinkai Hospital, Sapporo, Japan. (Control ID #3184849)

LEARNING OBJECTIVE #1: Recognize that social activity in elderly individuals can put them at risk for contracting meningococcal meningitis.

CASE: A 72-year-old female presented with a 2-day history of fever and sore throat. The fever got steadily worse, and she developed rigors. In the morning, she vomited so attended a nearby clinic, where her mental status deteriorated over 2 hours. She was transferred immediately to our hospital. Her past medical history was significant for hypertension, ischemic heart disease and osteoporosis. She was socially very active, participating in various activities. On examination, her temperature was 37.5 degrees Celsius, blood pressure 139/81, heart rate 96/min, respiratory rate 14-20/min and oxygen saturations 96% on room air. Her Glasgow Coma Scale was E4V2M3. She had nuchal rigidity and a positive Kernig's sign. There was no rash. Blood tests showed white blood count 9860/ μ L, LDH

293U/L and C-Reactive protein 158.6 mg/L. Cerebrospinal fluid (CSF) gram stain showed gram-positive diplococci. CSF microscopy showed white blood cells 483/ μ L (neutrophils 64%), protein 463 mg/dL, glucose 10 mg/dL and lactate 71mg/dL. Within an hour upon arrival, she was started on ceftriaxone 2g intravenously (IV) every 12 hours, vancomycin 900mg IV every 10 hours, ampicillin 2g IV every 4 hours and dexamethasone 8.25mg IV every 6 hours. On the second day, we changed to ceftriaxone treatment alone as her blood culture was positive for *Neisseria meningitidis*. 2 days after admission, her mental status recovered. Although she had ongoing visual hallucinations at night, which led to insomnia. She also suffered cognitive dysfunction. She underwent intensive cognitive rehabilitation and her symptoms gradually resolved over 1-2 weeks.

IMPACT/DISCUSSION: In this case of a healthy 72-year-old female, it is uncommon to see sporadic meningococcal meningitis. Her only potential risk factor was her active social activities. She volunteered at nursing homes once a week, participated in an exercise program twice weekly in an elementary school and at our hospital and attended aqua jogging sessions. Crowding and close contact is common in these facilities, and it is therefore relevant to ask about social activities when seeing individuals suspected of meningococcal meningitis. Invasive meningococcal disease has a high mortality and adverse outcomes are common if treatment is delayed. Supporting the evidence that in community-acquired meningitis, there is a reduction in mortality and a benefit in terms of neurologic outcome with early administration of antimicrobial therapy, our case showed resolution of neurological symptoms after initiating antibiotic therapy within an hour of admission.

CONCLUSION: Social activities are risk factors for sporadic cases of meningococcal disease in elderly patients and immediate antibiotic therapy is vital to avoid neurological sequelae.

EVEN WITH AN INTERPRETER, THINGS CAN GET LOST IN TRANSLATION

Sean Burke; Indira Bhavsar. University of Virginia, Charlottesville, VA. (Control ID #3183727)

LEARNING OBJECTIVE #1: Understand the importance of cultural competency and health disparities in Latino populations

LEARNING OBJECTIVE #2: Recognize the limitations of using a translator to conduct patient interviews

CASE: A 19-year-old male from Mexico with no past medical history presented to the hospital with abdominal pain. The interview was conducted by a telephone interpreter. He had two weeks of abdominal pain that was worse after eating and reported seeing a "sobador" who told him he had "empacho." His physical exam was notable for tenderness in the epigastrium and laboratory analysis was unremarkable. Imaging was pursued and revealed a jejunal filling defect concerning for a food bolus or other undifferentiated mass. He was admitted to the hospital. Small bowel follow through the next day was normal with passage of the mass.

IMPACT/DISCUSSION: This case illustrates the challenges that arise when caring for non-English speaking patients despite the use of an interpreter. Notably, the patient recounted his recent interaction with a "sobador," a word that strictly translates to "masseuse" and his new diagnosis of "empacho" which had no English translation. Sobadores are folk healers who practice in Mexico and other Central American countries. They use manipulative therapies to treat common illnesses including musculoskeletal pain and gastrointestinal distress. The patient recounted his visit to a "sobador" and resulting diagnosis. Given the strict Spanish to English translation, the team understood that the patient visited a masseuse for his abdominal pain. Empacho is a traditional Latino illness well described in the literature. Characteristics include constipation, cramping, and vomiting. It is thought to be caused by dietary indiscretion. The most commonly agreed upon etiology is "blocked digestion" and many believe it is caused by a bolus of food that sticks to the wall of the

intestine. Traditional treatment includes abdominal massage and herbal purgative teas. This case exemplifies multiple factors that can lead to disparities in health care. In retrospect, it is obvious that our patient had different cultural beliefs which he attempted to communicate during his initial interview. Given the translator's inability to provide correct translation and unawareness of folk illnesses, the team was unable to validate the patient's concerns. Factors such as these are routinely present during our interactions with minority populations further promoting disparities in the social determinants of health. Ongoing endeavors to foster cultural competence should be prioritized.

CONCLUSION: Latinos and other minority populations face multiple barriers leading to disparities in quality health care. Misinterpretation can occur despite the use of certified interpreters. Empacho is a traditional Latino folk illness, often of organic etiology, that leads to abdominal pain, cramping, and emesis.

EXPANDING YOUR DYSPNEA DIFFERENTIAL: A CASE OF AMIODARONE TOXICITY

Tammy Tavdy; Dawn Zhao; Darlene LeFrancois. Montefiore Medical Center/Albert Einstein College of Medicine, Bronx, NY. (Control ID #3185021)

LEARNING OBJECTIVE #1: Recognize the pathophysiology of amiodarone toxicity, and the risk factors for its development

LEARNING OBJECTIVE #2: Diagnose and manage amiodarone toxicity

CASE: An 80-year-old woman with ischemic cardiomyopathy, mild COPD, and atrial fibrillation (on amiodarone 200 mg for 14 months) presented with a two week history of progressive dyspnea and dry cough. One-month prior, the patient had been ambulating 5-6 blocks without difficulty. She is now unable to even ambulate within her one bedroom home. She did not have any sputum production, fevers, leg edema, or calf tenderness. She was afebrile, but hypoxic to 87% at rest. She had bibasilar rales with dullness to percussion. Lab results revealed no leukocytosis and a proBNP of 4580 (baseline). All microbiologic workup was negative. CXR revealed new bibasilar patchy opacities. In light of no clinical improvements with IV diuresis or antibiotics, a CT chest was performed, revealing hyperdense, ground-glass opacities of the lung and liver, findings highly specific for amiodarone toxicity. Amiodarone was stopped, and the patient was started on 60 mg oral prednisone daily, low flow oxygen, and trimethoprim/sulfamethoxazole and alendronate prophylaxis. On follow-up within one month of discharge she improved - walking comfortably around her house without requiring supplemental oxygen.

IMPACT/DISCUSSION: Amiodarone is one of the most widely used antiarrhythmic medications in North America. The drug is an iodine-containing compound that accumulates in several organs, most notably in the lungs and liver, leading to a direct toxic injury and an indirect immunologic reaction. Our case highlights that the presentation of amiodarone toxicity may be clinically indistinguishable from common pathologies of the lung or heart. The presentation is characterized by an insidious onset of non-productive cough with or without dyspnea, present in 50-75% of patients. Fever is also common, present in 20-30% of patients. CT imaging reveals bilateral ground glass opacities, which may also be seen in an acute CHF exacerbation or interstitial pneumonia. Age of patient, dose, and duration of amiodarone use are highly associated with the development of its toxicity. Incidence doubles to ~5% when doses of 400 mg or more are used daily. Patients over 60 years old, and those on amiodarone for 6-12 months have the highest risk of toxicity. In addition, an association between pre-existing lung disease and the development of amiodarone pulmonary toxicity has been reported. When amiodarone toxicity is diagnosed, the drug should be discontinued and steroids should be initiated. Treatment and recovery normally take months. In addition to clinical symptomatology, PFTs can be followed as a guide for recovery. In the setting of chronic steroid therapy, both antibiotic and bisphosphonate prophylaxis are appropriate therapies to begin.

CONCLUSION: A high index of suspicion should be maintained when patients on amiodarone therapy present with new onset dyspnea, even when heart and lung disease may pre-exist.

EXPECT THE UNEXPECTED: A RARE ETIOLOGY OF TRANSVERSE MYELITIS

Iman Afzal; Ivan Wong; Keerthana Keshava; Janaki Patel. New York-Presbyterian Brooklyn Methodist Hospital, Brooklyn, NY. (Control ID #3184761)

LEARNING OBJECTIVE #1: Recognize the various underlying causes of Transverse Myelitis (TM).

LEARNING OBJECTIVE #2: Diagnose and treat sarcoidosis with spinal cord involvement.

CASE: Our patient is a 53-year-old African American man who presented with worsening leg weakness, gait instability, and significant numbness radiating from his hips down to the toes and in his hands for 6 weeks. His physical examination was significant for decreased sensation in the hands, abdomen and lower extremities along with difficulty in tandem gait. Autoimmune work-up was negative, except for a mildly elevated ACE level. Magnetic resonance imaging of the brain and spine revealed severe spinal canal stenosis at C5-6 with loss of signal around the cord along with T2 hyperintensity in the spinal cord from C5-T1. A lumbar puncture was performed showing high protein, normal white blood cell count, normal cytology, and no oligoclonal bands. Given high suspicion for transverse myelitis he was given pulse dose steroids for five days. He had substantial improvement in his symptoms and was discharged home. At home, his symptoms of numbness and gait instability slowly worsened and he returned to the hospital. A computed tomography of the chest was done to further evaluate the elevated ACE level from prior admission and showed extensive mediastinal and bilateral hilar adenopathy. The patient was offered lymph node sampling via endobronchial ultrasound (EBUS) at a later date as he was simultaneously being evaluated by neurosurgery for his spinal cord stenosis. He subsequently underwent C5-6 anterior cervical discectomy and discharged home the next day. EBUS was performed with lymph node sampling taken from 4L, 7 and 11L. Histology was consistent with non-caseating granulomata supporting the diagnosis of sarcoidosis as the etiology behind the transverse myelitis. Given his persistent neurological symptoms despite surgery, he was started on Prednisone and showed excellent response to therapy.

IMPACT/DISCUSSION: Spinal cord involvement among patients with sarcoidosis is extremely rare at less than 1%. Establishing the diagnosis of sarcoidosis causing TM can be difficult given the diverse manifestations of this disease process. Patients who present with signs of TM such as weakness, decreased sensory function, bowel or bladder dysfunction with no obvious underlying etiology should be evaluated for sarcoidosis. Diagnosis of spinal involvement of sarcoidosis includes MRI of the spine and sampling of the lymph nodes to confirm diagnosis. Initial treatment usually involves corticosteroids. Other treatments include other immunosuppressive agents such as azathioprine and infliximab.

CONCLUSION: Sarcoid is a rare but potential cause of TM. Establishing a diagnosis of spinal cord sarcoidosis is challenging in patients with no preceding diagnosis of Sarcoid. Evaluation of patients with no underlying explanation of TM and/or failure of initial treatment warrants further investigation for Sarcoid.

EXPLAINING THAT DROP

Pakhi Goel¹; Vladislav Dieiev²; Magued W. Haroun²; Karishma Kitchloo^{1,2}. Montefiore Medical Center, Wakefield Campus, New York, NY; ²Montefiore Medical Center, Bronx, NY. (Control ID #3186076)

LEARNING OBJECTIVE #1: Diagnose beta blocker toxicity in patients using ophthalmic formulations.

LEARNING OBJECTIVE #2: Recognize risk factors for beta blocker toxicity.

CASE: An 85 year-old man presented with a one-day history of profound weakness. He had a history of hypertension, chronic kidney disease (CKD), and cataracts. He did not report any other complaints, but reported being treated with repeated instillation of topical timolol into his right eye at the ophthalmologist's office earlier that day. His home medications included amlodipine and tamsulosin. His blood pressure was 70/50 mmHg (baseline around 130/80). Electrocardiogram revealed sinus bradycardia with first-degree AV block. Labs were significant for potassium of 7.1 mEq/L. Later, his blood glucose dropped to 39 mg/dL; he was treated with intravenous glucagon, with improvement in bradycardia, hypoglycemia, and hyperkalemia. Further cardiac workup did not reveal any structural heart abnormalities. Bradycardia resolved within 24 hours.

IMPACT/DISCUSSION: Beta blockers (BB) are commonly prescribed medications in the United States. Main indications include cardiovascular disease (oral forms) and intraocular hypertension (ophthalmic suspensions). Side effects of oral forms are common and well recognized, but clinically significant systemic side effects of ophthalmic suspensions may remain unrecognized. Some studies demonstrate increased risk of hospitalization for bradycardia one month after initiation of timolol eye drops. In our case, clinical presentation of acute weakness with simultaneous bradycardia and prompt response to glucagon is likely to be explained by systemic absorption of ophthalmic timolol. Underlying CKD and history of receiving timolol in high doses may have contributed to the toxicity. Approximately 80 percent of topically administered timolol is reported to drain through the nasolacrimal duct and is systemically absorbed. Although symptomatic bradycardia and hypoglycemia are well known side effects of topical timolol, hyperkalemia, which occurred in our patient, is uncommon. High dose intravenous glucagon and insulin therapy are recommended in cases of severe overdose, similar to the treatment for oral BB toxicity.

CONCLUSION: Systemic absorption of BB may lead to serious cardiovascular adverse events - symptomatic bradycardia, orthostatic hypotension, conduction disorders in the heart, syncope, and falls. Certain comorbidities (heart disease, COPD, cerebrovascular disease, CKD) may increase the risk of adverse reactions to ophthalmic BB.

FACIAL TWITCHING UNMASKS UNDERLYING MYXEDEMA COMA

Zachary S. Bugos; Fnu Abhishek. UPMC Mercy, Etna, PA. (Control ID #3185837)

LEARNING OBJECTIVE #1: Recognize subtle findings associated with myxedema coma

CASE: 29 year old woman with medical history of cerebral palsy, traumatic brain injury compounded by hypoxic brain injury secondary to polyethylene glycol poisoning, seizure disorder and hypothyroidism presented from long-term nursing facility for seizure activity presenting as "facial twitching." Emergency responders gave intravenous diazepam for witnessed repetitive facial twitching lasting 30 seconds per episode. Per report, her seizure disorder was well controlled on topiramate with last known seizure 4 years ago. On arrival to ED, she was hypothermic (33.4°C rectal), bradycardic (39-66 bpm) and hypotensive (SBP 70-90 mmHg). Examination revealed an overweight, non-verbal patient with puffy facial features, non-palpable thyroid, cool skin, bilateral non-pitting lower extremity edema and only responsive to painful stimuli. Non-contrast head CT was unremarkable. Initially received IV antibiotics, fluid boluses with single pressor support and warming blanket for presumed septic shock. However, bloodwork significant for sodium 145 mmol/L, creatinine 0.47 mg/dL, ALT 202 IU/L, AST 145 IU/L, Alk phos 156 IU/L, albumin 3 g/dL, WBC count $4.3 \times 10^9/\text{L}$, hemoglobin 11.6 g/dL, MCV 103.1 fL. TSH and AM cortisol were ordered due to suspicion for hypothyroidism vs adrenal insufficiency in setting of persistent shock requiring transfer to ICU. TSH was elevated to 11.1 and AM cortisol

was 6.3ug/dL. Patient was administered 8mg IV dexamethasone and 200mcg IV levothyroxine with noted improvement in both vitals and mental status with cessation of seizures.

IMPACT/DISCUSSION: Myxedema coma is a rare, life-threatening, emergent presentation of hypothyroidism. It commonly presents in elderly females as depressed mental status along with hypothermia, hypotension, bradycardia and/or hypercapnia. Rarely, uncontrolled hypothyroidism can lower seizure threshold and contribute to onset of seizures as seen in this case. Laboratory indices that support the diagnosis, apart from elevated TSH with low free thyroid hormones, include hyponatremia, macrocytic anemia and elevated transaminases. Of note, the decreased AM cortisol level in our case was likely directly related to hypoalbuminemia, rather than adrenal insufficiency. Alteration in consciousness may be difficult to observe in patients with baseline impairment in cognition. However, this case elucidates the importance of recognizing and treating myxedema coma based on the characteristic presentation described above to avoid catastrophic and potentially fatal outcomes.

CONCLUSION: Myxedema coma is a rare, life-threatening, emergent presentation of hypothyroidism, making it important to recognize and begin treatment promptly to avoid sequela and death. Subtle clinical findings include hypothermia, hypotension, bradycardia and rarely, induction of seizure activity. Subtle lab findings suggestive of diagnosis include hyponatremia, elevated transaminases and macrocytosis

FAILING TO DELIVER: IMPROVING TRANSITIONS OF CARE FOR PERIPARTUM WOMEN WITH MEDICAL COMORBIDITIES

Chelsea Wiltjer¹; Meredith H. Lora^{2, 1}. ¹Emory University, Atlanta, GA; ²Emory, Atlanta, GA. (Control ID #3176067)

LEARNING OBJECTIVE #1: Recognize the disparity which exists among African American women in the United States regarding postpartum mortality rates.

LEARNING OBJECTIVE #2: Recommend a systems-based approach for addressing transitions of care between obstetrics and primary care to improve health care outcomes.

CASE: A 38-year-old African American female G1P0102 with past medical history of poorly-controlled hypertension, anxiety and chronic kidney disease underwent an emergent caesarian section to deliver identical twins due to pre-eclampsia. In the weeks following, while attending to her breastfed infants in the Neonatal Intensive care units, she continued to take her pre-partum antihypertensives. Six weeks after delivery, she was discharged from her obstetrician's office without adjustment of antihypertensives. Several days later, she was seen in urgent care for uncontrolled hypertension and her medications were adjusted. One week later, despite medication adherence and careful monitoring, she presented to the emergency department (ED) due to anxiety and uncontrolled hypertension. Her blood pressure reading upon arrival was 218/128 and she had evidence of a new acute kidney injury in addition to worsened proteinuria. She was admitted for intravenous anti-hypertensives. Over the next two months, she was hospitalized two additional times for uncontrolled hypertension.

IMPACT/DISCUSSION: This case highlights a woman who was actively engaged in her medical care, yet experienced a life-threatening complication of chronic hypertension due to a lack of primary care in the post-partum period. In recent years, high maternal morbidity and mortality rates within the United States have made national headlines. According to the Centers for Disease Control, black women within the U.S. have a three to four times higher maternal mortality rate, in comparison to their white counterparts. Cardiovascular and hypertensive disorders of pregnancy cause over one-fifth of these deaths. Management of chronic disease in the peripartum period can be challenging for new mothers and warrants close monitoring by a primary care provider. New mothers often struggle to navigate the system during this stressful period of their lives, and less than a third of women successfully establish with

primary care in the year following childbirth. Small studies have demonstrated a significant improvement in establishment of primary care in postpartum women through a systems-based approach involving patient education and assistance. Improving this transition of care remains an important area of study to further determine how to best care for postpartum women with chronic medical disease.

CONCLUSION: • Among already high maternal mortality statistics affecting all women in the United States, a large disparity exists in the United States for African American Women. • Facilitating transitions of care between obstetrics and primary care through a systems-based approach remains an important step for providing quality care to those with complex medical disease.

FALLING THROUGH THE CRACKS: A CASE OF SUBCLAVIAN STEAL SYNDROME

Matthew J. Klebanoff²; Ashutosh Pathak²; John J. Chang⁴; Shaili Gupta^{1, 3}. ¹Yale University School of Medicine, West Haven, CT; ²Yale School of Medicine, New Haven, CT; ³Veterans Healthcare System of CT, West Haven, CT; ⁴Yale, West Haven, CT. (Control ID #3160428)

LEARNING OBJECTIVE #1: Recognize subclavian steal syndrome (SSS) as an uncommon but important cause of syncope.

LEARNING OBJECTIVE #2: Identify signs of SSS that necessitate early surgical intervention.

CASE: A 63-year-old man with history of recurrent syncope and atrial fibrillation (AF) on warfarin presented to our hospital with headache. Within the last year, he had suffered several falls from syncope, which resulted in serious injuries, including jaw fracture and subdural hematomas (SDH). He used alcohol and marijuana daily. Prior workup for seizure activity, orthostatic hypotension, and vestibular dysfunction was negative; Holter monitor showed 0.4% AF burden and rare supraventricular tachycardia. On our exam, the patient had regular heart rhythm, with no orthostatic changes or focal neurologic deficits. Laboratory findings were notable only for an INR of 4.9. CT head did not show any pathology. His medical record revealed a prior carotid ultrasound showing retrograde flow in the left vertebral artery, raising suspicion for SSS. The patient disclosed that minimal exertion (e.g., unloading a few items from the dishwasher) caused left arm pain and paresthesias, accompanied by headache and lightheadedness. He had interarm systolic blood pressure (BP) difference of >40mmHg. CTA neck confirmed total occlusion of the left proximal subclavian artery and patent bilateral internal carotid arteries. We sought revascularization, which was deferred in favor of further evaluation of arrhythmia and substance use as causes of syncope. One month later, the patient sustained more falls, leading to multiple vertebral fractures and SDH. An event monitor revealed many syncope events without arrhythmia. He later died in neurology ICU.

IMPACT/DISCUSSION: Our patient's history suggested multiple possible causes of syncope. Several prior workups failed to recognize SSS as a likely etiology. Our case underscores the importance of assessing each patient with fresh eyes and avoiding anchoring bias. It also highlights SSS as an uncommon but important cause of syncope. SSS results from steno-occlusion of proximal subclavian artery with subsequent retrograde flow in the ipsilateral vertebral artery. Radiological SSS is usually asymptomatic, but can present with dizziness, syncope, ataxia, and arm claudication. Symptomatic patients often have additional disease in anterior vasculature (e.g., carotid stenosis), causing inadequate collateral circulation. Severe symptoms can occur despite patent carotid arteries and should dictate the urgency of surgical intervention, which has a high success rate with low morbidity (AbuRahma et al. J Vasc Surg. 2000 Sep). Arm BP discordance >40mmHg also correlates highly with the need for intervention (Labropoulos et al. Ann Surg. 2010 Jul).

CONCLUSION: In a patient with recurrent syncope, SSS should be included in the differential. Symptomatic SSS can occur despite patent carotid arteries. Clinicians should determine the urgency of revascularization in SSS based on clinical symptoms and signs, particularly arm BP discordance.

FATAL IMMUNOSUPPRESSION: A CASE OF DISSEMINATED COCCIDIODOMYCOSIS PRESENTING AS HYDROCEPHALUS

Tyler J. Trahan; Diana Slawski; Ryan Eid; Patricia Greenstein; Margaret Hayes. Beth Israel Deaconess Medical Center, Boston, MA. (Control ID #3176039)

LEARNING OBJECTIVE #1: Distinguish between infectious and non-infectious etiologies of granulomatous lung disease.

LEARNING OBJECTIVE #2: Describe the clinical features and diagnostic approach of disseminated fungal infection.

CASE: A 65-year-old man presented with pneumonia followed by three months of headaches after a brief stay in Arizona. Initial lumbar puncture revealed CSF with lymphocytic pleocytosis, increased protein, and low glucose. Cytology, infectious, and rheumatologic workup were unrevealing. Serum fungal cultures were negative. Serum Coccidioides IgG was negative. CSF Coccidioides tests were not sent. CT chest showed two pulmonary nodules. PET-CT revealed increased uptake in chest lymph nodes. Axillary lymph node biopsy showed noncaseating granuloma. Steroids were started for presumed sarcoidosis. After two weeks, patient developed diplopia and ataxia. CT head showed hydrocephalus. Repeat CT chest showed new reticulonodular opacities with hilar lymphadenopathy concerning for worsening sarcoid versus infection. He was transferred to a tertiary care facility for VP shunt placement and started on empiric antimicrobials. His course was complicated by worsening confusion and respiratory failure requiring intubation. Pathology from a transbronchial biopsy revealed fungal elements and he was immediately started on amphotericin and fluconazole; however he continued to deteriorate. After much discussion with the family, he was transitioned to comfort focused care, extubated, and died peacefully in the hospital. CSF and serum Coccidioides antibodies ultimately returned positive. Reevaluation of initial lymph node biopsy suggested necrotic granuloma.

IMPACT/DISCUSSION: The differential of granulomatous disease includes infectious and non-infectious etiologies. While sarcoidosis can cause granulomatous lung disease, it is a diagnosis of exclusion that relies on biopsy evidence of noncaseating granulomas and exclusion of infection. The most common organisms in pulmonary granulomas are mycobacteria and fungi. Coccidioides is commonly found in the southwestern United States. Even brief exposures to endemic areas, such as changing airplanes in Phoenix or driving through the San Joaquin Valley, have been sufficient to cause infection. Thus, it is critical to obtain a detailed travel history. Serologic testing for Coccidioides should not be relied upon as it may be negative early in the course, and even persistently negative in immunocompromised patients. If meningitis is suspected in a patient with granulomatous lung disease, a lumbar puncture should be performed and CSF sent for fungal culture and antibody testing, as routine CSF and imaging abnormalities are nonspecific. The diagnosis of coccidioidal meningitis requires positive CSF antibodies, growth of the organism, or the presence of coccidioidal antigen.

CONCLUSION: Reevaluate infectious workup if a patient with granulomatous disease decompensates on immunosuppression. In suspected meningitis, test CSF for Coccidioides antigen/antibody, as serology alone may be unreliable.

FEVER AND PULMONARY NODULES IN A RETURNING TRAVELER

John K. Bui; Alice Tang. New York Presbyterian/Weill Cornell Medical Center, New York, NY. (Control ID #3179254)

LEARNING OBJECTIVE #1: Develop an approach to fever and respiratory symptoms in a returning traveler.

LEARNING OBJECTIVE #2: Describe the diagnostic test characteristics for acute pulmonary histoplasmosis.

CASE: A previously healthy 20-year-old male recently returned from a 1-week vacation to Cancun, Mexico. Two weeks after returning, he developed fevers, chills, headache, anorexia, myalgias, and productive cough. He felt well throughout his trip and denied raw food consumption, contact with animals, or freshwater exposures. He did not have any tuberculosis risk factors. The physical exam and laboratory results did reveal any abnormalities. A chest x-ray showed bibasilar opacities. CT of the head without contrast and LP were unremarkable. He was empirically treated for community acquired pneumonia but continued to develop fevers up to 40°C despite 2 days of antibiotics. A CT chest showed bilateral lung nodules and hilar adenopathy. Laboratory tests were unrevealing, including serum beta-D-glucan, Histoplasma urinary antigen, respiratory cultures, and serologies for Blastomyces, Coccidioides, and Histoplasma. A diagnostic bronchoscopy with transbronchial lymph node biopsy was performed showing necrotizing granulomas with organisms consistent with Histoplasma. The fevers, headache, and cough spontaneously resolved and the patient was discharged home.

IMPACT/DISCUSSION: When encountering fever and respiratory symptoms in a returning traveler, it is reasonable to first rule out common etiologies including common respiratory viruses and bacteria. However, the epidemiology and exposure history are integral in guiding the differential. Histoplasma is endemic in Cancun (CDC, WHO). He did not have any animal or fresh water exposures, making zoonotic infections less likely. Absence of eosinophilia made parasitic infections such as filariasis or strongyloidiasis less likely. Lack of immunosuppression in this previously healthy, HIV-negative patient eliminated opportunistic pathogens from the differential. CT findings were suspicious for fungal pneumonia, although lymphoma and sarcoidosis were also considered. Serologic tests for Histoplasma can have limited utility in acute pulmonary Histoplasmosis, since they may take over a month to become positive [1-3]. Histoplasma serum and urinary antigens have a sensitivity of ~80% [3]. Fungal markers such as serum beta-D-Glucan has a sensitivity of 87% in disseminated Histoplasmosis, but likely lower in isolated pulmonary disease [4]. Respiratory cultures have a sensitivity of ~41% [3]. Although a lung biopsy helped establish the diagnosis in this case, histopathology also has its limitations, including the poor sensitivity (~35%) and non-specific morphology of Histoplasma [2,3,5]. **CONCLUSION:** Respiratory symptoms in a returning traveler should prompt work-up for common causes, while also considering epidemiologic exposures. The exposure history, presence or absence eosinophilia, immune status, and radiologic features can quickly narrow the differential.

FEVER, LEUKOCYTOSIS, AND PAINFUL SKIN NODULES: A SWEET DIAGNOSTIC CHALLENGE

Patrick Twohig; Jaclyn Rivington; Jennifer Hanrahan; David Soma. Case Western Reserve University - MetroHealth Medical Center, Cleveland, OH. (Control ID #3185625)

LEARNING OBJECTIVE #1: Recognize the relationship between Sweet Syndrome and other diseases

CASE: 60-year-old female presented with 4-days of right-sided anginal chest pain, palpitations, vaginal pain, and dysuria. Past medical history included CAD, type 2 diabetes, hypertension, essential thrombocytosis (JAK 2+), tobacco use and hepatitis C. She was febrile (T 103.8°F), tachycardic, and hypoxic (SpO2 80% on room air). She had tender right labial swelling without induration, fluctuance, or crepitus. The remainder of her exam was benign. Laboratory testing revealed: Leukocytosis (WBC 17,700 U/L with 22 bands), lactic acid 2.0, and D-dimer 707. CT abdomen/pelvis showed a complex 4 x 3 cm fluid collection involving the right labial fold. She was started on broad spectrum antibiotics and underwent incision and drainage. Intraoperative cultures were negative. Fevers persisted, and she developed acute respiratory distress syndrome (ARDS). Her labial lesion became increasingly necrotic with extension to the levator ani and urethra. Surgical pathology showed necrotic tissue but

was otherwise non-specific. Despite multiple courses of anti-microbial therapy, her clinical condition worsened, ultimately requiring mechanical ventilation. On her 16th hospital day, she developed new ulcerative skin lesions on her neck and R-wrist. She became increasingly hypotensive and transitioned to comfort care, with time of death called one day after skin biopsies revealed neutrophilic dermatosis consistent with Histiocytoid Sweet Syndrome (H-SS).

IMPACT/DISCUSSION: Only 100 cases of H-SS have been previously reported⁵. We present the first case of H-SS that presented with a labial abscess. We performed a retrospective analysis using a de-identified clinical database of >50 million unique patients in the US. Odds ratios (OR) were calculated to determine the relationship between Sweet Syndrome (SS) and other diseases. Although she had no history of cancer, she did have essential thrombocytosis (ET) which increases the risk for SS (OR 19.1). SS can often manifest after infection. We suspect that the labial abscess was the sentinel event causing her SS and her ET increased her predisposition for H-SS. Our case has similarities to those in the literature and in our analysis. First, she was female (OR 3.5). Second, she had an underlying myeloproliferative disorder (OR 19.1). Third, her skin lesions were typical of H-SS - asymmetric tender red-violaceous nodules on the neck and arms^{1,3,5}. Conversely, she was the first to present with labial ulcerations and chest pain. Most patients survive long enough to be treated, which often results in resolution of symptoms^{1,6}. However, our patient expired prior to initiation of therapy. This severity of H-SS has not been previously documented.

CONCLUSION: Consider SS in patient's with history of hematologic disorders with constitutional symptoms, fever, and leukocytosis not responsive to antibiotics. Early identification and rapid treatment of SS can be life-saving

FINDING A NEEDLE IN A FAT PAD: A CASE OF PRIMARY AMYLOIDOSIS COMPLICATED BY CARDIOMYOPATHY AND NEPHROTIC SYNDROME

Ali Ali; Ali Saadi; Elieth Martinez; Sagar Wagle; Natasha Singh. UCSF Fresno, CA. (Control ID #3185700)

LEARNING OBJECTIVE #1: Recognize the clinical features and diagnosis of AL amyloidosis

LEARNING OBJECTIVE #2: Assessing for infiltrative cardiomyopathy in the absence of a biopsy

CASE: A 66 year old male presented with 6 months of progressive weight gain, edema and paroxysmal nocturnal dyspnea. Patient was otherwise healthy and not on medications. He was born in Mexico, but currently lived in Washington state. He did not smoke, drink or use drugs. Exam notable for +3 pitting edema in all extremities. Labs notable for serum albumin 1.5 g/dl, protein 4 g/dl and corrected calcium of 8.7 mg/dl. Complete blood count, liver function and renal function labs were otherwise normal. A 24 hour urine protein of 13 g was consistent with nephrotic syndrome. HbA1c was 6. Serum immunofixation revealed trace free lambda monoclonal proteins with kappa to lambda ratio of 0.03. Fat pad biopsy was negative for amyloid. Bone marrow biopsy showed 15-20% cellularity with lambda restriction without amyloid deposits consistent with plasma cell dyscrasia. Kidney biopsy showed AL (lambda light chain) amyloidosis predominantly glomerular with focal interstitial and vascular involvement. Bone survey was negative. Patient also presented with persistent troponinemia of 0.1 ng/ml without chest pain. BNP 375. EKG showed sinus rhythm with low voltage in all leads. A transthoracic echocardiogram showed ejection fraction of 60-65% with moderate left ventricular concentric hypertrophy and impaired relaxation. Cardiac MRI with and without contrast showed abnormal myocardial gadolinium tissue kinetics and delayed enhancement consistent with amyloid deposition. Patient was diagnosed with AL amyloidosis complicated by nephrotic syndrome and cardiomyopathy. He was started on chemotherapy (CyBOR-D) and referred for stem cell transplant.

IMPACT/DISCUSSION: Light-chain (AL) amyloidosis is the most common form of primary systemic amyloidosis and normally associated with multiple myeloma, but can present as isolated plasma cell dyscrasia. It is a rare disorder with an incidence of nine per one million. The clinical syndromes can manifest as nephrotic-range proteinuria with or without renal dysfunction, hepatomegaly, congestive heart failure, and autonomic or sensory neuropathy. The diagnosis of AL amyloidosis requires tissue biopsy. In cases with limited organ involvement, biopsy of uninvolved sites, like fat pad, can have low sensitivity. Careful search for other organ involvement should be done as it impacts prognosis. In this case, the unexplained troponinemia and low voltage lead to further workup and diagnosis of amyloid cardiomyopathy.

CONCLUSION: - Consider amyloidosis in cases of unexplained nephrotic syndrome - Unexplained low voltage with mild troponinemia is consistent with infiltrative cardiomyopathy, cardiac MRI can often be diagnostic in the absence of cardiac biopsy.

FINDING PNEUMO: AN UNUSUAL PRESENTATION OF RECURRENT SPONTANEOUS PNEUMOTHORAX

Samer N. Muallem; Ami DeWaters. Penn State Hershey Medical Center, Hershey, PA. (Control ID #3184526)

LEARNING OBJECTIVE #1: Identify catamenial pneumothorax as a cause of pneumothorax.

LEARNING OBJECTIVE #2: Discuss treatment options to prevent recurrence of catamenial pneumothorax.

CASE: A 37-year-old woman with mild asthma presented to the internal medicine clinic one week after an emergency room visit for a spontaneous right apical pneumothorax which resolved on its own. She was asymptomatic in clinic, and the decision was made to monitor her condition. One month later, she presented to the emergency room with pleuritic chest pain and was found to have another small right-sided pneumothorax on x-ray. Computed tomography of the chest was obtained, and revealed no bleb disease to explain her recurrent pneumothorax. A thoracic surgeon evaluated her and performed an elective video-assisted thoracoscopic exploration. During this procedure, her right diaphragm was noted to have multiple fenestrations at the central tendon, as well as a small nodule which appeared consistent with endometriosis. She was thus diagnosed with catamenial pneumothorax. A patch was placed over the fenestrated area of the diaphragm, and mechanical pleurodesis was performed. She was started on oral norethindrone for progestin suppression, and had no further pneumothoraces.

IMPACT/DISCUSSION: Catamenial pneumothorax is an extremely rare condition caused by thoracic endometriosis, typically involving the parietal pleura, although the visceral pleura, diaphragm, or lung itself can also be involved. During menses, the aberrant endometrial tissue creates perforations in the pleura, resulting in the accumulation of air in the potential space. Symptoms of pleuritic pain or dyspnea classically present within three days of the onset of menstruation, but do not necessarily occur with every menstrual cycle. This condition is most common in women aged 30 to 40, although it can occur in any post-menarcheal woman. Given its rarity, catamenial pneumothorax is not classically taught in internal medicine training and is more often identified by subspecialists. Internists, especially primary care providers, are the patient's first point of entry into the healthcare system, so it is important for them to be aware of this entity and obtain a comprehensive gynecologic history when they suspect it. Once diagnosed with catamenial pneumothorax, patients should also be referred to thoracic surgery for evaluation. Typically, endometrial lesions will require resection, pleurodesis, and diaphragmatic repair to reduce the risk of further pneumothoraces. Following surgical intervention, these patients should be started on hormonal suppression with oral contraceptives as tolerated, and should continue medical therapy for at least 6-12 months, with close follow up.

CONCLUSION: Internists should consider the diagnosis of catamenial pneumothorax in a female patient of childbearing age with recurrent episodes of pneumothoraces. Secondary prevention of catamenial pneumothorax often requires pleurodesis, resection of the endometriosis, and diaphragmatic repair, in addition to hormonal suppression.

FINE NEEDLE ASPIRATION FOR DIAGNOSIS OF LYMPHADENOPATHIC KAPOSI SARCOMA IN THE HIV NEGATIVE PATIENT

Kaitlyn E. Takach; Arie Szeinfeld; Eliran E. Zadikov; Lauren E. Menzies; Mohamed Aziz, MD FCAP. American University of the Caribbean School of Medicine, Cupecoy, Sint Maarten (Dutch part). (Control ID #3185796)

LEARNING OBJECTIVE #1: Fine needle aspiration (slides and cell block) is adequate for full diagnosis of Kaposi Sarcoma.

LEARNING OBJECTIVE #2: Kaposi Sarcoma should be suspected even in a non-HIV positive patient when we have a suggestion of a vascular neoplasm in fine needle aspiration.

CASE: A 65 year-old Mediterranean man with history of colon cancer presented with right inguinal lymphadenopathy for several weeks. On physical exam, he was awake, alert and cooperative. Cardiopulmonary examination was normal. A 2.5cm nontender, right inguinal lymph node was noted. Concern for metastatic colon cancer prompted sampling of the lymph node. Fine needle aspiration (FNA) was performed and cytologic analysis demonstrated fragments of atypical spindle cells in a background of polymorphous lymphocytes and extravasated blood. Cell block prepared from the cytology specimen demonstrated a spindle cell neoplasm with hyperchromatic elongated nuclei infiltrating lymphoid tissue and no morphologic evidence of epithelial cells. Immunohistochemical studies showed tumor positivity for HHV-8, CD31, CD34 and vimentin and were negative for cytokeratins, S100, p63, and desmin all of which was consistent with a diagnosis of Kaposi Sarcoma (KS) and not metastatic colon carcinoma. Testing for human immunodeficiency virus (HIV) was negative. Lymph node was excised and there was no evidence of recurrence or disseminated disease with a follow up for three years.

IMPACT/DISCUSSION: Kaposi sarcoma is the most common HIV associated malignancy, however, KS can be initiated through mechanisms other than viral, such as iatrogenic immunosuppression and elevated expression of cytokines and angiogenic growth factors. Although KS commonly presents as skin lesions, it can be associated with visceral involvement and may run an aggressive disseminated course. Cytologically, the nodal tumor is identical to skin KS, regardless of patient's age or clinical presentation. KS should be considered as a potential diagnosis for patients with lymphadenopathy of unknown etiology, even in those with a known HIV-negative status.

CONCLUSION: Fine needle aspiration can be used to adequately obtain lymph node samples as well as for the diagnosis of KS.

FISTULIZATION OF HEMORRHAGIC PANCREATIC PSEUDOCYST

Kelsey R. Grossman; Stacey Wolfson; Ravi Shah; Michael Janjigian. NYU School of Medicine, New York, NY. (Control ID #3165653)

LEARNING OBJECTIVE #1: Recognize pancreatic-enteric fistulization as a rare complication of pancreatitis

LEARNING OBJECTIVE #2: Define the mechanisms for fistula formation in hemorrhagic pseudocysts

CASE: The patient is a 31-year-old female with a past medical history of systemic lupus erythematosus complicated by end stage renal disease on dialysis, and pancreatitis complicated by pseudocyst formation, presenting with acute onset abdominal pain, nausea, and vomiting. On presentation, she was afebrile and hemodynamically stable with exam notable for

diffuse abdominal tenderness and voluntary guarding without rebound. CT abdomen and pelvis showed hemorrhage into the known pancreatic tail pseudocyst with interval enlargement from 8 to 12 cm. CT Angiogram obtained four days after the onset of abdominal pain showed an open fistula between the pseudocyst and transverse colon, without evidence of active arterial bleeding. The patient then had two episodes of bright red blood per rectum. She became tachycardic and hypotensive with labs notable for a one-point hemoglobin drop from 9.7 to 8.5. She was triaged to the surgical ICU and underwent urgent exploratory laparotomy with transverse colectomy, partial pancreatectomy, and splenectomy, followed by staged colostomy creation.

IMPACT/DISCUSSION: Fistulization of pancreatic pseudocysts is an extremely rare complication, occurring in less than 3% of cases, and can involve a variety of abdominal organs. Connections with sources other than the colon often cause spontaneous drainage and resolution of symptoms, and thus do not require surgery. However, communication with the colon can lead to other complications such as hemorrhage and sepsis, as seen in this case, which require definitive management. A proximal diverting colostomy is standard practice in order to prevent further backup of fecal matter into the pseudocyst and prevent rupture into the abdominal cavity. Multiple mechanisms have been proposed to explain the cause of hemorrhage and rupture of pancreatic pseudocysts. These mechanisms include the presence of severe inflammation due to activated lytic enzymes of the pancreas, as well as persistent compression of blood vessels due to mass effect. Colonopancreatic fistula formation in the case of our patient with lupus is likely secondary to the pro-inflammatory environment compounded by high wall pressures and suppressed healing mechanisms due to chronic steroid use.

CONCLUSION: Given the gravity of a missed diagnosis, hospitalists must keep complications of pancreatic pseudocysts on their differential for patients with known pathology and acute abdominal pain. Management strategies differ based on the type of complication, however, urgent operative management is key in certain cases of fistula formation, especially when it involves the colon as in our patient.

FLACCID PARALYSIS AS A COMPLICATION OF NEUROINVASIVE WEST NILE VIRUS

Morris Jrada; Brandan Kovacs; Faryal Osman. NYU Langone Brooklyn, Brooklyn, NY. (Control ID #3185474)

LEARNING OBJECTIVE #1: Diagnose West Nile Virus (WNV) encephalitis

LEARNING OBJECTIVE #2: Recognize neurologic symptoms seen in Neuro-invasive WNV

CASE: A 79 year old male with a past medical history of CAD s/p CABG, hypertension and hyperlipidemia presented with a 4 day history of generalized weakness, fevers, decreased oral intake, and confusion. He was accompanied by his wife, who denied any respiratory, skin or urologic changes, and reported the patient had been at baseline, tending his garden a couple of days prior. He had no recent travel, but had a sick contact in a grandchild who was diagnosed with an unknown virus. Upon admission, he was febrile to 39.5C, hypotensive to 95/43 with otherwise normal vital signs. Exam was notable for lethargy and proximal muscle weakness with diffuse hyporeflexia. CT scan of the head, chest X-Ray and urinalysis did not show acute abnormalities. He was started on antibiotics to cover for meningitis with improvement in his vitals, but not his mental status. The following day, a lumbar puncture was performed and cell count was notable for a white blood cell count of 344 with 76% neutrophils, 97 protein and 53 glucose, and negative gram stain. His course was complicated by an aspiration event that resulted in hypoxia and he was subsequently intubated. Additional CSF studies were then sent to the state lab, returning positive for WNV IgM the following week. The patient's hospital course was again complicated by a second aspiration event post extubation and required reintubation and eventually a tracheostomy and PEG placement. He

continued to exhibit proximal and distal muscle weakness and an EMG was performed, which showed axonal and demyelination sensorimotor polyneuropathy. MRI of the spine showed enhancement of cauda equina consistent with Guillain Barre syndrome (GBS). Patient was started on plasmapheresis with improvement in his weakness.

IMPACT/DISCUSSION: The key aspect of this case was the atypical appearance of acute flaccid paralysis, a Guillain Barre-like picture, that developed in a case of confirmed West Nile Virus infection. Prior to 1996, WNV was associated with typical B symptoms. Following the NYC outbreak, neurological complications, including muscle weakness, became common. Another key point is the presentation difference between normal GBS and the flaccid paralysis seen in WNV infection. In standard GBS, weakness typically begins weeks after infection, while weakness in WNV occurs in the acute to subacute phase. As was present in this case, leukocytosis and elevated protein in CSF are both characteristic of WNV infection while typical GBS CSF shows elevated protein without leukocytosis, the classic albuminocytologic dissociation. While WNV-associated paralysis is a well-described phenomenon, it has not become commonplace knowledge in general medicine.

CONCLUSION: WNV often presents as a non-specific encephalitis that may be misdiagnosed as a bacterial pneumonia. It is imperative that WNV be part of the differential in an acutely ill patient presenting with muscle weakness.

FOLLOW THE GREEN BRICK ROAD: AN UNEXPECTED CAUSE OF ACUTE KIDNEY INJURY

Dennis C. Shi, Oregon Health & Science University, Portland, OR.
(Control ID #3186722)

LEARNING OBJECTIVE #1: Bile cast nephropathy should be considered as a possible cause when patients with liver disease present with AKI.

CASE: 64-year-old man with history of polysubstance use disorder and recently discovered pancreatic head mass with liver lesions presented with progressive jaundice and acute kidney injury in the setting of several months of progressive abdominal pain, distention, and weight loss. Physical exam was notable for jaundice, lower extremity edema and a distended abdomen. On admission, his creatinine was 2.01 increased from 0.8 the day prior. AST and ALT were elevated in the 100s, total bilirubin was 11.2, and alkaline phosphatase was 822. He was started on IV fluids, however creatinine continued to increase and patient was oliguric. FeNa was consistent with prerenal etiology. Renal US showed no evidence of hydronephrosis. TTE was unremarkable for hypo- or hypervolemia. Last contrast was two weeks ago. On day three of his hospitalization, Nephrology was consulted due to concern for bile cast nephropathy in the setting of acute obstructive jaundice. Urinalysis revealed large bile-stained granular casts consistent with bile cast nephropathy. Patient was switched to albumin with improvement of renal function.

IMPACT/DISCUSSION: Acute kidney injury in a patient with severe liver disease is often thought to be due to decreased kidney perfusion from intravascular volume depletion, acute tubular injury, or hepatorenal syndrome. Liver disease is also frequently complicated by hyperbilirubinemia, which can cause renal tubular injury as bile acids can act as endogenous nephrotoxins. Bile cast nephropathy is an important pathological factor that may account for renal dysfunction in some patients with liver disease. Though less common, literature has described numerous cases of bile cast nephropathy and reports that it is likely underdiagnosed. Typically, bile-case nephropathy presents in the setting of total bilirubin greater than 20. Interestingly, our patient's total bilirubin was only 13.6. However, bile casts were noted in the urine.

CONCLUSION: In summary, this case illustrates the importance of entertaining bile-cast nephropathy in the differential of AKI in patients with liver disease. AKI in this regard is caused by epithelial cell damage and tubular obstruction secondary to bile acid accumulation. Early identification is important for treatment, as correction of hyperbilirubinemia can address AKI, preventing further progression of renal disease.

FOOD COMA: A CASE OF THYROTOXIC PERIODIC PARALYSIS

Maryam Zamanian; Amanda Deis; Gena M. Walker. University of Pittsburgh Medical Center, Pittsburgh, PA. (Control ID #3185432)

LEARNING OBJECTIVE #1: Recognizing clinical characteristics of thyrotoxic periodic paralysis (TPP)

LEARNING OBJECTIVE #2: Managing initial lab abnormalities in TPP
CASE: A 20 year old male with no past medical history was admitted to the hospital after presenting to the ED with complaints of generalized weakness. He was in his usual state of health until the morning of admission when he woke up and was unable to stand up. He had some improvement over time and was able to walk to the ED with assistance. On presentation, his exam was notable for tachycardia and generalized weakness. Initial labs revealed a serum potassium of 2.2, with EKG demonstrating U waves consistent with hypokalemia. He denied any diuretic or drug use, but did note recent high carbohydrate intake. Further laboratory evaluation revealed an undetectable TSH and elevated free T4, raising concern for thyrotoxic periodic paralysis (TPP) triggered by his recent dietary changes. No thyromegaly was noted on exam. Family history was notable for Graves' disease in his aunts with no known history of Asian heritage. He received potassium replacement therapy with complete resolution of symptoms. Endocrinology was consulted and further evaluation revealed an elevated TSI, with concern for possible Graves' disease. He was started on propranolol as prevention for further attacks and methimazole for his hyperthyroidism with plans to pursue further imaging and definitive treatment outpatient.

IMPACT/DISCUSSION: TPP is more common in Asian countries, with an estimated incidence of 1.8-1.9% in thyrotoxic patients. In the US, there is significantly less exposure to this unique manifestation of hyperthyroidism. However, the incidence of TPP appears to be increasing in the US, making early recognition of this disease in all populations increasingly important. In particular, differentiation of TPP from the more common familial hypokalemic paralysis is essential to ensure appropriate treatment. Triggers of TPP attacks can include high carbohydrate meals, stress or exercise. Immediate management should involve potassium repletion to prevent cardiac complications with monitoring due to risk of rebound hyperkalemia during recovery. A non-selective b-blocker can be used in acute treatment and for recurrence prevention until a euthyroid state can be achieved. Ultimate treatment should focus on treating the underlying etiology of hyperthyroidism. References: Kung, Annie WC. "Thyrotoxic periodic paralysis: a diagnostic challenge." The Journal of Clinical Endocrinology & Metabolism 91.7 (2006) Pothiwala, Pooja, and Steven N. Levine. "Analytic review: thyrotoxic periodic paralysis: a review." Journal of intensive care medicine 25.2 (2010)

CONCLUSION: Thyrotoxic periodic paralysis should be considered as a potential diagnosis in patients presenting with sudden weakness and hypokalemia. Hypokalemia in TPP should be repleted immediately but with close monitoring to avoid rebound hyperkalemia. Non-selective B-blockers can be used in prevention of recurrent attacks until euthyroid state has been achieved.

FOR GOOD MEASURE: EXPLORING IMMUNODEFICIENCY IN PATIENTS WITH CMV RETINITIS

Ryan Knodle. Boston Medical Center, Boston, MA. (Control ID #3184884)

LEARNING OBJECTIVE #1: Assess for alternative causes of immunodeficiency in non-HIV infected patients presenting with CMV retinitis

LEARNING OBJECTIVE #2: Recognize Good's syndrome as a potential diagnosis in patients with thymoma and "immunodeficiency-defining" illness

CASE: An 82-year-old HIV-negative Chilean man with history of thymoma and bilateral retinal ischemia presented with acute loss of visual

acuity in his left eye. He had been evaluated for an infectious cause of retinal ischemia two years prior and serologic work-up was negative for toxoplasmosis, tuberculosis, and syphilis, as was PCR testing of vitreous humor for varicella-zoster virus. He was lost to follow-up until the current presentation. His review of systems was negative for fever, weight loss, night sweats, headache, or diarrhea. On exam, he had mild conjunctivitis, equally reactive pupils, and grossly intact extraocular movements. His heart sounds were distant parasternally but normal at the apex. He had no lymphadenopathy. Ophthalmologic examination was concerning for occlusive vasculopathy and vitritis so paracentesis of the anterior chamber was performed and PCR confirmed the diagnosis of CMV retinitis. He was initiated on systemic ganciclovir and intravitreal foscarnet. Further investigation for immune deficiency was performed and he was found to be pan-hypogammaglobulinemic (IgA 54, IgG 183, IgM 13) with a relative CD4 lymphopenia (CD4% 18, CD4:CD8 0.31). He did not have clinical evidence of systemic disease and was transitioned to oral valganciclovir at the time of discharge. A diagnosis of Good's syndrome was made on the basis of thymoma with pan-hypogammaglobulinemia, relative CD4 lymphopenia, and an immunodeficiency-defining diagnosis.

IMPACT/DISCUSSION: Though CMV retinitis in the immunocompetent individual has been described, it is rare and should prompt clinicians to evaluate for causes of immunodeficiency. In the non-transplant, non-HIV-infected patient, this leaves the spectrum of primary immunodeficiency syndromes. In adults with thymoma, the differential must include Good's syndrome, an adult-onset combined B- and T-lymphocyte deficiency characterized by recurrent sinopulmonary infections from encapsulated organisms, as well as organ-specific viral infections. Laboratory findings include decreased B cells, pan-hypogammaglobulinemia, CD4 lymphopenia, and an abnormal CD4:CD8 ratio. Prognostically, the literature suggests poorer long term outcomes compared to patients with X-linked agammaglobulinemia or combined variable immune deficiency. Treatment of CMV infection is identical to that in HIV-infected persons; management of Good's syndrome should include resection of thymoma and IVIG. Though the average age of patients at diagnosis is 40-50, our patient (82) represents one of the oldest cases described in the literature.

CONCLUSION: CMV retinitis in immunocompetent patients is rare and should prompt investigation into causes of immunodeficiency. Good's syndrome should be considered in adults age >40 with thymoma and immunodeficiency.

FOR STROKE'S SAKE: VARICELLA ZOSTER VIRUS (VZV) VASCULOPATHY

Chengcheng Ye; Albert Anderson. Emory University, Atlanta, GA. (Control ID #3186006)

LEARNING OBJECTIVE #1: Emphasize stroke as a rare neurological complication of VZV

LEARNING OBJECTIVE #2: Recognize empirical treatment with acyclovir and prednisone for VZV vasculitis

CASE: A 49-year-old African American man with a history of HIV/AIDS (CD4 66/6%), hypertension, and VZV encephalopathy presented with progressive right sided weakness. He reported falls and dysarthria. He denied any fevers, chills, rashes, headaches, or visual changes. Examination revealed decreased strength and slowed coordination of the right arm and leg along with a right hemiparetic gait. MRI brain showed new subacute frontal lobe infarction and small left cerebellum infarctions. Transthoracic echocardiogram was normal. A cerebral angiogram demonstrated right posterior inferior cerebellar artery fusiform aneurysm and scattered segmental narrowing involving the mid to distal bilateral anterior and middle cerebral arteries concerning for vasculitis. Given his immunocompromised status, a lumbar puncture was performed with normal opening pressure. Studies revealed no pleocytosis, cerebrospinal fluid (CSF) protein of 45 mg/dL, normal CSF glucose, negative VDRL, HSV, JCV, CMV, toxoplasmosis, cryptococcus, and culture. Polymerase chain reaction (PCR) for VZV was

negative but was positive for VZV IgG and IgM, confirming intrathecal production of anti-VZV antibodies. Acyclovir and prednisone were started, and patient's right sided weakness and motor function improved. Patient finished a 14-day course of acyclovir and prednisone and was discharged on valacyclovir for suppressive therapy.

IMPACT/DISCUSSION: The classic presentation of VZV vasculopathy is acute contralateral hemiplegia after ophthalmic zoster. Although our patient had no ophthalmic or dermatomal zoster, these absences should not deter a physician from pursuing a diagnostic evaluation for VZV especially in an HIV patient. Up to one-third of patients with VZV vasculopathy have no preceding rash. Importantly, the diagnosis of this treatable cause of stroke is often missed because one-third of patients have no zoster rash, one-third have normal CSF, and there is often a four-month delay from zoster to neurological symptoms. Characteristic data include MRI findings consistent with an ischemic or hemorrhagic infarction, and angiography reveals large and small vessel disease. CSF pleocytosis of less than 100 cells/mL is common. Although a positive VZV PCR in the CSF is helpful, a negative PCR does not exclude the diagnosis. Only if both VZV PCR and VZV IgG antibody are negative can VZV vasculopathy be reliably excluded. Treatment for both immunocompetent and immunocompromised patients include acyclovir and prednisone for inflammation.

CONCLUSION: Clinical suspicion should be high for VZV vasculopathy as a cause of stroke especially in an immunocompromised patient. A negative CSF VZV PCR does not exclude the diagnosis, and early therapy should be initiated for this reversible cause of stroke.

FORGOTTEN, BUT NOT GONE: A CASE OF LEMIERRE'S SYNDROME: THE FORGOTTEN DISEASE

Margaret V. Spinoso; Twomey Kathleen; Fidelis Ojewwe. Penn State Hershey Medical Center, Palmyra, PA. (Control ID #3186019)

LEARNING OBJECTIVE #1: Recognize Lemierre's Syndrome as a potentially life-threatening illness if left untreated.

LEARNING OBJECTIVE #2: Assess for multiorgan complications easily missed as features of Lemierre's Syndrome.

CASE: A 25 year old woman with neurofibromatosis presented with one day of nausea, vomiting, headache, diplopia and one month of sore throat and right ear pain. On physical examination, she was found to be hypotensive and tachypneic. She was unable to laterally abduct her right eye and her tongue deviated to the right with protrusion. She had an erythematous right tympanic membrane with effusion, bibasilar crackles and suprapubic tenderness. Initial laboratory studies were normal. Brain MRI and CT chest, abdomen and pelvis were ordered. Imaging revealed thrombosis of the right internal jugular vein extending into the right sigmoid, distal transverse and cavernous sinuses and inflammation of the internal carotid artery sheath. Right petrous apicitis, mastoid and middle ear fluid also was seen. Abdominal imaging showed a larger heterogenous pelvic mass. Chest imaging showed bilateral cavitating pulmonary lesions. An echocardiogram was notable for a small PFO and admission blood culture resulted positive for *Fusobacterium necrophorum*. The patient was examined with nasal laryngoscopy and found to have purulence in the Eustachian tub orifice and fullness of the right adenoid pad. She was treated with IV ampicillin-sulbactam. Interventional Radiology biopsied the pelvic mass which was notable for soft tissue inflammation with microabscesses and purulent exudate with no evidence of malignancy or neurofibroma. She completed a prolonged course of antibiotics and was started on anticoagulation due to extent of thromboses in her sinuses.

IMPACT/DISCUSSION: This case illustrates the potential for multiorgan consequences of Lemierre's Syndrome caused by *Fusobacterium necrophorum*, an anaerobe commonly found in the oropharynx and spread by septic thrombophlebitis of the internal jugular vein. Often a result of pharyngitis, in this case the inciting infection was likely acute otitis media. While septic emboli to the lung are a more

common feature of this Syndrome, the patient's pelvic mass may have been a result of septic emboli due to presence of small patent foramen ovale. The development of neurologic symptoms, due to the extensive involvement of the venous sinuses, could be misdiagnosed as a primary neurologic process. Lemierre's Syndrome is now regarded as a rare occurrence due to the timely treatment of oropharyngeal infections. However, with increasing antibiotic resistance and lack of awareness of the diagnosis, a resurgence of Lemierre's Syndrome may be seen in the future.

CONCLUSION: Lemierre's Syndrome is an easily missed diagnosis due to providers unfamiliarity with Fusobacterium infections. Atypical presentations of this Syndrome may delay appropriate therapy. Systemic involvement without early treatment is potentially life-threatening.

FRIEND OR FOE? A CASE OF IMMUNOTHERAPY-INDUCED HYPOPIITUITARISM AND EMPTY SELLA SYNDROME

Jeremy Chang¹; Jeffrey Tran¹; Dina Kamel²; Arnab Basu². ¹LAC+USC, Wilmington, CA; ²LAC + USC, Los Angeles, CA. (Control ID #3180700)

LEARNING OBJECTIVE #1: Recognize that the use of novel treatments such as immune checkpoints inhibitors (ICIs) can lead to a wide spectrum of adverse effects, including endocrinologic complications.

CASE: A 63-year-old Caucasian woman with history of stage IVA lung adenocarcinoma presented for worsening fatigue. Her symptom started 2 weeks prior to admission with associated non-productive cough, myalgias, and multiple episodes of non-bloody, non-bilious emesis. She was previously started on the immune therapy nivolumab 1 year ago for treatment of her cancer. Infectious work-up on admission including cultures and imaging were unremarkable. Subsequently, several hormonal tests were ordered to evaluate for an endocrinologic etiology of her symptoms. The results were significant for a low TSH of <0.01 mIU/L, low free T3 of 1.1 ng/dL, low free T4 of 2.4 ng/dL, low morning cortisol level of 5.6 µg/dL, and appropriately normal adrenocorticotrophic hormone (ACTH) of 8 pg/mL. An MRI of the sella was performed which showed a partially empty sella without evidence of any pituitary lesion. These findings were consistent with hypopituitarism leading to adrenal insufficiency and primary hypothyroidism. The patient was started on oral hydrocortisone 20 mg in the morning and 10 mg at night with rapid improvement in her symptoms. On discharge, she was prescribed oral prednisone 80 mg per day with a taper until follow-up with endocrinology.

IMPACT/DISCUSSION: The use of ICIs in the treatment of malignancies represents a monumental advancement in cancer therapy. However, the use of immunotherapy has also led to a wide range of adverse effects of varying severities. Endocrine toxicities occur infrequently during ICI use, but can include adrenalitis and thyroid dysfunction. Hypophysitis is an overall rare condition that refers to inflammation of the pituitary gland. While many subtypes were previously identified including lymphocytic, granulomatous, and plasmacytic, hypophysitis secondary to immunotherapy has emerged as a more recent etiology. Nivolumab-induced hypophysitis is an exceedingly rare phenomenon, occurring in <1% of patients in several prior studies. The results of our patient's hormonal work-up indicated that her hypophysitis resulted in hypopituitarism with associated adrenal insufficiency and hypothyroidism. In addition, the presence of a partially empty sella on MRI was consistent with a secondary empty sella syndrome following the pituitary inflammation.

CONCLUSION: Given the potential complications of immunotherapy including hormonal dysfunction, it is crucial for practitioners to be aware of possible adverse effects when managing patients on novel therapies.

FROM CLINIC TO THE CCU: A COMMON VIRAL SYNDROME WITH UNCOMMON MANIFESTATIONS

Anne G. Montgomery, UCSF, San Francisco, CA. (Control ID #3186010)

LEARNING OBJECTIVE #1: Recognize the clinical features of myocarditis and myopericarditis.

LEARNING OBJECTIVE #2: Understand the necessary outpatient follow up for a patient with myocarditis.

CASE: A 32 year-old woman with no medical history presented to clinic with one week of flu-like symptoms and progressive myalgias. Her exam was notable for pronounced tenderness of the bilateral calves without rash, swelling, or weakness. Initial blood tests revealed a leukocytosis to 15.8, creatine kinase of 735, CRP of 284, and creatinine of 0.93 (her baseline). Given concern for a viral myositis, the patient was instructed to stay hydrated and return for repeat labs in 48 hours. Prior to follow-up, the patient called the clinic to report fever and the onset of mild pleuritic chest pain. She was instructed to present to the Emergency Department where an EKG revealed ST-segment elevation in leads I, II, and V1-V3 with depressions in II, aVR, and V1. A troponin was elevated at 4.65, and a transthoracic echocardiogram showed a small pericardial effusion and possible wall motion abnormalities. She underwent urgent coronary angiography, which showed no evidence of disease, but given concern for rapid progression of myocarditis, she was admitted to the CCU for further monitoring. Fortunately, she remained hemodynamically stable, and over the next several days her myalgias and inflammatory markers improved. She was discharged on a low-dose ACE inhibitor and beta-blocker with instructions to follow up with her primary care provider.

IMPACT/DISCUSSION: This case highlights the fact that the initial presentation of myocarditis and myopericarditis can be overshadowed by a patient's viral symptoms. Because myocarditis can rapidly progress to depressed cardiac function and even cardiogenic shock, it is important to recognize its early manifestations. In 80-90% of cases of pericarditis and myocarditis, the etiology is idiopathic and presumed to be viral in nature. These cases are often preceded by days to weeks of vague viral symptoms. Patients may have chest pain, and those with myocardial involvement will have elevated cardiac enzymes and/or evidence of depressed left ventricular function. Those with evidence of depressed left ventricular systolic function should be started on guideline-directed heart failure therapy once stable and followed closely in the outpatient setting. While this patient was overall well-appearing during her first outpatient visit even with markedly elevated inflammatory markers, the development of mild chest pain prompted the clinician to triage her more rapidly to the Emergency Department. She ultimately required ICU-level care for what started as a viral syndrome.

CONCLUSION: Myocarditis can start slowly as a subtle viral syndrome and progress rapidly to hemodynamic instability. All patients with evidence of myocarditis require inpatient admission and close outpatient follow up.

FROM JAIL TO HOSPICE CARE

Libia M. Vasquez¹; Lucy M. Esteve²; Carolyn April³. ¹University of Texas Health Science Center San Antonio, San Antonio, TX; ²UT Health San Antonio, San Antonio, TX; ³University of Texas Health Science Center at San Antonio, San Antonio, TX. (Control ID #3139820)

LEARNING OBJECTIVE #1: Recognize the barriers incarcerated patients face in a health care system

LEARNING OBJECTIVE #2: Recognize "rule of rescue" (perceived duty to save endangered lives) practices do not result in better patient outcomes

CASE: A 61-year-old woman presented from county jail with nausea and vomiting for a week. In addition to dysuria, PO intolerance, chills, and abdominal pain. Urine and blood cultures grew E. Coli. She had bipolar disorder, type 2 diabetes, and hypertension. She lost 40-pounds in four months from early satiety and regurgitation after meals. EGD showed a friable mass at the GE junction, biopsy with poorly differentiated adenocarcinoma with signet cells. A week after diagnosis of GE cancer, she was compassionately released from the jail unit and moved to a regular floor. She was hospitalized for two months completing CT scans, PET scan, and diagnostic laparoscopy. She was diagnosed with stage IIa GE adenocarcinoma and was discharged to a homeless shelter with a 3-month supply

of a nutritional drink unable to eat solid food. A couple months later, after reinstating Medicaid, she returned to the emergency department with similar symptoms. She was restaged, including laparoscopy, and esophageal stent was placed. Two weeks later additional imaging was requested in clinic. A month later, homeless and uninsured, she returned to the hospital. After her clinic appointment, she expected her chemotherapy to begin during hospitalization. CT scan of the chest showed numerous sclerotic foci throughout her vertebra. She was diagnosed with metastatic disease and was discharged to a nursing home with hospice care.

IMPACT/DISCUSSION: Her physicians, abiding by the "rule of rescue", ensured her cancer was diagnosed, staged and a treatment plan was formulated. Completing this work up as an inpatient was costlier than outpatient. A more constructive way of advocating is by working on resolving the barriers that result in an inability to access. Physicians cannot eliminate all barriers, mental health or homelessness, but adjusting the health care system for timely access would be less costly and effectively "rescue" patients.

CONCLUSION: This case is an example of inequity and a complicated wasteful health care system. A health care system in the Bronx created transition clinics for patients post-incarceration to prevent lack of health care after release. Prompt follow up would have prevented multiple hospitalizations and set up an easier path for her to follow. It is shown that much like in this case, treatment received during incarceration loses effect after release since patients are unable to receive continuous health care. Invasive diagnostic procedures directed by advocating physicians led to a treatment plan that never began. It is our duty as physicians to not only advocate when patients are under our care but assist in creating policies for improved health care access. This patient had curable cancer with a clear treatment plan but ended up with a terminal illness because of a failing system.

FROM ORATOR TO NON-VERBAL: A RARE CASE OF COGNITIVE DECLINE

Saima M. Shikari; Chelsea Gordner; Aboorva Sudhakar. Baystate Medical Center, Springfield, MA. (Control ID #3186407)

LEARNING OBJECTIVE #1: Recognize Hashimoto's Encephalopathy (HE) as a differential in patients cognitive function decline

LEARNING OBJECTIVE #2: Recognize need for urgent steroid treatment to prevent permanent cognitive deficits

CASE: A 61 year old female with past medical history of hypothyroidism and sickle cell disease who presented with 4 months of progressive memory loss, weakness intermittent nausea, vomiting and extreme fatigue after eating. GI workup including EGD, colonoscopy and labs for autoimmune inflammatory hepatic conditions were negative. Infectious disease and neurology were consulted and had ruled out tick borne illness, West Nile virus and paraneoplastic syndrome when she had rapid decline in cognitive function. At baseline patient was a college professor, within 3 days of admission she was unable to follow commands, non-verbal, incontinent, hallucinating and persistently drooling. EEG was abnormal due to excessive slowing and repetitive slow sharp transients and given the differential of Creutzfeldt-Jakob Disease LP was performed but CSF analysis showed no acute pathology. Due to persistent tachycardia and history of hypothyroidism, thyroid studies showed TSH 0.05, Free T4 2.82 and Free T3 7.2. Endocrinology was consulted and ordered Thyrotropin receptor Ab <1.00 and Anti-TPO Ab 869.7 leading to suspicion for HE. High dose steroids were started with rapid improvement in mental status within 24 hours and return to baseline in 3 days.

IMPACT/DISCUSSION: Hashimoto's Encephalopathy is a steroid responsive encephalopathy associated with autoimmune thyroiditis. It's estimated prevalence is 2:100,000 patients, with the majority being females in their 50s-60s. The underlying pathogenesis is unknown but presentation is divided into two subsets. Subacute is described as multiple remitting and relapsing episodes of mental decompensation often accompanied by seizures. Chronic is described as a slower, gradual onset of

cognitive decline, confusion and hallucinations with a subset of patients having rapid decline into coma. HE remains a diagnosis of exclusion with exact diagnostic criteria not established. However, four main features are accepted; encephalopathy associated with cognitive dysfunction and psychiatric features, presence of high titer anti-TPO Ab, exclusion of neurological disease and rapid response to steroid treatment. Of note, so far there does not appear to be a link between the severity of hypothyroidism or antibody levels and severity of HE. Literature review describes a percentage of patients left with permanent cognitive deficits therefore early treatment should be encouraged. Cases of reversible dementia are likely being missed due to lack of awareness of HE. This should be on the differential for patients presenting with cognitive decline.

CONCLUSION: - HE is a diagnosis of exclusion - Early initiation of therapy can prevent permanent cognitive deficits. - Severity of hypothyroidism does not correlate with severity or speed of onset of HE.

FROM OVERDOSE TO BUPRENORPHINE INTAKE IN UNDER ONE HOUR!

Alessandra Calvo-Friedman³; Meredith Lynn¹; Angela Arbach¹; Kathleen Hanley²; Sondra Zabar³. ¹New York University, New York, NY; ²NYU, New York, NY; ³NYU School of Medicine, New York, NY. (Control ID #3179270)

LEARNING OBJECTIVE #1: Recognize and manage opioid overdose in a community health center setting

LEARNING OBJECTIVE #2: Improve linkage to effective treatment for opioid use disorder after overdose

CASE: A 54 yo man was found unresponsive at the door of our community health center. Rapid Response was called and the patient was found to be unresponsive to sternal rub, with 6 breaths per minute, and pinpoint pupils. One dose of 4mg of intranasal naloxone was administered, and soon the patient was alert and oriented. He declined transfer to the ED but was amenable to observation, stating that he had just purchased his usual 3 bags and used them outside of his primary care clinic. His PMH was notable for 36 years of IV/intranasal heroin use, prior stroke, GERD, glaucoma, hyperlipidemia, lumbar radiculopathy, and tobacco use. He had one overdose in the 1990s, attempted detox several times and tried self-treating himself with methadone and buprenorphine. He lived with his girlfriend and was unemployed. His medications included cyclobenzaprine and ranitidine. The medical assistant from our addiction medicine clinic engaged the patient, who reported that the overdose scared him, and offered medication treatment which he accepted. The addiction clinic nurse and physician saw the patient that day and gave an initial buprenorphine prescription, instructions and follow-up appointment. He is now stable on buprenorphine 8mg daily.

IMPACT/DISCUSSION: The overdose described in this case represents one of three overdoses in the past month at our NYC health center. Urban health centers often serve as community hubs and may be seen as a safer place to use opioids. Overdoses at community health centers represent an important point of patient engagement in treatment for OUD. Treatment with opioid agonist therapy after overdose has been shown to reduce all-cause and opioid-related mortality. However, only a small percentage of patients receive medication therapy after overdose. (Larochelle et al. Annals of Internal Medicine. 2018) Initiation of medication treatment for OUD at the time of ED presentation has also been shown to improve engagement in treatment. (DONOFRIO et al. JAMA 2015.) Institutional commitment to training all providers and staff to recognize the signs of opioid overdose and administer intranasal naloxone has direct impact on patient outcomes. Our experience with this case has demonstrated the importance of immediate engagement in care at the time of overdose. Having a team available at the time of overdose that cares for patients with addiction enabled us to quickly engage this patient in care and start medication therapy when he felt most receptive to treatment.

CONCLUSION: Our case demonstrates two crucial steps for improving outcomes in opioid overdose: widespread availability of and training for intranasal naloxone use, along with community health sites equipped to treat patients with opioid use disorder at the time of overdose.

FROM PSEUDOHYPOLYCEMIA TO DIABETIC KETOACIDOSIS

Saliha Saleem; Ejaz Shah; Syed Maisam Abbas; Colette Knight. Montefiore Medical Center, Bronx, NY. (Control ID #3186254)

LEARNING OBJECTIVE #1: Recognizing peripheral arterial disease (PAD) as possible etiology of pseudohypoglycemia

LEARNING OBJECTIVE #2: Consider alternate sites/methods for glucose testing in patients with suspected pseudohypoglycemia

CASE: 76 year-old man with Diabetes mellitus, Peripheral Arterial Disease (PAD), Dementia was sent from Nursing Home (NH) to Emergency department (ED) for hypoglycemia (28 mg/dl) and altered mental status. He was given 50% Dextrose (D50) and glucagon injection in NH but continued to have recurrent hypoglycemia. In ED he was given D50 again, but his finger sticks remained less than 40 mg/dl. He was otherwise hemodynamically stable. On examination he was less alert from his baseline and had decreased pulses in both upper extremities. Initial labs drawn in ED from a peripheral vein revealed Bicarbonate 12 meq/l, Anion Gap 24, Blood Glucose level 604 mg/dl, White count 17k and Ph 7.17. Chest X-ray was consistent with pneumonia. He was started on insulin drip, intravenous fluids and antibiotics. Point of care (POC) site was changed from fingers to right shoulder; subsequent readings were found to be parallel to venous blood glucose readings. Within 24 hours he was transitioned to subcutaneous insulin regimen. His prior records showed evidence of PAD in both upper extremity vessels. Patient clinical status improved back to baseline.

IMPACT/DISCUSSION: Pseudohypoglycemia can be caused by Hypovolemic shock, Hypothermia, Raynaud's, Leukemia, and Polycythemia. PAD affects millions of people in United States, yet only one published case report identifies it as a cause of pseudohypoglycemia. Although PAD most commonly affects lower extremity arteries, it is not uncommon for upper extremities to also be involved. The pathophysiology of pseudohypoglycemia in PAD is almost same as for Raynaud and hypovolemic shock: decreased blood flow. [KS1] Atherosclerotic plaque formation decreases the blood flow to the respective extremity and digital microcirculation, blood stays in the capillary bed for a longer period, increasing glucose consumption, leading to finger stick glucose reading to be abnormally low. Capillary blood glucose measurement from finger tips is the main tool for the checking blood glucose levels. Other sites that can be used for POC glucose monitoring include palm, forearm, upper arm and thigh. These sites are especially useful when finger tips may be considered unreliable. Venous/arterial blood glucose measurement is the most reliable method for an accurate blood glucose reading. In cases of severe hypo/hyperglycemia, this reading should always be validated by alternate measures before aggressive management for hypo/hyperglycemia is initiated.

CONCLUSION: Pseudohypoglycemia should be considered whenever a low POC glucose is encountered. Use of alternate sites for POC glucose testing and checking venous/arterial blood samples can help differentiate between a true and pseudohypoglycemia.

FUNCTIONAL CARCINOID TUMOR ASSOCIATED WITH POLYCYTHEMIA VERA: A RARE DIAGNOSIS AND CHALLENGING MANAGEMENT DILEMMA

Shawnt Tosonian¹; Zenia Sattar². ¹Eisenhower Medical Center, Glendale, CA; ²Eisenhower Health, Rancho Mirage, CA. (Control ID #3181675)

LEARNING OBJECTIVE #1: Recognize association of NET and polycythemia

LEARNING OBJECTIVE #2: Identify risks of thrombosis management in this condition

CASE: A 69-year-old woman with duodenal neuroendocrine tumor (NET) and alcoholic cirrhosis presented with diarrhea. NET had been diagnosed 3 months prior, after 2 years of unexplained isolated diarrhea. Endoscopic ultrasound (EUS) had shown a submucosal lesion, with immunohistochemistry of well-differentiated NET (carcinoid tumor). She had no metastases nor functional hormonal syndrome. One week prior to admission, she developed new nocturnal diarrhea, abdominal pain, vomiting, cutaneous flushing, diaphoresis, and pruritis. On admission, vitals were normal; labs showed WBC 16.1 K/uL and Hgb 19 g/dL. Abdominal CT (Fig 1) revealed duodenal enteritis and cirrhotic liver. Her presentation and labs [Table 1] suggested carcinoid crisis. Octreotide scan (Fig 2) revealed regional node metastasis. Symptoms improved with octreotide therapy and antacids, but facial plethora, pruritis, polycythemia, and leukocytosis persisted. Low serum erythropoietin indicated primary polycythemia vera (PV), confirmed by JAK2 mutation [Table 1]. She started therapeutic phlebotomy and cytoreductive hydroxyurea. Lower extremity DVTs were found, so enoxaparin was started, leading to large volume melena requiring emergent endoscopy. EGD showed bleeding from multiple duodenal ulcers and the ulcerated NET (Fig 3). Embolization of the gastroduodenal branch artery of the ulcer controlled the bleed; IVC filter was placed. With cirrhosis and low functional performance, she was deemed a poor surgical candidate. She was discharged and recovered well on outpatient follow up.

IMPACT/DISCUSSION: Carcinoid tumors have an age-adjusted incidence of 4.7/100,000. Increasing incidence in recent decades is likely due to improved detection. Most tumors are in the small intestine, with less than 3% of cases duodenal; only 5-7% exhibit hormonal production. Only two cases of carcinoid tumor have been associated with PV, one of which was also duodenal. Polycythemia is felt to be secondary; an association between NETs and primary polycythemias has not been established. Active functional carcinoid tumors with polycythemia have not been previously reported. Overlapping clinical manifestations of carcinoid syndrome and PV include facial plethora, pruritis, epigastric distress, and diarrhea; distinguishing these entities is difficult. Lab features can be misinterpreted; in our case, polycythemia and leukocytosis were attributed to hemoconcentration from diarrhea. Management is complicated by increased risk for thrombotic events, given malignancy and hyperviscosity. Risk for hemorrhage is also high, given carcinoid gastrin production.

CONCLUSION: Our case suggests an association between NET and polycythemia. Balancing thrombosis and hemorrhage risks is individualized; care should include multidisciplinary teams with use of serial gastrin levels, IVC filter, and early surgical evaluation.

GASTROINTESTINAL AL-AMYLOIDOSIS PRESENTING AS PROTEIN LOSING ENTEROPATHY

kavya Kelagere Mayigegowda; Rinad Tabbalat; Aditya Kalakonda. Baystate Medical Center, Springfield, MA. (Control ID #3187027)

LEARNING OBJECTIVE #1: Physicians should consider gastrointestinal amyloidosis in their differential when patients present with diarrhea and unexplained hypoalbuminemia.

LEARNING OBJECTIVE #2: Understanding the pathophysiology of different clinical syndromes seen in gastrointestinal amyloidosis.

CASE: 82-year-old male with a history of CKD stage III and prostate cancer in remission presented with a four month history of worsening lower extremity edema, abdominal pain and watery diarrhea. Initial laboratory work-up was significant for a serum albumin of 2.0 and a normocytic anemia with hemoglobin of 7.5 gm/DL. A stool infectious work-up to include Clostridium difficile was negative. A CT scan of the abdomen done on admission showed pan-colonic wall thickening suggestive of colitis and mild abdominal ascites. Colonoscopy showed diffuse continuous abnormal vascularity, congestion, erythema, friability,

inflammation and ulceration throughout the colon compatible with severe colitis. Biopsy showed diffuse mucosal and submucosal amyloidosis with a positive Congo red stain. Serum electrophoresis showed IgG kappa and lambda monoclonal gammopathy with elevated free lambda chain. Subsequent bone marrow biopsy showed plasma cell neoplasm with involvement of 9% of plasma cells and evidence of focal amyloid deposits. This was consistent with systemic AL light chain amyloidosis with likely lambda light chain deposition. Further work-up was done to evaluate for other organ involvement. Cardiac MRI showed minimal cardiac involvement and there was no evidence of proteinuria on urine analysis. Patient was initiated on chemotherapy with bortezumib and dexamethasone.

IMPACT/DISCUSSION: Clinical syndromes in gastrointestinal AL and AA amyloidosis are different due to the unique patterns of tissue involvement. AA amyloidosis causes Mucosal infiltration of amyloid protein, leading to diarrhea and malabsorption syndromes, while the muscularis mucosal deposition of AL amyloid often presents with constipation or pseudo-obstruction. Contrary to routine findings, our case of gastrointestinal AL amyloidosis presented with diarrhea and protein losing enteropathy. Mucosal erosions or ulcerations and submucosal hematomas are the most common endoscopic findings. The gold standard for diagnosis is with a biopsy with Congo red staining. The treatment of AL amyloidosis includes high-dose chemotherapy and hematopoietic stem cell transplantation. Patients with AL amyloidosis with gastrointestinal involvement have poor prognosis. Chemotherapy causes suppression of plasma cell clones and reduces the concentration of toxic light chains by suppression of plasma cell clones. This is necessary to improve organ function and prolong survival.

CONCLUSION: Physicians should consider gastrointestinal amyloidosis in their differential when patients present with diarrhea and unexplained hypoalbuminemia as prompt recognition and treatment is crucial.

GASTROINTESTINAL BERIBERI CAUSES REFRACTORY LACTIC ACIDOSIS

Zachary S. Bugos; Fnu Abhishek. UPMC Mercy, Etna, PA. (Control ID #3185860)

LEARNING OBJECTIVE #1: Recognize various causes of lactic acidosis

LEARNING OBJECTIVE #2: Identify major risks for thiamine deficiency

CASE: 44yo F w/PMHx of EtOH abuse presented to ED w/ emesis. Pt reported 4d drinking binge w/ unknown amount of vodka. By d5, she had episodes of non-bloody bilious emesis. Denied fever, chills, abd pain, diarrhea, sick contacts. While in ED, vitals 36.6°F, BP 137/59, HR 128, RR 19 satting 98% on RA. Labs revealed AG 32.4, bicarb 17, Cr 1.61 (baseline Cr 0.4); mild LFT abnormalities, unremarkable lipase and PT/ INR of 21.8/1.9; leukocytosis & plt 570. UA, UCx, UDS & ethanol were all unremarkable. Pt had persistent bilious emesis & tachycardia. Received 2L NS + GI cocktail. With concern for sepsis, a lactate returned at 6.6. Pt started on D5NS + 20mEq KCl at 75cc/hr. Admitted to floors for AKI & IVF resuscitation. Following AM, pt reassessed s/p 3L IVF, appearing better w/ minimal nausea. K 2.9, AG 17.9, AKI improved w/ down-trending creatinine to 1.31. Repeat lactate still elevated to 6.6. Management revolved around EtOH keto-acidosis, however did not explain persistent hyperlactatemia. Over next 2d, lactate stayed elevated to 5.3, 5.0 and 4.0 despite receiving 7L IVF over 3.5d. By HD4, pt was asx w/ near normals lytes and resolved AKI except for refractory hypokalemia and hypomagnesemia. With suspicion for rare causes of lactic acidosis, thiamine level found to be non-existent (lab value <6; range 8-30nmol/L). Thiamine 500mg IV was given and lactate ~12hrs later normalized to 1.5. Dx of thiamine deficiency causing persistent lactic acidosis was made, and pt d/c home the following AM with thiamine.

IMPACT/DISCUSSION: Hyperlactatemia, a common occurrence in critically ill pts, results from accumulation of lactate d/t impaired mitochondrial

oxidation. Lactate is a marker of illness severity, higher levels correlate w/ worse outcomes. Elevated lactate is generally attributed to tissue hypoperfusion, however other causes of cell dysfxn can result in high levels, such as infection, liver dysfunction, severe trauma, uncommon ADRs & in this rare case, d/t thiamine deficiency Vitamin B1, aka thiamine, is a cofactor for enzymes involved in metabolism & biosynthesis of neurotransmitters. Thiamine deficiency is a clinical dx, as direct serum measurements are not indicative of thiamine status, as only 0.8% of total body stores are present in blood. Elevated blood pyruvate & lactate measurements can be useful, however false positives in setting of sepsis & cardiogenic shock are associated w/ lactic acidosis, imitating thiamine deficiency. Refractory lactic acidosis s/p glucose load supports dx of thiamine deficiency, making it more practical to give thiamine & monitor for response.

CONCLUSION: Lactic acidosis is used to describe accumulation of lactate, a surrogate marker for hypo-perfusion & cell dysfxn Major causes of elevation are attributed to hypovolemic states, sepsis or poor clearance (i.e. renal or liver failure) Thiamine, aka Vitamin B1, when deficient, causes lactic acidosis refractory to fluid resuscitation

GENERAL PARESIS: A FORGOTTEN PSYCHIATRIC SYNDROME OF NEUROSYPHILIS

Joseph Boyle¹; Kelly White². ¹University of Colorado SOM, Denver, CO;

²University of Colorado SOM, Aurora, CO. (Control ID #3150083)

LEARNING OBJECTIVE #1: Recognize and diagnose neurosyphilis

LEARNING OBJECTIVE #2: Recognize emergent psychiatric symptoms may be due to neurosyphilis

CASE: A 61-year-old woman with a history of CIN I, seasonal allergies, low back pain, and homelessness presented to primary care clinic with 3 years of worsening mood lability, paranoid delusions, and increasingly confrontational behavior toward staff with frequent missed appointments. Attempted referrals to psychiatric care were unsuccessful and an accurate psychiatric diagnosis remained elusive. At a subsequent appointment, she complained of tingling pain in her hands and feet, but declined lab testing. Months later she presented with a new chronic headache and a c-spine CT report from an outside ED showing diffuse cervical lymphadenopathy. At that time, she agreed to testing and was found to have positive RPR, with normal CBC, TSH, B12, and negative HIV Ab. Confirmatory testing showed a positive serum Treponema Ab, and LP showed 46 lymphocytes and positive VDRL. There were no notable neurological findings or palpable lymphadenopathy. The patient denied sexual contact for more than 20 years, and abstinence had been documented in the chart for at least 6 years. She was admitted to the hospital for treatment with IV penicillin. At the time of admission her MOCA was 23. She will be followed with serial cognitive exams, psychiatric evaluations, and CSF studies to document remission.

IMPACT/DISCUSSION: It is known that syphilis can go undiagnosed in the early stages before entering a long latent period. Screening recommendations exist for at risk populations including MSM and HIV+ individuals.¹ US prevalence is increasing to 31/100,000 since nadir in the year 2000.² Only a small minority of cases are in women. Late symptoms were thought to have been largely eliminated since the antibiotic era but the psychiatric symptoms are frequently misdiagnosed.³ Late manifestations of syphilis include skin changes, neurological findings: including headache, psychiatric symptoms, and finally, dementia. The psychiatric symptoms are classically named general paresis, which can include emotional lability, memory deficits, and psychosis⁴, as seen in this patient. Diagnosis of neurosyphilis is made by CSF with increased lymphocytes and either Treponema Ab or VDRL. VDRL is more sensitive than RPR on CSF.⁵ The goal of treatment for general paresis is to halt progression to dementia, but reversal of symptoms is uncommon.⁶ 1. CDC, 2016. 2. CDC, 2017. 3. Yanhua W, BMC Psychiatry. 2016;16(1):1-6. 4. Mattei PL, Am Fam Physician. 2012;86(5):433-440. 5. Marra CM, Sex Transm Dis. 2012;39(6):453. 6. Hook EW. Syphilis. Lancet. 2017;389(10078):1550-1557. Ref abbrev due to space limits.

CONCLUSION: Neurosyphilis may cause significant morbidity, and can be extremely challenging to diagnose. Consideration must be given to this important and potentially treatable cause of memory loss, psychiatric symptoms, and personality changes in all patients, not just those known to have an increased risk or known history of syphilis.

GETTING TO THE HEART OF THE MATTER: A CASE OF SERONEGATIVE ANTIPHOSPHOLIPID SYNDROME

Sonia D. Silinsky Krupnikova; Linda Yue; Jeffrey Tefft; Rodolfo Curiel. The George Washington University, Washington, DC. (Control ID #3179062)

LEARNING OBJECTIVE #1: Recognize seronegative antiphospholipid syndrome as a distinct clinical entity.

CASE: A 52-year-old gentleman with past medical history of lupus nephritis, non-ST-elevation myocardial infarction, venous thromboembolism (on anticoagulation), and peripheral vascular disease requiring arterial bypass grafting presented to the hospital with two days of left toe pain, fever and chills. Physical examination demonstrated gangrenous changes of the left second toe as well as nontender, nonblanching erythematous macules and patches along the plantar surface of the foot. Laboratory evaluation revealed prolonged partial thromboplastin time and elevated inflammatory markers without leukocytosis. Infectious serologies and final blood cultures were negative. Hypercoagulability studies, including antiphospholipid antibody titers and lupus anticoagulant, were normal. On imaging, he was found to have a patent bypass graft but was noted to have a 2.5-cm vegetation on the tricuspid valve. He had no atrial septal defect. Intravenous antibiotics were initiated for four weeks without resolution, and the patient underwent surgical tricuspid valve replacement and toe amputation. Intraoperative pathology was notable for sterile vegetation and toes with arterial thrombus but no vasculitis nor organisms on Gram stain or final culture.

IMPACT/DISCUSSION: Antiphospholipid syndrome (APS) is a hyper-coagulable state which often occurs secondary to systemic lupus erythematosus (SLE). The diagnostic criteria for APS require the presence of at least one clinical and one laboratory criterion. Clinical criteria include vascular thrombosis or pregnancy morbidity and laboratory criteria include the presence of lupus anticoagulant, anti-cardiolipin, or anti- 2-glycoprotein. APS also predisposes to the development of sterile thrombotic Libman-Sacks endocarditis, which most commonly affects the mitral valve. Seronegative APS (SN-APS) is diagnosed when clinical criteria are met but serologic testing is persistently negative. Testing must be performed outside the contexts of acute thrombosis and treatment with anticoagulation, as these conditions can cause a transient loss or consumption of antiphospholipid antibodies. This patient's case was unusual for several reasons. His Libman-Sacks endocarditis was located on the tricuspid valve, a rare presentation. Moreover, his toe ischemia was the result of an arterial thrombus rather than embolism or ischemia from graft stenosis. Given his extensive history of hypercoagulability in the setting of known SLE, thrombosis secondary to SN-APS was the unifying diagnosis.

CONCLUSION: APS is a hypercoagulable state associated with SLE. It confers increased risk of developing Libman-Sacks endocarditis as well as peripheral thrombotic events which may mimic other clinical entities such as limb ischemia or embolism. SN-APS is a clinically important diagnosis to consider in patients with clinical manifestations of the syndrome but persistently negative serology.

GLYCOGENIC HEPATOPATHY: AN UNDERRECOGNIZED CAUSE OF HEPATOMEGALY

Jessica Sang. Carolinas Medical Center, Charlotte, NC. (Control ID #3186268)

LEARNING OBJECTIVE #1: Recognize that elevated plasma lactate levels can be part of the clinical presentation of glycogenic hepatopathy

LEARNING OBJECTIVE #2: Review methods to distinguish GH from non-alcoholic fatty liver disease (NAFLD)

CASE: An 18-year-old female presented to the hospital after three-days of nausea, vomiting, and abdominal pain. She had a history of uncontrolled type 1 diabetes mellitus (HbA1c: 11.7%) diagnosed at age 12 with recurrent hospital admissions for diabetic ketoacidosis (DKA). Her medications included insulin detemir 10 units daily and a 1:10 insulin to carbohydrate ratio of insulin aspart with meals. She reported non-bloody emesis and continuous right sided abdominal discomfort. On physical examination she was tachycardic. She had a distended abdomen that was moderately tender in the right upper and lower quadrants with palpable liver edge. Conjunctival icterus and jaundice were not present. Initial labs revealed: ALT 42 IU/L, AST 54 IU/L, INR 1.3, total bilirubin 0.6 mg/dL, alkaline phosphatase 90 IU/L, anion gap 19 mmol/L, glucose 1,060 mmol/L, lactic acid 8.9 mmol/L, and urine ketones. CT abdomen and pelvis showed hepatomegaly. The liver measured 23.4 cm in length and extended to her left upper quadrant. No liver masses were visualized. Given the patient's history, lab results, and imaging the diagnosis highest on the differential for her hepatomegaly was glycogenic hepatopathy (GH) from poorly controlled diabetes. Both DKA and GH were treated with glycemic control. Her elevated lactic acid slowly trended down and she was discharged with close hospital follow-up.

IMPACT/DISCUSSION: GH is a complication of poorly controlled diabetes mellitus characterized by transient liver dysfunction with elevated liver enzymes.¹ Patients with GH can be asymptomatic or can present with abdominal pain, hepatomegaly, recurrent DKA, and elevated lactate levels.¹ Lactic acidosis can be present in patients even if they are not in DKA.² The pathophysiology is not well understood. One hypothesis is that the reduction in gluconeogenesis and lack of conversion of pyruvate to glucose may raise lactate levels in the body.³ In regards to the hepatomegaly in GH, it is caused by a reversible accumulation of excess glycogen in hepatocytes and can be misidentified as NAFLD on imaging.¹ It is important to discriminate between them because NAFLD can progress to advanced liver disease. The gold standard for diagnosis is biopsy.⁴ Although ultrasound and CT cannot differentiate between the diseases processes, gradient-dual echo liver MRI can help distinguish hepatic glycogen in GH from the fat seen in NAFLD and is a less invasive alternative to biopsy.⁵ Treatment of GH is glycemic control and improvement of symptoms can be seen in days to weeks.

CONCLUSION: GH is an underrecognized complication of poorly controlled diabetes mellitus that can present with elevated lactic acid and hepatomegaly and can be misidentified as NAFLD. Gradient-dual echo liver MRI may help distinguish between these two entities.

GOUT OF THE ORDINARY: CLAVICULAR GOUT IN HIV

Jay Thetford¹; Emil Heinze²; Hirshikesh Belani³. ¹UCLA-Olive View, Los Angeles, CA; ²David Geffen School of Medicine at UCLA, Sylmar, CA; ³Olive View - UCLA Medical Center, Los Angeles, CA. (Control ID #3184713)

LEARNING OBJECTIVE #1: Tophi may involve axial joints and develop prior to active gout flares

LEARNING OBJECTIVE #2: HIV infection is associated with hyperuricemia and gout

CASE: A 69 year-old male with HIV well-controlled on comprehensive anti-retroviral therapy (cART), HCV, HTN, and CKD stage 3 presented with 6 weeks of worsening pain in his right sternoclavicular (SC) joint. The patient noted clavicular bony enlargement over 1 year and denied any fevers, chills, night sweats, or unintentional weight loss. Physical exam revealed bony prominence of the right SC joint with tenderness to palpation, but without overlying erythema or warmth. MRI showed joint effusion, bone marrow edema, and bone erosions about the SC joint concerning for inflammatory arthritis or osteomyelitis. Arthrocentesis demonstrated extracellular birefringent crystals consistent with urate crystals. Synovial fluid

bacterial, fungal, and AFB cultures were all negative. Interestingly, the erythrocyte sedimentation rate (ESR) was only mildly elevated at 52 mm/hr and both serum uric acid, and white blood cell count (WBC) were within normal limits at that time. Soon after, he received an intralesional corticosteroid injection, which provided marked pain relief and significantly reduced the size, swelling, and tenderness of the SC joint.

IMPACT/DISCUSSION: While most episodes of gout occur in the lower extremities, gout may occur in nearly any joint in the body [1]. In this case, tophi formation occurred in the axial skeleton prior to onset of pain and the typical hallmarks of acute gout attacks were absent. Without these tell-tale clinical signs, the diagnosis of gouty arthritis was dependent on synovial fluid analysis, which is the gold standard [1]. While elevated serum uric acid, ESR, and WBC may help increase suspicion for gout, they are not necessary for diagnosis [1]. This case also highlights the association of HIV infection with hyperuricemia and gout [2]. This is thought to be due to a number of factors including increased T-cell turnover, HIV nephropathy, the creation of an inflammatory milieu, and, in some cases the effects from antiretroviral medication itself [2,3]. Didanosine, stavudine, zalcitabine, and ritonavir, for example, are all antiretrovirals associated with increased urate levels [2,4]. Interestingly, poorly controlled HIV and AIDS has been associated with hypouricemia due to malnutrition and increased renotubular losses; in patients started on cART may develop gout as part of an immune reconstitution inflammatory syndrome (IRIS) [2,3,5,6].

CONCLUSION: Tophaceous gout may involve axial joints and develop in the absence of acute gout flares. Our patient was one such case, presenting with slowly developing tophaceous gout in his SC joint prior to any acute episodes. HIV infection and the antiretroviral therapy used to treat it can produce elevated serum uric acid levels. Our patient was on a number of ART medications, including ritonavir, which has been associated with elevated uric acid levels and possibly contributed to his unique presentation.

GRANULOMATOSIS WITH POLYANGIITIS MANIFESTING AS SYMPTOMATIC SELLAR MASS IN A YOUNG WOMAN
sachin gadani¹; Fahid Alghanim¹; rohini nadgir³; Annika Windon²; Lisa Rooper²; Karan Desai¹. ¹Johns Hopkins Bayview Medical Center, Baltimore, MD; ²Johns Hopkins Hospital, Baltimore, MD; ³Johns Hopkins Hospital, Baltimore, MD. (Control ID #3180086)

LEARNING OBJECTIVE #1: Recognize that pituitary mass is a complication of GPA

LEARNING OBJECTIVE #2: Diagnose hypopituitarism based on review of systems, physical, and labs

CASE: A 25 y.o. Puerto Rican woman with granulomatosis with polyangiitis (GPA) and known sellar mass presented to the ED with headache and vomiting. The day prior she developed left sided headache and fever, followed by nausea and profuse vomiting, symptoms she had been experiencing weekly for the past several months. Detailed review of systems revealed 8 months of amenorrhea, fatigue, cold intolerance, 20lb weight gain, and constipation. Physical exam showed no meningismus, papilledema, or visual field deficit. Lab studies showed TSH 0.06 u/mL, free T4 0.4 ng/dL, LH 0.4 u/mL, and FSH 2.5 u/mL, consistent with hypopituitarism. These findings led to investigation of her known sellar mass. 10 months prior a cystic, nonenhancing sellar lesion was seen incidentally on MRI, thought to represent Rathke's cleft cyst. Repeat MRI showed notable enlargement, spread, and post-contrast enhancement, not consistent with Rathke's cyst. Diagnostic biopsy of the sellar mass demonstrated acute and chronic inflammation, reactive histiocytes, and necrobiosis, consistent with autoimmune inflammation related to GPA. She was treated with prednisone and cyclophosphamide. 2 months later the patient requested to be transitioned from cyclophosphamide to rituximab because of concerns about impaired fertility associated with cyclophosphamide.

IMPACT/DISCUSSION: Here we report the case of a woman who was found to have hypopituitarism due to a GPA-related sellar mass. A challenge in this case was the initial diagnosis of Rathke's cleft cyst based on the first MRI, which may have delayed accurate diagnosis of her pituitary lesion. This case sheds light on temporal imaging changes that such a lesion can undergo as it progresses, and underscores the non-specific nature of imaging findings. Previously reported cases of pituitary GPA have showed varied MRI findings, with T1 hypo- or hyperintensity, T2 hyperintensity, and heterogeneous enhancement typical. When approaching a pituitary lesion in a patient with GPA suspicion for autoinflammation should remain high, and, in lieu of biopsy, careful consideration of patient history and disease progression is needed. Previous reports suggest that pituitary GPA lesions are often amenable to treatment. In one case series of 8 GPA patients with pituitary lesion all achieved remission after therapy with corticosteroids (CT) combined with either cyclophosphamide (CYC) or rituximab. In another series of 9 patients, all but one achieved remission after CT combined with secondary immunosuppression. Notably, however, prior studies have reported chronic hypopituitarism in many patients,

CONCLUSION: - GPA can cause symptomatic pituitary lesions, which may be associated with significant morbidity - The diagnosis of pituitary GPA is difficult to make on imaging alone - Routinely employing a thorough review of systems is critical to ensure the accurate diagnosis be made.

GREEN URINE: BENIGN OR PATHOLOGIC?

Ermias Sori. UT Health San Antonio, San Antonio, TX. (Control ID #3186120)

LEARNING OBJECTIVE #1: Logical inexpensive evaluation of acute green urine color change.

CASE: A 55-year-old veteran presented to the hospital for worsening shortness of breath and severe hyponatremia found to have acute respiratory failure due to fluid overload treated with hemodialysis. His past medical history included alcoholic cirrhosis and hyperlipidemia. On exam, he was tachycardic(120 beats per minute), with reminder of exam unremarkable. On laboratory evaluation, he was noted to have a sodium level of 109 mEq/L that was suspected to be beer potomania. While on mechanical ventilation, he was sedated with a continuous propofol infusion. On day two, he developed green urine discoloration. Infectious work-up, especially for pseudomonas urinary tract infection, was negative. It was believed that the urine color change was suspected of propofol. The urine color changed back to normal after 12hr propofol discontinuation.

IMPACT/DISCUSSION: Urine discoloration is uncommon encounter in intensive care units. Many factors can cause green urine discoloration. The most common infectious etiology is Pseudomonas urinary tract infection. Other causes include Dyes such as Methylene blue, Biliverdin, Indigo blue and food colorings, and drugs including Propofol, amitriptyline, indomethacin, Cimetidine, metoclopramide, methocarbamol and promethazine. Clinicians must rule out infectious etiology on initial observation of green urine specially in intensive care setting. Propofol-induced urine discoloration is a rare occurrence. Blakey et al. reported incidence of less than 1%. Propofol is metabolized in liver. It is conjugated to glucuronides and sulphate and subsequently excreted by kidney. These metabolites are biologically inactive and do not affect kidney function. It is reported that overflow of the extrahepatic elimination plays a critical role in green discoloration of urine. It has been reported that propofol-related urine discoloration in a patient with fatal atypical intracerebral hemorrhage treated with hypothermia and osmotic therapy. It is known that glucuronosyltransferase and sulfotransferases enzymes play major role in phase II-drug metabolism in liver. In a cirrhosis and hypothermia state, the function of those enzymes is extensively compromised. As a result, overflow of extrahepatic elimination may be increased which will result in green urine. Our patient is a perfect example of this scenario.

CONCLUSION: This case illustrates a case of acute discoloration of urine in cirrhotic patient after propofol infusion. Awareness of this benign side effect would help clinician to approach the cases in a cost-effective way.

HAART-BROKEN: A CASE OF TENOFOVIR INDUCED FANCONI SYNDROME AND ASSOCIATED OSTEOMALACIA

Kristin Berger; Carla L. Spagnolletti. University of Pittsburgh Medical Center, Lewisburg, PA. (Control ID #3185752)

LEARNING OBJECTIVE #1: Recognize and diagnose Fanconi syndrome in patients treated with tenofovir.

CASE: The patient is a 54-year-old male with HIV infection and chronic kidney disease who presented to the hospital due to 3 days of nausea and vomiting. He also reported months of diffuse bone pain and lower extremity myalgias. He reported adherence to his antiretroviral medication regimen including emtricitabine-tenofovir and lopinavir-ritonavir, which was unchanged for many years. His HIV viral load was undetectable and CD4+ count was 890 two weeks prior to presentation. Examination revealed an afebrile, normotensive male with diffuse 4/5 strength in his extremities. Labs were remarkable for serum sodium 139, potassium 2.1, chloride 111, bicarbonate 16, creatinine 4.1, glucose 92, and phosphorus 2.1. Urinalysis was positive for 2+ glucose and 1+ protein. The patient's CT abdomen and pelvis demonstrated subacute bilateral rib and inferior pubic rami fractures. Fanconi syndrome was suspected given the presence of nonanion gap metabolic acidosis with associated hypokalemia, hypophosphatemia, glucosuria, and proteinuria. Given the suspected diagnosis, the patient's tenofovir was discontinued and he was rehydrated with intravenous fluids. His creatinine returned to his prior baseline of 2.1 by hospital discharge. He was seen in renal clinic at outpatient follow up for ongoing repletion of electrolytes and bicarbonate. Months following hospital discharge, his muscle and bone pains had resolved and his urinalysis had normalized.

IMPACT/DISCUSSION: Fanconi syndrome is characterized by a defect in the renal proximal tubules resulting in phosphaturia, glucosuria, tubular proteinuria, hypokalemia, and proximal renal tubular acidosis due to impaired bicarbonate reabsorption. Acquired Fanconi syndrome is most commonly due to adverse drug reactions, multiple myeloma, and heavy metal toxicity. Prolonged hypophosphatemia in patients with Fanconi syndrome may result in osteomalacia causing bone pain and myalgias as well as increased risk of fracture.¹ Prognosis of tenofovir-associated Fanconi syndrome is generally good, with reversible renal toxicity following drug discontinuation.² It is more likely to occur in patients who have underlying kidney disease. Patients benefit from electrolyte and bicarbonate repletion until the proximal tubule defect improves.

CONCLUSION: Tenofovir has a known association with proximal tubule dysfunction, including in HIV-uninfected patients taking the medication as HIV pre-exposure prophylaxis (PrEP).³ Increasing recognition of this potential adverse drug effect is critical for early discovery and drug discontinuation, particularly as increasing numbers of primary care doctors are prescribing tenofovir for PrEP. Delay in diagnosis may result in prolonged hypophosphatemia and subsequent osteomalacia in some cases. Regular renal function panel and urinalysis is recommended for patients treated with tenofovir for early detection of tubulopathy.

HASHIMOTO ENCEPHALOPATHY: REVERSING ALTERED MENTAL STATUS WITH STEROIDS

Jiyeon Son¹; Ayako W. Fujita¹; Joseph M. Rocco². ¹University of Pittsburgh Medical Center, Pittsburgh, PA; ²University of Pittsburgh, Pittsburgh, PA. (Control ID #3177048)

LEARNING OBJECTIVE #1: Recognize the diagnostic criteria and clinical features of Hashimoto encephalopathy.

LEARNING OBJECTIVE #2: Identify differential diagnoses of rapidly progressive altered mental status without evidence of stroke or seizure.

CASE: A 75-year old man with history of heart failure, COPD, and prior stroke presented with two months of progressive confusion, aphasia and hypersomnolence. Patient was previously independent and could manage his finances without assistance. Symptoms were initially attributed to infection, and he received multiple courses of antibiotics without improvement. On exam, vital signs were normal, but he was minimally responsive. He was not oriented and not following commands. No rigidity or hyperreflexia were noted. Mild myoclonus was present. CT was unchanged from prior, and EEG was negative for seizure. MRI was not obtained due to his pacemaker. Symptoms continued to progress, and he developed new onset of seizures. Extensive workup was negative including B12, RPR, HIV, ANA and TSH. CSF showed elevated protein at 71mg/dL but no cells. CSF viral PCRs and cytology were negative. However, his serum anti-thyroglobulin (TG) and anti-thyroid peroxidase (TPO) antibodies were elevated at 23 IU/mL and 484 IU/mL, respectively. Given his clinical symptoms and elevated anti-thyroid antibodies, he was diagnosed with Hashimoto encephalopathy. Patient was treated with pulse steroids and IVIG with improvement in his mental status. However, steroids were discontinued due to complications including ischemic colitis and bacteremia. Family decided to focus on comfort care and he passed away peacefully shortly thereafter.

IMPACT/DISCUSSION: With rapidly progressive cognitive decline it is important to evaluate for reversible processes including occult metabolic, infectious, and autoimmune/paraneoplastic etiologies. Hashimoto encephalopathy is often responsive to steroids and can be reversible.

CONCLUSION: Hashimoto encephalopathy (HE), also known as steroid responsive encephalopathy, is believed to be immune mediated, rather than a direct effect of altered thyroid state on the CNS. Clinical manifestations include acute to subacute onset of confusion with alteration of consciousness. Other presentations include seizures, hallucinations, somnolence, myoclonus, and diffuse hyperreflexia with other pyramidal tract signs. HE can be diagnosed with elevated serum level of anti-TPO or anti-TG autoantibodies in the appropriate clinical setting. CSF typically has elevated protein concentration, EEG shows nonspecific slowing of background activity, and MRI is usually normal. It is imperative that other causes of rapidly progressive dementia are ruled out, including Creutzfeldt-Jakob disease, metabolic diseases, infectious meningoencephalitis, psychiatric disease, and autoimmune encephalitis. HE is treated with corticosteroids, and symptoms can be reversible over months. Other immunosuppressive treatments such as IVIG or plasmaapheresis can be pursued but have not been well-studied.

HASHING OUT THE UNKNOWNNS OF THE CBD CRAZE

Jessica Bass. Naples Community Hospital, Naples, FL. (Control ID #3184977)

LEARNING OBJECTIVE #1: Consider CBD toxicity in the differential when urine toxicology is negative.

LEARNING OBJECTIVE #2: Recognize the potential for harm in CBD products sold OTC.

CASE: A 57 year old male with no history of substance abuse presented by ambulance to the hospital after being found by his coworkers acting strange, vomiting, and slurring his speech. He had legally purchased CBD gummies marketed for pain and anxiety relief at a gas station several hours prior. Vitals upon arrival were: T 36.8, HR 79, RR 12, BP 113/60 and O2 sat of 84% on RA that improved with arousal. Physical exam showed a morbidly obese man in no acute distress with a depressed level of consciousness but whom awoke to stimuli. Neuro exam was significant for dysarthric, hypophonic speech. ABG at that time showed pH 7.3, pCO2 50.4 pO2 83.3 Lac 2.4. Labs were notable for WBC 17.8, Na 140, K 5.8, Cl 109, CO2 25, BUN 21, Cr 1.2, CK 341, CKMB 4.4 and a comprehensive tox screen including cannabis was negative. Vitals 3 hours after presentation deteriorated, showing: HR 47, RR 8-12, BP 88/52, O2 78%. EKG revealed sinus bradycardia. The patient progressively became

more obtunded and required constant stimuli in order to maintain his airway. CPAP was not administered due to continued emesis. The next morning, the patient was A&O x3 and vitals had improved. Further history from the patient revealed he had consumed 2 packages of CBD gummies, totaling 370mg total of CBD (serving size on the package was 30mg). He felt the products were healthy and safe based on packaging and did not believe they would have any adverse effects.

IMPACT/DISCUSSION: CBD is one of many cannabinoids found in marijuana and marijuana-derived products. It is generally considered safe unlike its more psychoactive counterpart, THC, which has been linked to seizures, respiratory depression, and cardiovascular complications. CBD has surged in popularity recently, being marketed in oils, capsules, and candies as a health supplement, claiming to treat everything from glaucoma to pain to preventing cancer. Most studies currently available do not look at isolated CBD nor their synthetic equivalents, and purity is not guaranteed, thus leading to unforeseen side effects and toxicities. Moreover, these compounds do not show on traditional toxicology screens, posing a diagnostic dilemma for physicians. This case of respiratory depression and cardiovascular compromise in a relatively healthy man is just one example of the importance of considering synthetic CBD toxicity in the differential, as little data is currently available for diagnosis or treatment. Furthermore, misleading marketing of such products poses a risk to public safety; thus educating patients when prompted is vital.

CONCLUSION: CBD toxicity is likely to be seen more frequently as access to unregulated products surges and given their enticing claims of safety and health benefits. Clinicians should be aware of the potential for serious harm for both diagnostic and patient-counseling purposes as well as to fuel further research in the area.

HAVE YOU SEEN LIVER ENZYMES THIS HIGH IN CONGESTIVE HEPATOPATHY: A CASE REPORT

Laith Numan; Ahmed A. Elkafrawy; Andrew Tomaw; Khalil Abuamr. University of Missouri-Kansas City, Kansas City, MO. (Control ID #3163001)

LEARNING OBJECTIVE #1: Recognize that congestive hepatopathy can present with liver enzymes higher than three times the normal levels.

LEARNING OBJECTIVE #2: Treat as soon as the etiology is identified to avoid irreversible damage to the liver, and trend the liver enzymes to assess the response.

CASE: A 33-year-old male previously healthy presented to the emergency department with epigastric pain of two weeks duration. At the same time, he noticed yellowish discoloration of his eyes. He denied acetaminophen use. On review of systems, he was complaining of increased shortness of breath and new lower limbs swelling. He denied any illicit drug use, excessive alcohol intake, recent travel, or mushrooms consumption. On physical examination, he had scleral icterus, bilateral crackles on auscultation, and lower limb pitting edema. On labs, his liver function test was trending up: AST(U/L) 883 > 2251, ALT (U/L) 1334 > 2527, and total bilirubin (mg/dL) 3.2 > 3.6. Acetaminophen level was negative at presentation and 4 hours after presentation. International randomized ratio (INR) was trending up as well: 3.2 > 3.6. Chest x-ray showed cardiomegaly. Computed tomography (CT) of the abdomen with contrast showed volume overload with small right pleural effusion, ascites and anasarca. There were no signs of liver ischemia or infarct on CT scan. Ultrasound Doppler of the liver showed patent vasculature and congestion of the inferior vena cava. Throughout his hospitalization, he remained normotensive. Hepatology team recommended to trend his liver enzymes, INR and to do neuro checks every 2 hours. Given his fluid overload, an echocardiogram was done, and it showed severely dilated left ventricle, ejection fraction of less than 20%, severe global hypokinesis of the left and right ventricles, severe aortic regurgitation and bicuspid aortic valve. Cardiology team recommended to start the patient on intravenous furosemide twice daily, and then he underwent left heart catheterization which showed normal coronary arteries. After the first dose of furosemide, his liver enzymes and

INR started trending down till they reached normal levels. He was diagnosed with congestive hepatopathy that was due to congestive heart failure secondary to severe aortic insufficiency. The patient improved and was discharged on Spironolactone, Carvedilol, and Torsemide. He was scheduled for an outpatient aortic valve replacement.

IMPACT/DISCUSSION: Congestive hepatopathy is common with congestive heart failure, especially with right-sided heart failure. Typically, the liver enzymes will be elevated but not higher than three times the normal value. It is rare for congestive hepatopathy to presents with liver enzymes as high as this case. However, you always have to rule out other causes of acute transaminitis.

CONCLUSION: Identifying the cause of acute transaminitis is time sensitive, as the outcome could be catastrophic. Do not exclude congestive hepatopathy if the liver enzymes are very high, think about it if other physical signs of congestive heart failure are present.

HE WHO STILL KNOWS SYPHILIS KNOWS MEDICINE

Samantha R. Pop. Beth Israel Deaconess Medical Center, Boston, MA. (Control ID #3186045)

LEARNING OBJECTIVE #1: Recognize the clinical manifestations of secondary syphilis.

LEARNING OBJECTIVE #2: Consider empiric treatment of patients with high clinical suspicion of secondary syphilis at risk for poor follow-up prior to laboratory confirmation of diagnosis.

CASE: A healthy 22-year-old woman presented to a primary care clinic requesting screening for sexually transmitted infections. She reported unprotected sexual intercourse with a male partner three months prior to presentation. On review of systems, she reported a new rash involving her palms and soles, patchy hair loss, and a painless genital lesion. She reported a recent history of fever, myalgias, and sore throat that had since resolved. Her exam was notable for multiple 0.5 to 1.5 cm annular red-brown erythematous papules and plaques with collarette of scale located on her palms and soles. She had bilateral mobile, non-tender anterior cervical and inguinal lymphadenopathy. Gynecologic exam showed a 0.5 cm gray-white papule on the left labia minora. Her physical exam findings and sexual history raised a high clinical suspicion for secondary syphilis and she was treated empirically with 2.4 million units of penicillin G benzathine intramuscularly during the initial encounter. Laboratory studies were significant for a rapid plasma reagin that finalized after 72 hours as reactive with a 1:64 titer. A reflexive treponemal antibody test was reactive confirming the diagnosis. HIV antibody testing was negative. Cervical specimens sent for nucleic acid amplification testing were positive for *Chlamydia trachomatis* and negative for *Neisseria gonorrhoea*. She was treated with 1 gram of azithromycin PO for chlamydia co-infection. The diagnosis was reported to local and state departments of public health. The patient was scheduled for follow up at one month to monitor for resolution of symptoms and unfortunately was lost to follow up.

IMPACT/DISCUSSION: William Osler suggested "he who knows syphilis knows medicine" reflecting how common the disease caused by the spirochete *Treponema pallidum* was during his tenure in the early 20th century. The manifestations of secondary syphilis are varied and include constitutional symptoms such as fever, myalgias, pharyngitis, a generalized papulosquamous eruption involving the palms and soles, lymphadenopathy, condyloma lata (gray, moist anogenital lesions) and patchy alopecia or telogen effluvium. Now it is often thought of as a rarity, however, the reported rates of syphilis in the United States are rising. While, mostly attributed to an increased number of cases among men who have sex with men, within the last five years, the rates of primary and secondary syphilis among women have more than doubled. This increase is of particular concern given its association with congenital syphilis.

CONCLUSION: Syphilis is making a return and clinicians must recognize the manifestations of secondary syphilis and administer early treatment, especially in women of child-bearing age.

HELP, I'M FALLING! A CASE OF CEFEPIME-ASSOCIATED THROMBOCYTOPENIA

Andraya Gower²; Meghana Gadgil¹. ¹Dell Medical School, Austin, TX; ²Dell Medical School, Oklahoma City, OK. (Control ID #3186595)

LEARNING OBJECTIVE #1: Recognize cefepime as a rare cause of thrombocytopenia

LEARNING OBJECTIVE #2: Recognize the applications of the Naranjo scale for assessing adverse drug reactions

CASE: A 35-year-old female with no significant PMH presented with one day of right-lower quadrant abdominal pain radiating to the back associated with fever, hypotension, nausea and vomiting. Vital signs in the ER were: BP 89/55, temp 98.4, HR 70, RR 15. Physical exam was significant tenderness to palpation in RLQ without rebound tenderness, right CVA tenderness and suprapubic tenderness to palpation. Labs were significant for lactate of 4.15, moderate blood in urine, potassium of 2.7, anion gap of 15. Platelets were 171. Renal ultrasound revealed R sided mild hydronephrosis. MRI Abdomen/Pelvis showed R side hydronephrosis and hydroureter with R perinephric fat stranding. The patient was admitted to the ICU with severe sepsis from obstructive pyelonephritis likely secondary to obstructive renal calculus. The patient was started on ceftriaxone, but developed worsening hypotension and was broadened to cefepime overnight on day 1 of admission. The patient was on heparin for DVT prophylaxis. On day 2, platelets were found to be 79 (>50% drop) and continued to trend down on day 3 down to 67[GMA1]. Her 4T score showed a low (<5%) likelihood of HIT. The patient was switched to cefazolin on day 3 after E coli sensitivities resulted. Thrombocytopenia[GMA2] resolved with a platelet count of 139 on day 6. Ultimately, the patient received a percutaneous nephrostomy tube and was discharged on oral antibiotics.

IMPACT/DISCUSSION: Cefepime is a rare cause of thrombocytopenia in critically ill patients. Clinical trial data show cefepime-associated thrombocytopenia incidence between 0.1 - 1%. Here, our patient developed thrombocytopenia with a low 4T score and an interesting temporal pattern related to the initiation of cefepime that prompted further investigation. The Naranjo scale assessing adverse drug reactions showed a possible relationship between cefepime and thrombocytopenia, which was further bolstered by the increase in platelets following discontinuation of cefepime. This case highlights the importance recognizing drug-induced thrombocytopenia in the critically ill.

CONCLUSION: Cefepime is a rare cause but important of thrombocytopenia in the critically ill Application of a probability scale to test for possible adverse drug reactions can help elucidate etiologies of important clinical findings in the critically ill

HEMATOGENOUSLY SPREAD SEPTIC THROMBOPHLEBITIS AS A CAUSE OF SPINAL EPIDURAL ABSCESS

Mrunal Kulkarni; Kakageldi Hommadov; Ajinkya Kulkarni; Gul Madison. Mercy Catholic Medical Center, Yeadon, PA. (Control ID #3186014)

LEARNING OBJECTIVE #1: Spinal epidural abscess is a rare clinical diagnosis with incidence of 0.2 to 2 cases per 10,000 hospital admissions and is considered a medical emergency.

LEARNING OBJECTIVE #2: Delay in diagnosis is common due to non specific presentation and can result in permanent neurological deficits.

CASE: A 27 year-old African American female presented with fever, chills, urinary frequency, worsening pain in right hip and flank region for 2 days. Temperature 100.5 C, normal white cell count: 9.9 Thou/uL (4.5-11 Thou/uL). Urine analysis: bacteruria, pyuria. CT abdomen (with contrast) unremarkable. With recent history of fall, Xray lumbar spine was done that showed no fracture. IV Ceftriaxone was started for clinically presumed urinary tract infection (UTI). Next day she continued to have lower back pain and also complained of pain, swelling of left arm

where an IV access was obtained during her previous hospital admission for asthma exacerbation last week. Exam: tenderness over the lumbar spine region, mild proximal leg weakness (strength 4/5). Right sided straight leg raising test positive. Left arm: erythema, induration, tenderness, purulent drainage. Blood cultures grew Methicillin sensitive staphylococcus aureus (MSSA), 4/4 bottles. Antibiotic was switched to IV Cefazolin. Elevated Erythrocyte sedimentation rate: 70 mm/HR (0-20 mm/HR), C-reactive protein: 177 mg/L (<10mg/L). MRI lumbar spine: L3-L4 epidural abscess, mass effect on exiting right L3 nerve root, L3-L4 right facet septic arthritis. CT Left arm: septic thrombophlebitis of cephalic vein, medial cubital vein, basilic vein. Patient underwent right L3-4 laminotomy for epidural abscess aspiration. Thrombophlebitic vein was excised for source control. Surgical cultures from both left arm and lower back, grew MSSA. Patient was treated with IV Cefazolin for 6 weeks with uneventful post-operative course and full functional recovery.

IMPACT/DISCUSSION: We present a rare case of spinal epidural abscess (SEA) in a young female with no history of diabetes, IV drug abuse or spinal instrumentation. Source of infection was her recent IV access. She had developed localized septic thrombophlebitis at the iv site, that had resulted in bacteremia and metastatic spread of the infection to the lumbar spine causing SEA. SEA was not considered as a differential initially as symptoms were masked by the clinical suspicion of UTI and a recent fall. Emergency surgical decompression and antibiotics are treatment of choice. This case led us to review our hospital policy on IV lines and appropriate changes were made for careful, timely monitoring in the future.

CONCLUSION: In appropriate clinical setting, it is important to consider spinal epidural abscess as a differential diagnosis even in the absence of classic risk factors and symptoms. Timing is a critical factor in determining ultimate prognosis, as a delay in diagnosis and treatment can result in permanent neurological deficits.

HEMOLYSIS AND THROMBOCYTOPENIA IN THE SETTING OF COBALAMIN DEFICIENCY

Jake A. Gibbons. University of Texas Medical Branch, Galveston, TX. (Control ID #3139824)

LEARNING OBJECTIVE #1: Recognize the clinical features of cobalamin deficiency.

LEARNING OBJECTIVE #2: Differentiate pseudothrombotic microangiopathy from true microangiopathic hemolytic anemia.

CASE: A 65-year-old male presented with dyspnea beginning 3 months ago. Additionally, he endorsed 15-pound weight loss, fatigue, and decreased appetite. His family noticed yellowing in his eyes. He had no known past medical history. He described his diet as balanced, consisting of meat, eggs, milk, and vegetables. Review of systems was positive for intermittent heart palpitations. The patient had scleral icterus on physical examination. Complete blood count was significant for a decreased hemoglobin of 7.1 g/dL, decreased white blood cell count of $3.1 \times 10^3/\mu\text{L}$, and decreased platelet count of $98 \times 10^3/\mu\text{L}$. Reticulocyte index was low at 0.36. Mean corpuscular volume was high at 122 fL. Total bilirubin was elevated at 2.3 mg/dl with a predominance indirect bilirubin. Peripheral smear revealed schistocytes and hypersegmented neutrophils. Additional blood work showed an elevated lactate dehydrogenase and undetectable haptoglobin. Cobalamin level was found to be significantly decreased at 48 pg/mL. Methylmalonic acid and homocysteine were both elevated. Intrinsic factor antibodies came back positive. Low cobalamin coupled with positive intrinsic factor antibodies suggested a diagnosis of pernicious anemia, which was confirmed by endoscopy. It was determined that the hemolysis and thrombocytopenia were both due solely to the cobalamin deficiency, as additional testing was negative. The patient was started on cobalamin replacement therapy. His laboratory abnormalities improved, he experienced improvement of his symptoms, and was discharged.

IMPACT/DISCUSSION: Cobalamin deficiency is relatively common with a prevalence of approximately 15% in patients 60 years and older.

With that said, cobalamin deficiency presenting as pseudothrombotic microangiopathy with hemolytic anemia, schistocytes on peripheral smear, and thrombocytopenia is uncommon. A study of 201 patients with cobalamin deficiency showed that only 2.5% of those patients presented with pseudothrombotic microangiopathy. This particular presentation can pose a diagnostic challenge for clinicians, as it can mimic a true microangiopathic hemolytic anemia such as thrombotic thrombocytopenic purpura (TTP). An incorrect diagnosis of TTP, for example, could lead to admission to the intensive care unit and the unnecessary initiation of plasmapheresis. In patients with hemolysis, thrombocytopenia, and macrocytic anemia, cobalamin deficiency should be considered on the differential diagnosis.

CONCLUSION: Cobalamin deficiency can uncommonly present as pseudothrombotic microangiopathy with hemolytic anemia, schistocytes on peripheral smear, and thrombocytopenia. This presentation can resemble a true microangiopathic process such as thrombotic thrombocytopenic purpura. Correct diagnosis of pseudothrombotic microangiopathy is essential in avoiding mismanagement of the patient and unnecessary treatments.

HEMOLYTIC ANEMIA AS AN UNUSUAL PRESENTATION OF B12 DEFICIENCY

Margaret M. Mongare¹; Arash Nafisi^{2, 1}. ¹University of Los Angeles California, Los Angeles, CA; ²Olive View - UCLA Medical Center, Encino, CA. (Control ID #3181867)

LEARNING OBJECTIVE #1: -Recognize sequelae of severe B12 deficiency, including hemolysis

LEARNING OBJECTIVE #2: -Determine the etiology of B12 deficiency

CASE: A 44 year-old woman presents to clinic with generalized fatigue, dyspnea and easy bruising for one month. She notes 40 pound unintentional weight loss and chronic diarrhea over the past one year. She is otherwise healthy, has no known autoimmune disease, endorses a well-balanced diet and denies use of medications, supplements, abdominal surgeries and recent travel. Patient was referred for hospital admission after she was found to be severely anemic. On presentation to the emergency department, her blood pressure was 126/74, pulse 70 beats per minute with an exam significant for conjunctival rim pallor, multiple areas of ecchymosis on her lower extremities, abdomen without hepatosplenomegaly and no jaundice or lymphadenopathy. Laboratory studies were significant for pancytopenia and severe macrocytic anemia - Hemoglobin 6.8, MCV 137, Platelets 77K, WBC 3.5. Liver tests showed unconjugated hyperbilirubinemia (TB 1.4, DB 0.2) and urinalysis demonstrated urobilinogen. Hemolysis labs were significant for LDH of 1398, Haptoglobin < 15, D-Dimer 0.59, coombs negative and peripheral smear with hypersegmented neutrophils, few schistocytes. Additional workup revealed B12 < 146 with a negative intrinsic factor (IF) antibody. Folate, iron studies, stool cultures, stool ova & parasites and celiac testing were normal. Hematology was consulted. Patient's severe anemia and pancytopenia with intramedullary hemolysis were attributed to severe B12 deficiency. She was treated with parenteral B12 and referred to gastroenterology for endoscopic evaluation. At three months follow up, patient was asymptomatic, felt well and all laboratory studies had returned to normal.

IMPACT/DISCUSSION: Severe anemia from intramedullary hemolysis is a rare manifestation of B12 deficiency that results from ineffective erythropoiesis, peripheral breakdown of fragile red blood cells and a pseudo-microangiopathy from homocysteine-induced endothelial damage. This patient's clinical symptoms along with her laboratory findings are supportive of the above processes. Pernicious anemia is the most likely cause of this patient's B12 deficiency despite a negative IF antibody, given IF sensitivity is only 50% and due to her responsiveness to B12 treatment, her age and lack of other identifiable causes or risk factors for B12 deficiency. Endoscopic evaluation can offer more definitive diagnosis.

CONCLUSION: -Severe B12 deficiency can cause hemolytic anemia and pancytopenia -Clinicians should maintain a high index of suspicion for pernicious anemia as the cause of B12 deficiency, even when IF antibodies are negative, particularly in the absence of other clinical risk factors for B12 deficiency.

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS: A FATAL DISEASE LEADING TO POOR PATIENT OUTCOMES SUMAIRA ZAREEF MD, MPH. DAVID FERNANDES MD MONTEFIORE MEDICAL CENTRE, DEPARTMENT OF INTERNAL MEDICINE.

Sumaira Zareef. Montefiore Medical Centre, Bronx, NY. (Control ID #3185643)

LEARNING OBJECTIVE #1: Hemophagocytic lymphohistiocytosis (HLH) is an aggressive and life-threatening syndrome of excessive immune activation.

LEARNING OBJECTIVE #2: Early intervention is the only tool that can help achieve better clinical outcomes

CASE: A 52-year old Ghanaian man without significant past medical history was brought to the ER for abdominal pain, cough, and multiple fever spikes above 102. He was found to be in septic shock, liver failure and respiratory failure. He was intubated, and treated with broad spectrum antibiotics and multiple pressors. CT of chest, abdomen and pelvis revealed bilateral consolidations, hepatosplenomegaly and diffuse moderate abdominopelvic adenopathy. He had pancytopenia; Total leukocyte count was 2.4 k/ μ L (4.8-10.8), Red blood cell count 3.5 ml/ μ L (4.5- 5.9), platelet count was 31 k/ μ L (150-400). His kidney function declined, and he was started on dialysis. His ferritin and triglycerides were elevated at 5104 ng/ml and 1071 mg/dl respectively. Microbiological testing for tuberculosis, Schistosoma, giardia, strongyloidiasis, malaria, cryptosporidium, HIV, and viral hepatitis panel were negative. He was started on dexamethasone in view of suspicion for Hemophagocytic lymphohistiocytosis (HLH) as he fulfilled five out of eight HLH 2004 criteria. He was medically too unstable to be started on platin based chemotherapy which is the definitive treatment for HLH. Bone marrow biopsy revealed trilineage hematopoiesis, without hemophagocytes. His medical condition worsened, and he passed away after cardiac arrest. His soluble CD25 level was elevated at 19475 unit/ml (45 -1105), and his natural killer cell (NK cells) function was reduced further solidifying HLH diagnosis.

IMPACT/DISCUSSION: HLH diagnosis requires molecular diagnosis/ genetic testing or fulfillment of at least five out of eight variables on diagnostic criteria. HLH-2004 diagnostic criteria includes fever more than 38.5 C; splenomegaly; peripheral blood cytopenias including two of the following (hemoglobin less than 9 g/dL, platelets less than 100,000/ μ L or ANC 1000/ μ L); hypertriglyceridemia (fasting triglycerides greater than 265 mg/dL) and/or hyperfibrinogenemia (less than 150 mg/dL) ; Ferritin more than 500 ng/ml; hemophagocytes in bone marrow, spleen, lymph nodes or liver; low or absent NK cell activity, and elevated soluble CD25 (soluble IL2 receptor alpha). The reported incidence of hemophagocytes on bone marrow examination ranges from 25 to 100 %. The sensitivity of NK cell activity and soluble CD-25 levels approaches 100% based on HLA 2004 diagnostic criteria. Therapy based on the HLH-94 protocol consists of eight weeks of induction therapy with etoposide (VP-16) and dexamethasone. If left untreated, patients with HLH survive only a few months due to progressive organ failure. Therapy should not be delayed while awaiting results of immunologic testing.

CONCLUSION: HLH is a potentially life threatening disorder of extensive inflammation which requires prompt recognition and early introduction of definitive therapy.

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS IN THE SETTING OF SYSTEMIC LUPUS ERYTHEMATOSUS AND HISTOPLASMA CAPSULATUM

Kavita Agrawal; Vijaya Kankanala; Nirav Agrawal. Overlook Medical Center, Summit, NJ. (Control ID #3163090)

LEARNING OBJECTIVE #1: Recognise hemophagocytic lymphohistiocytosis (HLH) based on clinical presentation and laboratory abnormalities

LEARNING OBJECTIVE #2: Identify secondary causes of HLH Treatment modalities for HLH

CASE: A 28-year-old female with a history of systemic lupus erythematosus (SLE) presented with high grade fevers to 104 F, right upper quadrant abdominal pain and nausea for 2 weeks. Based on the initial presentation, there was a concern for infectious etiology of the symptoms. There was no apparent source based on history and physical examination. She underwent work up including computed tomography (CT) chest, abdomen and pelvis, venous doppler, echocardiogram, tagged white blood cell scan and magnetic resonance cholangiopancreatogram (MRCP) which was negative. The symptoms were initially attributed to lupus flare. However, the hospital course was complicated by persistent fevers, pancytopenia and worsening transaminitis AST 211 IU/L and ALT 111 IU/L. Blood work showed hemoglobin (Hb) of 7.5 g/dL, platelet 79000/nl, elevated ferritin of 22,682 ng/ml, triglycerides 308 mg/dL and soluble IL-2R 12,820 pg/mL. Bone marrow biopsy showed normocellular bone marrow with hemophagocytosis. Based on the above findings, diagnosis of HLH was made. She was started on cyclophosphamide and pulsed dose steroids. Following the treatment, she had improvement of her symptoms and blood work and was discharged. However, four weeks after the discharge, she was readmitted with unremitting fevers for two weeks. She also had erythematous nodules on her back, thigh and legs. CT chest showed tree in bud nodularity pattern in left lung. Blood fungal cultures came positive for histoplasma capsulatum. She was treated with amphotericin for disseminated histoplasmosis. Blood work showed worsening serum ferritin >40,000 ng/ml, TG 291 mg/dL, pancytopenia with Hb 7.5 g/dL, platelets 13,000/ml and IL-2R 18,910 pg/ml. This was consistent with the flare of HLH in the setting of SLE and disseminated histoplasmosis in immunocompromised patient. She was started on etoposide and dexamethasone. The patient showed consistent recovery of her symptoms and blood work.

IMPACT/DISCUSSION: HLH is an aggressive and life-threatening syndrome of excessive immune activation. HLH can occur as a sporadic or familial disorder or secondary to different conditions that disrupt the immune homeostasis. The most common conditions include malignancies, immunodeficiencies, infections and rheumatologic disease such as idiopathic juvenile rheumatoid arthritis, SLE, systemic sclerosis and mixed connective disease. Common findings include fever, rash, neurologic symptoms, elevated liver enzymes and ferritin. Treatment involves etoposide and dexamethasone given at tapering doses over eight weeks and therapies for underlying cause

CONCLUSION: HLH presents as febrile illness with multiorgan involvement HLH is a fatal disease that requires early recognition and assessment of secondary causes. Urgent treatment is required and therapeutic modalities may differ accordingly to the underlying cause

HEMORRHAGIC COMPLICATIONS OF PARACENTESIS

Kayvon Sotoudeh¹; Christopher Lee¹; Andrew Young². ¹University of Southern California, La Crescenta, CA; ²Keck School of Medicine, Los Angeles, CA. (Control ID #3184778)

LEARNING OBJECTIVE #1: Recognize and treat a serious complication of paracentesis

CASE: A 32-year-old male with history of Child C alcoholic hepatic cirrhosis presented with worsening abdominal distension. His history was notable for

alcohol and methamphetamine abuse. Vital signs were normal. Physical exam was remarkable for scleral icterus and jaundice. His abdomen was distended, without tenderness or rebound, with distended superficial abdominal veins and a positive fluid wave. Bilateral lower extremities were edematous. His initial laboratory values were notable for a sodium level of 109 mmol/L and a hemoglobin of 10.3 g/dL. Hypertonic saline, salt tablets, and diuresis were administered with resolution of hyponatremia. His ascites was managed with serial abdominal paracentesis. On hospital day 9, the patient underwent a third abdominal paracentesis with ultrasound guidance via the left lower quadrant with removal of 5 liters of sero-sanguinous fluid, consistent with his prior paracenteses. Post-procedural vital signs revealed a blood pressure of 112/63 mmHg, heart rate 98, respiratory rate 19, and saturating well on ambient air. His initial post procedure hemoglobin was 7.5 g/dL, unchanged from before the procedure. His international normalized ratio (INR) was 2.13. Sixteen hours following the procedure, he became hypotensive to 83/40 mmHg with a hemoglobin of 5.7 g/dL. The patient was transfused with 2 units of packed red blood cells and transferred to the intensive care unit where he was started on norepinephrine. He continued to require multiple transfusions with only minimal improvements in his hemoglobin. A CT scan of the abdomen and pelvis without contrast showed a dense collection of fluid within the greater omentum, likely representing a hematoma. On an angiogram performed by interventional radiology, active hemorrhage from a branch of the left inferior epigastric artery was revealed. The vessel was embolized. The patient's condition gradually improved. The patient was discharged on hospital day 16 in stable condition.

IMPACT/DISCUSSION: Severe hemorrhage as a complication of abdominal paracentesis has been shown to occur in less than 1% of cases with an average time to symptom onset between 6 to 48 hours after paracentesis, with some cases occurring up to 1 week post-procedure. Types of hemorrhage include abdominal wall hematomas, hemoperitoneum, and pseudoaneurysm formation and are usually associated with damage to the inferior epigastric artery. Complication rates have not been associated with operator experience, elevated INR or thrombocytopenia. In cases of severe hemorrhage, transcatheter intervention has been shown to have significantly lower rates of mortality than surgical intervention (25% versus 75%).

CONCLUSION: For hospitalists performing abdominal paracentesis, this case demonstrates the importance of rapid recognition of this complication. As in this case, Interventional Radiology is critical in managing the source of bleed in hemorrhage following abdominal paracentesis.

HEPATITIS IN AN IMMUNOSUPPRESSED PATIENT

Joseph S. Needleman¹; Austin Portolese¹; Abdul Basit². ¹Penn State College of Medicine, Hershey, PA; ²Penn State Hershey Medical Center, Hummelstown, PA. (Control ID #3184394)

LEARNING OBJECTIVE #1: Consider syphilis as an etiology of acute hepatitis in immunosuppressed patients

CASE: An African-American male in his 20s with human immunodeficiency virus (HIV) infection on highly active antiretroviral therapy (HAART), end-stage renal disease on dialysis, and type 1 diabetes presented with 10 days of fevers, nausea, vomiting, abdominal pain, and pruritus. He reported high-risk sex with other men, but denied drug and alcohol use. His exam was notable for scleral icterus, periorbital edema, and right upper quadrant pain. Alanine aminotransferase (ALT) was 127 u/L and aspartate aminotransferase (AST) was 106 u/L, both 3x the upper limit of normal (ULN). Alkaline phosphatase (ALP) was 740 u/L (5-6x ULN), total bilirubin 2.9 (2-3x ULN), and gamma-glutamyltransferase 1715 u/L (28x ULN). CD4+ count was 360 cells/MM3 and HIV viral load was undetectable. Viral hepatitis serologies were negative. Abdominal CT revealed biliary sludge and periportal edema without ductal dilation. Out of concern for drug-induced hepatitis and cholangitis his HAART medications, darunavir, ritonavir, and rilpivirine, started seven months prior, were held and he received piperacillin/tazobactam. Two days after

admission the patient disclosed a painless penile chancre, and a reactive treponemal antibody screen with reflex rapid plasma reagin (RPR) was positive. He was diagnosed with syphilitic hepatitis and received the first of three intramuscular penicillin benzathine shots.

IMPACT/DISCUSSION: Syphilis infection rates in the United States have increased in recent years. The Centers for Disease Control and Prevention reports over 30,000 new cases of primary and secondary syphilis in 2017, with ~7,000 cases in HIV-positive individuals, principally men who have sex with men. Syphilis-induced hepatitis is a rare manifestation occurring in an estimated 10% of immunocompetent patients, and is characterized by a disproportionately large elevation of ALP compared to ALT and AST. Standard stage-dependent antibiotics are the current recommended treatment. Of note, evidence has emerged that syphilitic hepatitis may develop in up to 38% of HIV-positive patients. Current recommendations for acute hepatitis include screening for Hepatitis B and C viruses. However, given this disproportionate rate of occurrence in HIV-positive patients, we recommend additional screening for syphilis when evaluating acute hepatitis in immunocompromised patients or high-risk patients with hepatitis secondary to an unclear etiology. As our patient shows, a thorough history and exam, as well as continued development of rapport, is vital to obtaining an early and accurate diagnosis.

CONCLUSION: - Syphilitic hepatitis is an increasingly common etiology of acute hepatitis - It is characterized by ALP elevations significantly greater than AST and ALT - HIV-positive patients are particularly at risk for syphilitic hepatitis

HEPATORENAL SYNDROME SECONDARY TO ABDOMINAL COMPARTMENT SYNDROME

Merza Nooraldin¹; Taylor Lindgren¹; Deborah Lin²; Dylan Murray²; Tareq Naguib¹. ¹tuhsc, Amarillo, TX; ²Texas Tech University Health Sciences Center, Amarillo, TX. (Control ID #3184720)

LEARNING OBJECTIVE #1: 1-Recognize Increased intra-abdominal pressure (IAP) as a cause of acute kidney injury (AKI). 2-Identify massive ascites, increased IAP, and hepatorenal syndrome as complications of liver cirrhosis. 3-Demonstrate paracentesis as therapeutic management and treatment of increased IAP.

CASE: A 28-year-old Hispanic male with medical history significant for morbid obesity, recreational drug use, and alcohol-induced liver cirrhosis resulting in ascites presented to our facility complaining of increasing abdominal girth, nausea, generalized abdominal pain, and swelling. He reported decreased urine output over the past two days. CT of the abdomen showed a cirrhotic-appearing liver without masses, massive ascites, and mild splenomegaly. Urine drug screen was positive for cocaine and opiates. Initial labs were significant for a total bilirubin of 10, ALP of 113, AST/ALT of 59/32, lipase of 205, and creatinine of 1.4. Baseline creatinine was around 0.9. An initial diagnosis of AKI due to hepatorenal syndrome (HRS) was made, and the patient was started on octreotide, midodrine, albumin, and furosemide. Serum creatinine improved initially to baseline before increasing to 2.2. IAP also increased, and a diagnosis of abdominal compartment syndrome (ACS) was made. An IR-guided paracentesis was performed, during which 6L of fluid were removed. After the paracentesis, the patient's renal function returned to baseline.

IMPACT/DISCUSSION: HRS is defined as an association between liver disease and oliguric renal failure characterized by reduction in glomerular filtration rate in patients with liver cirrhosis and hepatic failure. There are several theories on its pathogenesis, but arterial vasodilation in the splanchnic circulation is a significant contributing factor. Decline in renal perfusion also plays a role, and increased IAP can contribute to this. Patients may recover from HRS following liver transplant. However, if the disease progresses, end-stage liver failure may result in ascites, which then further increases IAP and may advance to ACS, therefore, while the precise mechanism of HRS is unknown, increased IAP is one significant contributing factor.

CONCLUSION: Surgical treatment for increased IAP (particularly ACS) includes decompressive laparotomy, but non-surgical management for increased IAP is effective as well. This includes sedation and analgesia, avoidance of the head of bed >30 degrees, paracentesis, percutaneous drainage, nasogastric decompression, avoiding excessive fluid resuscitation, diuretics, hemodialysis, vasopressors, optimizing ventilation/alveolar recruitment, and antibiotic therapy in septic patients. Physicians should be aware of the association between increased IAP, ACS, and HRS. Prevention of increased IAP and subsequent ACS can help avoid the development of HRS, which can then be treated via paracentesis.

HEREDITARY ANGIOEDEMA FLARE MIMICKING CELLULITIS

Praneet Kalkat¹; Sara Wikstrom². ¹George Washington University, Washington, DC; ²George Washington University, Potomac, MD. (Control ID #3184487)

LEARNING OBJECTIVE #1: Consider hereditary angioedema in non-resolving erythema and edema of extremities

CASE: 60 y/o African-American woman with history of hereditary angioedema, hypertension, fibromyalgia, chronic lower back pain, and chronic lower extremity edema presenting with left lower extremity erythema, pain, and swelling of 2 days. She denied any recent trauma to the area. She also denied any abdominal pain, lip swelling or trouble breathing. She was afebrile and on physical exam had 2+ pitting edema of her left lower extremity with erythema, warmth and mild tenderness to palpation. Labs showed a normal white count. An ultrasound showed no evidence of thrombosis. She was discharged on a 7-day course of clindamycin for presumed uncomplicated cellulitis. She presented to the emergency room 6 days later now with bilateral lower extremity pain, erythema, and swelling despite clindamycin treatment. Labs again showed no leukocytosis. Given her bilateral presentation, no response to antibiotics and no leukocytosis concern for hereditary angioedema flare was raised. C1 esterase inhibitor was found to be low at 17.1 mg/dl. She received 1 dose of Berinert IV 10-20 u/kg which she tolerated well with improvement of symptoms.

IMPACT/DISCUSSION: Hereditary angioedema is a rare autosomal dominant disease characterized by either low levels of C1 esterase inhibitor (type 1), as seen in our patient, or dysfunction of C1 esterase inhibitor itself (type 2). This genetic defect unleashes a break in the kallikrein-kinin pathway allowing for an increase in vasodilation and vascular permeability. During a flare, patients classically suffer from angioedema involving the layers of the gastrointestinal and upper respiratory tracts. We present an atypical presentation of hereditary angioedema, solely involving the skin of the lower extremities. Cutaneous attacks usually involve non-pitting edema with ill-defined margins that are non-pruritic and can be erythematous, but are usually not warm or tender to palpation as seen in our patient, likely leading to a delay in diagnosis. First-line treatment includes intravenous C1 esterase inhibitor, which our patient received with improvement in symptoms. As seen in our patient, it is important to consider non-infectious causes of erythematous and edematous lesions especially in the setting of no fever and leukocytosis. Earlier recognition can lead to unwarranted antibiotic use and rehospitalization. Finally, while patients with hereditary angioedema are usually screened for troubling upper respiratory or gastrointestinal symptoms it is important to screen for cutaneous symptoms in patients as well, which can be distressing for patients.

CONCLUSION: Consider hereditary angioedema in one's differential for a patient with non-resolving erythema and edema of extremities with no other signs of infection. It is important to screen patients with hereditary angioedema for cutaneous symptoms

HIDDEN ANSWER IN THE BONE MARROW

Aivi Doan. University of Connecticut, Middletown, CT. (Control ID #3186178)

LEARNING OBJECTIVE #1: Recognize clinical manifestations and diagnosis of thrombocytopenia

LEARNING OBJECTIVE #2: Understand the approach to adult with unexplained thrombocytopenia

CASE: 33 year-old female with past medical history of bipolar disorder on lithium and bupropion presented with one month of petechia rash evolving into ecchymoses without known trauma and several days of bleeding gums. On admission, CBC showed WBC 8.1, hemoglobin/hematocrit 11.6/33.5, and platelet 11. Patient was started on dexamethasone and later switched to high dose 1mg/kg prednisone based on working diagnosis of immune mediated thrombocytopenia. Bupropion was discontinued because of its implication in platelet antibody production and subsequent thrombocytopenia. Platelet did not improve with steroid; therefore a course of 5 days of IVIG-Privigen was started. Patient had intermittent epistaxis requiring transfusions. She also experienced menorrhagia and was started on medroxyprogesterone acetate. Her platelet remained low, and she received one dose of romiplostim. Her hospital course was complicated with acute intracranial hemorrhage along tentorium and posterior interhemispheric fissure likely subdural in location. Given the subdural hematoma, patient was given one dose of rituximab. Bone marrow biopsy was performed. In the interim, she became agitated and not directable concerning for side effect of steroid and cessation of bupropion. She was also found to have emphysematous cystitis and Escherichia coli bacteremia that might have contributed to the thrombocytopenia. Pathology from bone marrow was consistent with metastasis from breast cancer negative for progesterone, estrogen, and HER2/neu. Patient was started on chemotherapy of gemcitabine and carboplatin and steroid was stopped.

IMPACT/DISCUSSION: The case highlights the importance of recognizing uncommon cause of thrombocytopenia. On presentation, patient was severe thrombocytopenic with platelet about 11,000. Even though, thrombocytopenia is most often due immune mediated in relatively young and healthy individuals, alternative explanations should be investigated when the platelet does not improve with steroid or IVIG, which are considered first-line treatments. Patient's hospital course was complicated by acute intracranial hemorrhage, which is a rare, but can have devastating consequences. Therefore, any new headache in patients with severe thrombocytopenia should warrant a thorough neurological exam and likely an immediate CT head to rule out bleeding.

CONCLUSION: -Evaluate for wide range of explanations in patients with thrombocytopenia -Perform bone marrow biopsy in patients with persistent anemia and thrombocytopenia

HIDE AND GO SEEK: A CASE OF VANCOMYCIN-RESISTANT ENTEROCOCCUS IN THE BONE MARROW

Joannie M. Ivory¹; Khadeeja Ashai¹; Jennifer Schmidt². ¹Saint Louis University School of Medicine, St. Louis, MO; ²Saint Louis University, Saint Louis, MO. (Control ID #3179388)

LEARNING OBJECTIVE #1: Describe a case of VRE isolated in the bone marrow of a fungemic patient

LEARNING OBJECTIVE #2: Recognize VRE in the bone marrow as a potential cause of fever of unknown origin

CASE: We present a 67-year-old woman with history of recurrent urinary tract infections (UTI) initially admitted to the intensive care unit (ICU) with sepsis secondary to *Escherichia coli* (*E. coli*). She completed a 14-day course of ceftriaxone for *E. coli* bacteremia. Despite adequate treatment, her cognitive function declined. The patient was somnolent, less talkative, stopped following commands, and often had a blank stare. Repeat blood cultures from hospital day six turned positive for *Candida glabrata* after five days. The patient was started on micafungin; she remained febrile without improvement in mental status. Subsequent blood cultures were negative. Due to her prolonged fever the team began a workup for fever of unknown origin (FUGO) including evaluation for encephalitis, pulmonary, abdominal

and pelvic infection sources, and malignancy. A left ureteral lesion (unable to biopsy due to active infection), was concerning for possible malignancy vs fungal ball. In addition, she was neutropenic with a white cell count of 3,200 per microliter, so we obtained a bone marrow biopsy. Bone marrow culture grew Vancomycin-resistant *Enterococcus* (VRE) at 11 hours. Once we obtained the bone marrow results, we immediately started daptomycin and patient fever resolved within 24 hours of first dose, along with improvement in mental status.

IMPACT/DISCUSSION: VRE emerged as an organism of importance in the 1980s, largely due to its prevalence as a hospital-acquired infection. It is most commonly found in the gastrointestinal tract, as well as the genitourinary tract, skin, and oral cavity. It can also cause bloodstream infection (i.e. bacteremia). The factors most associated with a high risk of VRE bacteremia include bone marrow and solid organ transplants (due to immunosuppression), cancer, prior antibiotic exposure and ICU admission. Healthy individuals are at low risk of VRE infection; however, healthy individuals can spread disease to those who are critically ill through contact or contaminated objects. In the hospital, VRE accounts for ~35.5% of enterococcal infections, making it the second most common nosocomial infection in the United States. VRE bacteremia is typically treated with daptomycin or linezolid, with the former being preferred due to its bactericidal nature and low drug-to-drug interactions.

CONCLUSION: On review of the literature, there are no cases reported of VRE being isolated from the bone marrow of a non-transplant patient. However, clinicians should be aware of this organism's affinity for hematopoietic tissue. The work up for FUGO can include a bone marrow biopsy, but does not always lead to a diagnosis. However, it is helpful when clinicians suspect the source of fever is malignancy, as it can detect limited production of cell lines, or even yield a source of infection.

HIDING AMONGST THE RASHES—A CASE OF ECZEMA HERPETICUM IN A PATIENT WITH ACTIVE BENIGN FAMILIAL PEMPHIGUS

Rachael A. Gordon¹; Rebecca E. Mancoll². ¹University of Pittsburgh, Pittsburgh, PA; ²UPMC, Pittsburgh, PA. (Control ID #3170197)

LEARNING OBJECTIVE #1: Recognize eczema herpeticum in adults with underlying dermatological disorders.

CASE: A 75-year-old man with a history of benign familial pemphigus presented with a diffuse rash and fever. Eight days prior to admission, the patient developed pruritic, erythematous lesions on his genitals and inguinal folds, which he attributed to a benign familial pemphigus exacerbation. He applied topical clotrimazole/betamethasone dipropionate without improvement. Three days later, he developed a blistering rash over his right eye and mouth, along with worsening crusting plaques on his neck. The patient sought care at a local ED. He was given one dose of IV steroids and discharged on 40mg of prednisone for a presumed flare of his chronic disease. At follow-up with his PCP, he had a fever of 102.5°F and was referred back to the ED. There, his WBC was 8.5, with 80.5% neutrophil predominance, but laboratory studies were otherwise unremarkable. Blood and urine cultures were obtained. He received ampicillin/sulbactam and vancomycin for presumed bacterial superinfection prior to admission. On arrival, he reported bilateral blurry vision, headache, nausea, and diarrhea. Physical exam was notable for multiple small ulcers under the tongue, buccal mucosa, and soft palate with tender, erythematous, crusted plaques over his head, neck, and groin. Vesicular lesions with red bases were superimposed on the aforementioned lesions. Ophthalmological exam was unremarkable. He was started on IV acyclovir due to concerns for disseminated varicella (VZV) and continued on both antibiotics for possible bacterial superinfection. Blood and urine cultures remained negative. PCR of unroofed blisters at two different sites tested positive for herpes simplex virus (HSV)-1, suggesting a diagnosis of eczema herpeticum (EH). Antibiotics were discontinued on hospital day three. He was discharged on hospital day eight on valacyclovir to complete a total of 14 days of therapy.

IMPACT/DISCUSSION: Though more common in children, EH can affect adults. Patients with bullous disorders are prone to superimposed HSV and VZV. Clinical and histological identification of these infections remains challenging in the context of the underlying skin disease. Failure to recognize EH delays the initiation of definitive antiviral therapy, increasing the risk of dissemination, multi-organ failure, and fatal outcomes. It remains controversial whether the use of topical and systemic steroids to treat bullous disorders, as in this case, potentiates extension of localized infection and increases the risk for systemic dissemination of HSV. Intriguingly, occult HSV, but not VZV, colonization has been reported in patients with bullous dermatitides. EH may be more common than previously appreciated in patients with bullous disorders.

CONCLUSION: • EH is a serious complication of benign familial pemphigus that can mimic the underlying disease. • For patients presenting with a presumed exacerbation of their bullous dermatitis, testing for HSV/VZV should be pursued.

HIDING IN PLAIN SIGHT: PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA WITH NO CONTRAST ENHANCEMENT ON IMAGING

Saboor E. Randhawa¹; ahmed munir¹; Daniel A. Ermann¹; Ahmed Aly¹; Carrie Valenta². ¹Creighton University, Omaha, NE; ²Creighton University School of Medicine, Papillion, NE. (Control ID #3186150)

LEARNING OBJECTIVE #1: Diagnose central nervous system lymphoma when there is no contrast enhancement on imaging studies.

LEARNING OBJECTIVE #2: Assess for central nervous system lymphoma clinically based on symptoms and signs.

CASE: A 37-year-old female with history of migraines had frequent visits to the Emergency Department (ED) with severe progressive headaches. These were different in character from her migraines and associated with nausea, vomiting, photophobia and syncope. She was HIV negative and had no history of seizures or substance abuse. On her first ED visit, she had a syncopal episode with unremarkable neurological exam and laboratory findings. CT without contrast showed non-specific hypodense areas with no evidence of acute abnormalities. MRI with contrast revealed extensive but non-specific changes suggestive of demyelination and inflammation. There were minimal patchy contrast enhancement areas that extended along the course of the perforator vessels in the basal ganglia on both sides, left greater than right. There was otherwise no contrast enhancement. She was readmitted within the same month for similar symptoms. Neurology was consulted. Cerebrospinal fluid (CSF) cell count, glucose and protein were within normal limits. Further investigations including CSF PCR for various pathogens for meningo-encephalitis were negative. The patient was started on a five-day course of steroids. A few immunoblasts were found on CSF fluid analysis. Peripheral blood smear did not reveal abnormal cells, and another LP was performed for CSF flow-cytometry to rule out malignancy. Due to the above inconclusive results, Neurosurgery suggested stereotactic brain biopsy which revealed Primary Diffuse Large B-Cell Lymphoma of the CNS. Repeat CT and MRI scans also did not reveal contrast enhancement. The patient was then started on appropriate chemotherapy with improvement in her symptoms.

IMPACT/DISCUSSION: Early diagnosis of PCNSL often requires a high degree of suspicion, as symptoms can evade diagnosis for many months. Presenting signs and symptoms vary, depending on the site of involvement. Evaluation of PCNSL should include imaging of the CNS, ideally with contrast-enhanced MRI. CT with contrast can be used if MRI is contraindicated. Tissue diagnosis should not be delayed and definitive diagnosis requires histopathological evaluation. In population-based studies, five-year survival for immunocompetent adults is approximately 30 percent. In another study, treatment delay (greater than 30 days after diagnosis) was the most important clinical variable associated with decreased survival, independent of baseline performance status. Non-enhancing lesions can delay the diagnosis, hence delaying the initiation of treatment.

CONCLUSION: - PCNSL can present without contrast enhancement, and delay in the treatment directly affects the survival of these patients. - PCNSL must be in the list of differential diagnoses even when non-enhancing, diffuse lesions are seen on CT/MRI.

HIT YOU WHILE YOU'RE DOWN: EARLY STENT THROMBOSIS DUE TO HEPARIN-INDUCED THROMBOCYTOPENIA

Elizabeth Ocypok; Joshua M. Haswell; Amar Kohli. UPMC, Pittsburgh, PA. (Control ID #3186125)

LEARNING OBJECTIVE #1: List risk factors for and clinical signs of early stent thrombosis

LEARNING OBJECTIVE #2: Diagnose HIT based on established clinical and laboratory data

CASE: A 45-year-old man with hypertension and hyperlipidemia presented with chest pain. EKG revealed acute inferior wall ST-elevation myocardial infarction. Left heart catheterization showed a large occlusive thrombus in the right coronary artery, which was treated with three drug-eluting stents. The patient was started on a heparin drip, aspirin, and clopidogrel for high-risk STEMI with large thrombotic burden. On hospital day 7, the patient developed chest discomfort and diaphoresis with several self-terminating runs of polymorphic ventricular tachycardia. Repeat catheterization revealed a large occlusive thrombus in the RCA at the site of previous stent placement. No further stenting was done. The patient's platelets were observed to acutely drop from 216 on hospital day seven to a nadir of 30 on hospital day nine. 4T score was 6 and heparin platelet factor-4 antibody OD was 1.658 (high probability of HIT). Serotonin release assay was negative. Patient was transitioned from heparin to argatroban on hospital day 9, and his platelet counts recovered to baseline. He was discharged on hospital day 18 on aspirin, ticagrelor, and warfarin.

IMPACT/DISCUSSION: Heparin-induced thrombocytopenia is an uncommon, life-threatening, "can't miss" diagnosis. Cardiac patients are commonly exposed to heparin in the setting of acute myocardial infarction. Stent thrombosis can occur in up to 3.1% of STEMIs and can present with recurrent ischemic changes on EKG or arrhythmias such as polymorphic VT. Dual antiplatelet therapy and newer generation drug-eluting stents decrease rates of stent thrombosis, however, procedural characteristics such as emergent stent placement and residual thrombus near the stent, as well as patient factors such as low ejection fraction, underlying hypercoagulable state, and diabetes can increase stent thrombosis risk. If there is high clinical concern for HIT based on the 4T score, confirmatory testing should be sent, all heparin products should be stopped, and the patient should be anticoagulated with a non-heparin agent. In this case, the patient's 4T score was elevated on hospital day 8, but was not initially recognized, leading to a delay in treatment. Also, his serotonin release assay, considered the "gold standard" of HIT diagnosis, was negative, illustrating that false negatives are still possible in sensitive tests. Consideration of clinical context remains important.

CONCLUSION: 1) HIT should be considered as a possible cause of early stent thrombosis. 2) Stent thrombosis has a 30-day mortality rate of 10-25% and has a high recurrence rate, necessitating close monitoring and careful choice of antiplatelet therapy. 3) Test characteristics of the 4T score, confirmatory immunoassay, and functional assay should be carefully considered when making clinical decisions about suspected HIT cases.

HOG HUNTING GONE WILD: A RARE ZOONOSIS CAUGHT CLOSE TO HOME

Syeda A. Raza. Methodist Health Systems Dallas, Dallas, TX. (Control ID #3185804)

LEARNING OBJECTIVE #1: Recognize infection with zoonotic organisms as a cause of sepsis in humans

LEARNING OBJECTIVE #2: Recognize importance of investigation of zoonotic staphylococcal infections to ensure correct species identification

CASE: A 57-year-old man with past medical history of hypertension and left partial nephrectomy for renal cell carcinoma presented to the emergency department with several days of fevers, diarrhea, and fatigue. On examination, the patient was lethargic and febrile to 103 degrees Fahrenheit with a blood pressure of 80/50 mmHg. His labs were notable for an elevated serum lactic acid of 2.06 with the remainder of labs otherwise unremarkable. Given complaints of diarrhea, a CT of his abdomen was performed showing enterocolitis. The patient was admitted for concern of sepsis and a set of blood cultures were collected on admission that ultimately grew *Staphylococcus hyicus*. He was started on fluids and IV Vancomycin resulting in improvement in his clinical condition. A subsequent trans-thoracic echocardiogram (TTE) and trans-esophageal echocardiogram (TEE) were negative for endocarditis. After the cultures grew this unusual organism, the patient was questioned more pointedly. He admitted recently visiting a farm where sausage had just been made from feral hogs. He had eaten the sausage just days prior to onset of illness and he further reported that he had undergone extensive dental work just prior to that meal. This additional history helped explain how our patient may have been infected from bacterial translocation/seeding to the blood.

IMPACT/DISCUSSION: *Staphylococcus hyicus* is a part of the natural flora of several animals. It is mainly involved in exudative epidermitis in pigs but has also been isolated from skin infections in horses, mastitis in cows, and even from a human wound infection from a donkey bite. On our review of literature, there was only one other case of *S. hyicus* bacteremia in a patient who came in close contact with his piglets. In our case, the patient's presumed source of infection came from consumption of wild hog meat after recent dental work.

CONCLUSION: This case highlights several important points for clinical practice when making the diagnosis. First, it is important to note that *S. hyicus* can present as sepsis in humans, especially those that are immunocompromised. Second, a thorough history is imperative to help with the clinical diagnosis. Third, *S. hyicus* is often misidentified as *S. aureus*. Therefore, further investigation is indicated in zoonotic staphylococcal infections to ensure correct species identification.

HOLD YOUR HORSES: THIS AIN'T NO ORDINARY STREP

Rui Jiang^{2, 1}; Michael Herscher³; Harish Jasti². ¹The Mount Sinai Hospital, New York, NY; ²Icahn School of Medicine at Mount Sinai, New York, NY; ³The Mount Sinai Hospital, New York, NY. (Control ID #3185046)

LEARNING OBJECTIVE #1: Identify the clinical features of *Streptococcus equi* infections.

LEARNING OBJECTIVE #2: Recognize the similarities to common features of other *Streptococcus* infections.

CASE: A 63yo woman presented with purulent drainage from a right breast mass. She first noticed the breast mass 8 years prior, but had declined work up at the time. A month prior to presentation, she had noted red discoloration overlying the mass and subsequently developed a draining wound. She also reported right upper extremity swelling, chills, shortness of breath, and dry cough. She owns and operates a horse-rescue farm, but denied any contact with sick horses over the past 1-2 months. On exam, she was afebrile with a HR of 116. She had a 10x20cm irregularly-shaped wound with eschar and purulent drainage extending from the right breast into the axilla. Underlying muscles were visible. She had 3+ pitting edema extending from the right shoulder to hand. Labs were significant for WBC of 31.7 with 96.9% PMNs, and creatinine of 3.82, with unknown baseline. Blood cultures grew *Strep. Equi* in 4 out of 4 bottles. A CT chest showed a left pleural effusion, and possible osteomyelitis in the anterior ribs below the right breast mass. Thoracentesis revealed empyema with no malignant cells, and TTE did not show any valvular vegetation. Breast biopsy revealed poorly-differentiated duct

carcinoma, ER/PR+, HER2-. She subsequently underwent chest tube placement for empyema and completed a 6-week course of antibiotics. She eventually accepted only hormone-modulating treatment for breast cancer with goals to be DNR/DNI.

IMPACT/DISCUSSION: *Streptococcus equi* (SE) infection is a zoonotic disease with a variety of clinical presentations. The subspecies *zooepidemicus* is a part of the normal flora of horse respiratory tract, and is the most commonly reported to cause human infections. Transmissions have mainly been reported by direct contact with horses, dogs, cats, cattle, sheep and goats. Epidemics have been reported through ingestion of unpasteurized milk and cheese from cows with mastitis. SE is a Lancefield C, beta-hemolytic *Streptococcus* that shares > 80% DNA sequence as well as virulence factors with *Strep. pyogenes* (SP). It can cause rheumatic fever, glomerulonephritis, purulent arthritis, and skin infections similar to SP. In addition, pneumonia, bacteremia of unknown focus, meningitis, and more complex sequelae such as aortitis and endocarditis have been reported. Though all strains are penicillin sensitive, case-fatality rate can be as high as 63% in small outbreaks. Hand washing after handling animals has been proposed as the key intervention to prevent this infection.

CONCLUSION: Given that 30.5% of US households have a horse enthusiast and many more come in contact with barn animals, *Strep. equi* has the potential to become an emerging zoonosis with threat to human life. Prompt recognition of this infection with its similarities to that of *Strep. pyogenes* is important because appropriate management can lead to mitigation of its high mortality rates.

HORSES DRESSED AS ZEBRAS - THE DIAGNOSTIC CHALLENGES OF AN OUTPATIENT WORKUP

Joshua W. Harbaugh¹; Claudia L. Campos². ¹Wake Forest University School of Medicine, Winston Salem, NC; ²Wake Forest University, Winston-Salem, NC. (Control ID #3186423)

LEARNING OBJECTIVE #1: Appropriate utilization of outpatient diagnostic workups in clinically complex patients

CASE: A 61-year-old Caucasian male presented to clinic for his first adult medical evaluation with complaints of progressive weakness. Along with this symptom, he experienced daily dry cough, dyspnea on exertion, fatigue and unintentional weight loss of thirty pounds over six months. He denied fever, chills, night sweats, chest pain, orthopnea, PND or edema. No changes in bowel or bladder function. He denied past medical history and took no medications or supplements. He is an 80 pack-year smoker with remote history of alcoholism and poly-substance abuse. He recounts severe life stress from losing his electricians job due to inability to climb ladders. Family history was unclear, but knew parents lived into their late 70's. On physical examination, BP 143/90, pulse 68, RR 16, height 5' 8", 158lbs, SpO2 95% on RA and 85% with ambulation. Frail appearance with thinning hair. Lung examination revealed a barrel chest and diffuse expiratory wheezing. Cardiac examination: normal S1, S2, no murmurs and no JVD. Extremities: no edema, normal pulses, hands with digital clubbing. Neurological Examination: Hip flexion strength: 3 of 5 bilaterally, 4+ elsewhere. Reflexes: 2+ symmetric.

IMPACT/DISCUSSION: The patient was diagnosed clinically with a chronic proximal myopathy, COPD with hypoxemia and unexplained weight loss concerning for underlying malignancy with possible paraneoplastic syndrome (presumed lung cancer). Supplemental oxygen and inhalers were prescribed for severe COPD. Results of his work-up spanned over four weeks and were unconventionally obtained by the patient. First, his CT Chest showed severe destructive centrilobular emphysema, no nodules or masses, severe coronary calcification and a small pericardial effusion. Then, he underwent EMG/NCS, his results pending at the time of his two-week follow-up when his complaints were unchanged. Laboratory analyses were notable for Hb 11.5, Na 134, Cr 1.79, BUN 25, AST 41, Total Cholesterol 392, LDL 314, TG 291, HDL 30,

normal B12, folate, Iron panel. TSH of 90.422 with free thyroxine <0.03. EMG was consistent with hypothyroid myopathy. Diagnosis was hypothyroidism and initiated on levothyroxine. High intensity statin for hypercholesterolemia. Work-up for chronic kidney disease, anemia and HTN was started but patient did not return to clinic and was not completed.

CONCLUSION: This case, largely suspenseful secondary to the labyrinthine outpatient workup, highlights challenges faced by internists embarking on ambulatory evaluations of weakness in medically complex patients. After CT excluded lung malignancy, and his EMG results and lab analysis were available, hypothyroidism was finally diagnosed. While thyroid myopathy is not rare, the multisystem physical and laboratory manifestations of hypothyroidism are perfectly showcased in this presentation. His weight loss remains puzzling but could be attributed to severe COPD (lung cachexia) or other malignancy.

HOST BY AN ACCIDENT!

Rani Bhatia; Brett Styskel; Nautam Ganatra. Baylor College of Medicine, Houston, TX. (Control ID #3185998)

LEARNING OBJECTIVE #1: Assess exposure history and recognize potential endemic disease in a patient presenting with atypical infectious symptoms.

CASE: A 41-year-old male with non-alcoholic steatohepatitis presented with a week of high fevers to 105 F, myalgias, abdominal pain, diarrhea, and 2 days severe headache associated with visual hallucinations. Vitals on presentation were T 102 F, BP 93/55 mmHg, HR 120 bpm, and SaO₂ 96%. Physical exam was remarkable for nuchal rigidity, jaundice, diffuse abdominal tenderness without peritoneal signs, and hepatosplenomegaly. Lab results showed leukocytosis 10,300/mm³ with 91% PMNs, new thrombocytopenia 75,000/mm³, creatinine 1.6 (baseline 0.8) mg/dL, AST 139 IU/L, ALT 178 IU/L, ALP 236 IU/L, total bilirubin 7.9 mg/dL, direct bilirubin 5.3 mg/dL, lipase 88 U/L, and lactate 1.8 U/L. Influenza, RSV, C. difficile, HIV, hepatitis panel, acetaminophen level, hemolysis and disseminated intravascular coagulation labs were negative. CT scan of the head was unremarkable. Abdominal ultrasound showed no acute hepatobiliary pathology. Lumbar puncture showed white blood cell count 6 (neutrophil 80%), protein 22 mg/dL, and glucose 46 mg/dL. Detailed history revealed that he spent an hour picking fleas off his pet dog eight days prior to the onset of fever. He also lived in a wooded area with opossums in his neighborhood. He was started on empiric doxycycline for presumed murine typhus with rapid improvement in his symptoms. Labs showed *Rickettsia typhi* IgG and IgM immunofluorescence assays >1:256. All cultures as well as Leptospirosis, EBV, CMV antibodies and syphilis titer were negative.

IMPACT/DISCUSSION: In the US, the classic rat-flea-rat cycle as a reservoir for *Rickettsia typhi* was targeted by aggressive rat control in the 1940s. These efforts led to a decrease in annual cases of murine typhus from 5,000 to less than 100 by the 1980s. The infection is now seen mainly in suburban areas of Texas and California, and instead perpetuated by cat fleas (*Ctenocephalides felis*) that reside on opossums, dogs, and cats, with humans as the "accidental" host. Incidence of disease in Texas has been increasing over the last 15 years, with 519 cases in 2017 alone (40% increase from the year prior). Although murine typhus is generally a self-limited illness, the risk of complications and mortality may be up to 4% if treatment with doxycycline is delayed. Typhus presents a diagnostic challenge for clinicians, as symptoms are often nonspecific. In fact, the classic triad of fever, rash, and headache may only be seen in 33% of adults. Thus, awareness of murine typhus is important to ensure a timely diagnosis and reduce the risk of serious complications e.g. respiratory failure, aseptic meningitis, seizures, acute renal failure and septic shock.

CONCLUSION: -Murine typhus has increased in incidence in the US recently, with cat fleas as the new vector for *R. typhi*. -Awareness of murine typhus is important to ensure a timely diagnosis and reduce the risk of serious complications including mortality.

HOW LOW CAN YOU GO? AN INTERESTING CASE OF HYPOGLYCEMIA

Christopher Vercammen-Grandjean. St. Jude Heritage Medical Group, Orange, CA. (Control ID #3162765)

LEARNING OBJECTIVE #1: Recognize the problem of rebound hypoglycemia in diabetic patients with CKD or ESRD

LEARNING OBJECTIVE #2: Learn how best to manage this problem with dietary changes

CASE: A 75 year old man with a history type 2 diabetes managed with insulin and sulfonylurea, end-stage renal disease recently started on hemodialysis, and obesity presented to a community hospital after a witnessed syncopal event at home. Prior to his loss of consciousness he had started to feel light headed and dizzy, but he quickly regained full consciousness after. His family checked his serum glucose and it was 37, they had him drink orange juice and his symptoms resolved. He was then brought to the hospital. Later that evening a re-check of his glucose revealed a low of 67 and he was given orange juice, resulting in a rise in his blood sugar and resolution of symptoms of hypoglycemia. He was placed on a diabetic diet. In spite of this he continued to have frequent low blood sugars in the hospital ultimately requiring an infusion of dextrose containing normal saline. On further history, his family discussed how this had been an ongoing problem at home and that he was constantly eating candy bars throughout the day to avoid hypoglycemia, even after his insulin and sulfonylurea medications were discontinued. An endocrine consultation was then placed and he was started on a strict low carbohydrate diet without concentrated sugar, with higher protein and fat content. Low blood sugars were treated with combinations of complex carbohydrates and protein containing foods. Ultimately he was weaned off the dextrose infusion and his blood sugar stabilized. He continued the diet after discharge, at three month follow-up he had lost 40 pounds and had had no low blood sugars at home. His diet was liberalized without subsequent hypoglycemia.

IMPACT/DISCUSSION: Hypoglycemia in diabetic patients with chronic kidney disease is a well-recognized problem. (Rhee, 2018) As renal function worsens, insulin half-life lengthens, in combination with reduced renal gluconeogenesis and impaired metabolism of hypoglycemic medications. Hospitalizations for hypoglycemia can increase in the years leading up to initiation of renal replacement therapy. (Rhee, 2018) Thus it is important for the internist to recognize rebound hypoglycemia as described above, and intervene early to avoid unnecessary hospitalizations or prolonged hospital stays. Early consultation with endocrinology, a diabetes educator, and dietitian can help though further research is needed. In our case, a diet that limited concentrated sugars to almost none, and ensuring co-ingestion of protein and/or fat with carbohydrate helped avoid hypoglycemia.

CONCLUSION: Early recognition of normalizing blood glucose and the increasing risk of hypoglycemia in patients with CKD and diabetes is important to prevent adverse events for patients.

HYDROXYCHLOROQUINE TOXICITY LEADING TO CARDIAC ARREST IN A 23-YEAR-OLD

Michael Grzeskowiak²; Daniel Pu¹. ¹Montefiore Medical Center, San Antonio, TX; ²University of Texas Health Science Center at San Antonio, San Antonio, TX. (Control ID #3185812)

LEARNING OBJECTIVE #1: Recognize that hydroxychloroquine (HCQ) can cause atrioventricular block, bundle branch block, and QT prolongation which can occur over weeks to years of treatment.

LEARNING OBJECTIVE #2: Treat HCQ toxicity by discontinuing the medication and follow for the resolution of the toxicity, which does not always occur.

CASE: A 23-year-old woman with systemic lupus erythematosus (SLE) and end-stage renal disease (ESRD) presented to the hospital with

hyperkalemia after missing dialysis and her HCQ for several months. Electrocardiograph (ECG) showed a normal QT interval and a transthoracic echocardiogram (TTE) revealed an ejection fraction of 55%. She was subsequently restarted on dialysis and her home hydroxychloroquine. Three weeks after her admission she suffered a cardiac arrest from ventricular fibrillation during dialysis. Both pre-arrest and post-arrest labs were within normal limits. ECG showed no ischemic changes but revealed a prolonged QT interval of 600 msec. Repeat TTE revealed new severe biventricular failure with an ejection fraction of 15%. HCQ was then discontinued and a cardiac biopsy revealed changes consistent with HCQ toxicity. Repeat TTE showed minimal improvement in ejection fraction and a subcutaneous implantable cardioverter defibrillator (ICD) was placed. Follow up TTE one month later showed continued severe left ventricular dilation with an ejection fraction of 25%. However, ECG showed resolution of QT prolongation. The patient's mental status improved and she was discharged to acute rehabilitation.

IMPACT/DISCUSSION: Hydroxychloroquine (HCQ) has been associated with conduction disease including atrioventricular block, bundle branch block, and QT prolongation. Though these changes often take years to develop, they may rapidly worsen in patients on dialysis. If screening is not initiated and these changes are left unnoticed, the cardiotoxicities can lead to death.

CONCLUSION: HCQ is known to cause cardiotoxicities such as cardiomyopathies and conduction disturbances. These cardiotoxicities usually develop after long-term use with literature reviews demonstrating a mean of 10 years. Furthermore, the prognosis of HCQ cardiotoxicity ranges from complete improvement in cardiac function, to requiring cardiac transplant, to death. In our case, the QT interval demonstrated normalization following discontinuation of HCQ, as has been reported in prior cases. However, her cardiomyopathy did not improve and she required an ICD placement. With HCQ undergoing renal and hepatic excretion, toxicities can often be rapidly exacerbated in patients with renal insufficiency and can develop more rapidly than the 10-year average. Caution should be taken when starting or continuing patients on HCQ in patients on or nearing dialysis. Moreover, clinical suspicion should be high for cardiotoxicity in patients who have been on HCQ for many years. If caught early, these patients could reverse their cardiotoxicities and avoid premature death.

HYPERAMMONEMIC ENCEPHALOPATHY IN ROUX-EN-Y GASTRIC BYPASS WITH AFFERENT LOOP SYNDROME

Hanyuan Shi¹; Kevin Lee²; Erik Johnsen¹. ¹Tulane University, New Orleans, LA; ²Columbia University, New York City, NY. (Control ID #3162974)

LEARNING OBJECTIVE #1: Consider not only nutritional deficiencies in RNYGB patients but also encephalopathy and defects in the ammonia cycle

CASE: A 33-year-old female with elective gastric bypass surgery 10 years prior (Roux-en-Y, complicated by afferent loop syndrome requiring subsequent small bowel resection), untreated Hepatitis C (but persistently negative RNA titers), bipolar disorder initially presented to the hospital with rash on thighs and forearms thought to be due to drug allergy from furosemide. The patient was found to be encephalopathic and malnourished. Labs on admission were significant for INR 1.2 (0.9-1.1), total bilirubin 3.1 (0.1 - 1.2 mg/dl), alkaline phosphatase 238 (44-147 IU/L), ammonia 168 (15-45 u/dl), lactate 2.4 (0.5-1.0 mmol/L). Abdominal CT showed diffuse fatty infiltration of the liver but no signs of bowel ischemia. Ammonia peaked at 180 but stayed elevated to 110-130 despite administration of optimal doses of rifaximin and lactulose. Found to have E. Coli UTI, treated with ceftriaxone. Stepwise decline in mental status along with worsening respiratory requirements led to intubation in the ICU. Imaging showed pulmonary edema and patient underwent diuresis with ethacrynic acid. She was extubated a few days later without complication and steadily improved in her mental status. Liver biopsy showed focal pericellular and perisinusoidal fibrosis on

trichrome stain (stage 2/4), negative iron deposition, negative intracytoplasmic inclusion, and negative reticulin stain. She had >66% steatosis, some lobular inflammation, few ballooned hepatocytes for a non-alcoholic fatty liver disease activity score (NAS) of 5/8. Further work-up was significant for micronutrient deficiencies (Vitamin A, Vitamin D), low copper 38 (80-155 ug/dl), low zinc 24 (60-120 ug/dl).

IMPACT/DISCUSSION: A recent review noted a newly recognized, almost lethal syndrome related to hyperammonemia after Roux-en-Y gastric bypass (RYGB) surgery. 95% of these patients are women. Previous cases have involved urea cycle deficiencies (ornithine transcarbamylase deficiency, carbamoyl phosphate synthetase deficiency) leading to impaired ureagenesis and elevated serum glutamine levels. Physiologic stressors can then predispose these non-cirrhotic patients to encephalopathy. In this patient's case, the trigger may have been an infection (UTI), nutritional changes (given hypoalbuminemia). Treatment includes lactulose, neomycin, arginine infusions, phenylbutyrate, citrulline, zinc supplements; the latter therapies work to remove nitrogen via alternative pathways in the ammonia cycle.

CONCLUSION: In RYGB, significant weight loss after surgery creates a catabolic setting where increased breakdown and subsequently deposition of nitrogenous waste in the liver can lead to encephalopathy. Our particular anatomically challenging case demonstrates life-threatening hyperammonemia that was exacerbated by a combination of liver disease and abnormal nitrogen processing from nutrition deficits.

HYPERCALCEMIA AS THE ONLY MANIFESTATION OF COCCIDIOMYCOSIS

Mais Abdou¹; Nooraldin Merza¹; Asrar Abdou³; Kaylee J. Shepherd².

¹TTUHSC, Amarillo, Amarillo, TX; ²Texas Tech University Health Sciences Center, Amarillo, TX; ³St Joseph Mercy Oakland, Troy, MI. (Control ID #3181584)

LEARNING OBJECTIVE #1: Learn to include fungal infections such as coccidioidomycosis in your differential diagnosis of hypercalcemia. Recognize the diagnostic algorithm of hypercalcemia.

CASE: An 82 year-old male with medical history of hypertensive chronic kidney disease stage III presented to our hospital for near syncope during a routine outpatient laboratory draw. He reported generalized weakness, malaise, unintentional 30lbs weight loss, constipation, nausea and decreased appetite for several months. Vital signs stable and exam revealed palpable lymphadenopathy of the cervical chain. Laboratory workup showed normal white blood cell count and differentiation, hemoglobin 9.9 g/dl, calcium 12.1 mg/dl with ionized level 1.62 mg/dl, creatinine 2.03 mg/dl from a baseline of 1.3 mg/dl, intact parathyroid hormone (PTH) 45 pg/ml, PTH related peptide 8 pg/ml, 25 hydroxyvitamin D 45 pg/ml, but an elevated 1,25 dihydroxyvitamin D at 60 pg/ml. CT neck and chest showed cervical lymphadenopathy and thyroid nodule. Bone scan showed no lytic or destructive osseous lesion. Parathyroid sestamibi scan showed a focal abnormality, which correlated with the thyroid nodule detected on the CT scan. Fine needle aspiration pathology was consistent with benign follicular adenoma. Peripheral blood smear revealed moderate anemia with normal WBCs and no dysplastic features. Serum and urine protein electrophoresis were normal. Bilateral bone marrow biopsy showed normocellular marrow with no evidence of myeloma or malignancy. Cervical lymph node biopsy was consistent with granulomatous lymphadenitis with fungal spherules of *Coccidioides immitis*. There was no evidence of malignancy. On further history, he reported visiting rural Arizona frequently. The patient was placed on fluconazole 400 mg daily with 3 month follow up showing significant symptomatic relief with calcium level down to 9.7 mg/dl.

IMPACT/DISCUSSION: Hypercalcemia has been described in patients with granulomatous disorders, especially sarcoidosis and tuberculosis, but rarely with fungal granulomas like coccidioidomycosis. The mechanism of hypercalcemia in patients with coccidioidomycosis is unclear and there is

no evidence of increased production of 1,25-dihydroxyvitamin D. Most cases reported hypercalcemia either due to disseminated disease or during the treatment phase. In our patient, his hypercalcemia was the main clinical finding that led to the diagnosis and interestingly his 1,25 dihydroxyvitamin D was elevated and hypercalcemia improved with antifungal treatment. This implies that more studies are needed to determine the underlying etiology for hypercalcemia in Coccidioidomycosis infections.

CONCLUSION: Coccidioidomycosis should be considered in the differential diagnosis of hypercalcemia. The mechanism of the hypercalcemia is unclear and more studies are needed. However, it appears to be independent of parathyroid hormone. Hypercalcemia in those patients is usually a reversible complication with treating the underlying infection.

HYPERCALCEMIA FROM PNEUMOCYSTIS JIROVECII PNEUMONIA IN A RENAL TRANSPLANT RECIPIENT

Alisha Hossain¹; Vincent Lipari²; Snigdha Reddy². ¹Michigan State University College of Osteopathic Medicine, Exton, PA; ²Henry Ford Hospital, Detroit, MI. (Control ID #3173935)

LEARNING OBJECTIVE #1: Recognize clinical and laboratory features of *Pneumocystis jirovecii* pneumonia (PJP) in immunocompromised patients

LEARNING OBJECTIVE #2: Treat hypercalcemia in the setting of acute kidney injury

CASE: A 63-year-old male with a past medical history of a living unrelated donor renal transplant secondary to autosomal dominant polycystic kidney disease presented with 3 weeks of fatigue, persistent non-productive cough, subjective chills, and worsening exertional dyspnea. Chest computed tomography showed ground-glass opacities and increased interstitial markings involving the left lung and right perihilar region without pleural effusion, pneumothorax, or cardiomegaly. He was empirically started on daily intravenous (IV) azithromycin and ceftriaxone due to suspected multifocal pneumonia. Acute kidney injury (AKI) with a creatinine of 3.4 mg/dL and BUN of 67 mg/dL was noted. He was admitted to the intensive care unit with hypoxic respiratory failure and escalation to broader spectrum antibiotics: vancomycin and piperacillin/tazobactam. He was noted to have coarse breath sounds with wheezing on lung exam. Initial labs revealed a serum calcium (Ca^{+2}) of 12.0 mg/dL. Vancomycin was subsequently changed to IV Linezolid. IV Clindamycin and Primaquine daily were added due to suspected PJP. Bronchoscopy with bronchoalveolar lavage revealed a white blood cell count of 103/ μL with no organisms. PJP on polymerase chain reaction and elevated -D-glucan were noted. Antibiotics were then tailored to 3 weeks of Clindamycin and Primaquine to treat PJP. His Ca^{+2} increased to 13.5 mg/dL likely due to PJP and AKI. Additional laboratory data revealed suppressed parathyroid hormone (PTH) levels at 15 pg/mL and elevated 1,25-dihydroxy-vitamin D (1,25-(OH)₂ D₃) at 156 pg/mL. His hypercalcemia proved resistant to IV fluids followed by IV diuresis, ketoconazole, and calcitonin. However, his Ca^{+2} corrected to 10.0 mg/dL after administration of a denosumab injection.

IMPACT/DISCUSSION: This case demonstrates the intricate care and teamwork needed to care for a patient with a complicated clinical course. Approaching the treatment of hypercalcemia in a stepwise manner with attention to AKI resulted in improvement. Previously, hypercalcemia has been reported with PJP in many case reports. Ling et al. presented cases of PJP-induced hypercalcemia. It has been suggested that in PJP, interferon-induced alveolar macrophage activation of 1-hydroxylase converts 25-(OH) vitamin D to active 1,25-(OH)₂ D₃. In turn, activated vitamin D₃ increases Ca^{+2} absorption from the intestine and bone. PTH is suppressed as the normal inhibitory feedback mechanism is not affected.

CONCLUSION: We present a particularly resistant case of PJP-induced hypercalcemia, which resolved with a single denosumab injection. Reference: Ling, Jonathan, et al. "Hypercalcaemia preceding diagnosis of *Pneumocystis jirovecii* pneumonia in renal transplant recipients." *Clinical kidney journal* 10.6 (2017): 845-851.

HYPERCALCEMIA IN SETTING OF MILK ALKALI SYNDROME

Nihar Shah¹; Khary Edwards¹; Toishi Sharma¹; Jennifer Baldwin². ¹University of Connecticut, Hartford, CT; ²University of Connecticut, Farmington, CT. (Control ID #3186273)

LEARNING OBJECTIVE #1: Milk-alkali syndrome refers to a triad of hypercalcemia, metabolic alkalosis and acute kidney injury caused by the excessive ingestion of calcium and base - typically in the form of milk and calcium-containing antacids. It was common prior to the introduction of histamine-2 antagonists and proton pump inhibitors for the treatment of peptic ulcer disease. A resurgence has been seen now with the widespread availability of calcium supplements.

CASE: We present a case of a 49-year-old female who was sent by her primary care physician (PCP) after she was found to have a calcium level of 15.7 mg/dL. She endorsed a one-week history of decreased appetite, generalized weakness and increased lethargy. Past medical history was significant for GERD for which she took 2 g of over-the-counter Calcium Carbonate daily over the past 30 years. She had also been started on a thiazide diuretic one month prior to her presentation. She denied any history of renal disease or malignancy. Physical exam was only significant for a psoriatic rash on her bilateral lower extremities. On admission, her laboratory results were significant for an elevated creatinine of 1.6mg/dL (her baseline was 0.9mg/dL), Calcium of 14.8mg/dL, bicarbonate of 33meq/L. EKG showed a normal sinus rhythm with a QTc of 414ms. She was admitted for management with aggressive IV fluid hydration and she was also given one-time doses of calcitonin and zoledronic acid. Her hospital course was complicated by fever to 102.6 and diarrhea thought to be secondary to zoledronic acid. These symptoms resolved and at discharge, her serum calcium was 8.3mg/dL. She was started on a proton pump inhibitor and counseled to stop taking calcium carbonate tablets. Three days following discharge, she was sent by her PCP once more for assessment of a calcium level of 7.6mg/dL and phosphate of 1.5mg/dL. She was treated with 1g IV calcium gluconate and discharged. Laboratory results two days later showed a calcium of 8.1mg/dL.

IMPACT/DISCUSSION: Milk-alkali syndrome represents the third most common cause of hypercalcemia. Excessive intake of calcium leads to vasoconstriction of the afferent renal arterioles, decreased GFR and decreased ability to filter calcium. This is only exacerbated by introduction of a thiazide diuretic, further reducing calcium excretion. Zoledronic acid can cause delayed hypocalcemia as in this case, making close monitoring important. This case highlights the importance of a thorough medication history and the need for patient education on over the counter medication use.

CONCLUSION: This case highlights how fluid resuscitation forms the cornerstone of initial management of hypercalcemia and highlights that use of bisphosphonates in the acute setting should only be initiated in refractory or severely symptomatic cases. It also re-emphasizes how dangerous over-the-counter medicines can be as well as the importance of thorough medication history and medication reconciliation to avoid potential dangerous drug-drug interactions.

HYPERCALCEMIA OF MALIGNANCY: A CASE OF VITAMIN-D MEDIATED HYPERCALCEMIA IN LYMPHOMA

Maham Awan¹; Shannon Devlin¹; Simerjot K. Jassal^{1, 2}. ¹University of California San Diego, San Diego, CA; ²VASD, San Diego, CA. (Control ID #3186430)

LEARNING OBJECTIVE #1: Recognize mechanisms of hypercalcemia in lymphoma

LEARNING OBJECTIVE #2: Review treatments of hypercalcemia in malignancies

CASE: An 86-year-old man with splenic marginal zone lymphoma was admitted with hypercalcemia and acute kidney injury. Presenting symptoms

included weakness and abdominal pain with exam notable for left upper quadrant tenderness. Admission labs revealed a corrected calcium level of 13.7 mg/dL and a creatinine of 2.62 mg/dL (baseline 1 mg/dL). On review of history, hypercalcemia led to his diagnosis of lymphoma. He required prior admissions for treatment with fluid, furosemide, calcitonin, and bisphosphonates. Before his diagnosis, the patient was healthy and running two miles per day. Work-up to determine the etiology of his hypercalcemia showed low parathyroid hormone intact molecule and parathyroid hormone related protein, at 9 pg/mL and 12 pg/mL respectively. His urinary calcium was 9.9 mg/dL. His vitamin D2 1,25 (OH)2 was <8 pg/dL but his vitamin D3 1,25 (OH)2 was found to be elevated at 91 pg/mL. He was treated with fluids, furosemide, calcitonin and zoledronic acid. Despite these therapies, his calcium increased to abnormal levels and creatinine worsened each time fluids were stopped, requiring inpatient chemotherapy. Definitive treatment of his hypercalcemia required treatment of his lymphoma. He received rituximab, bendamustine, and high-dose steroids at the recommendation of oncology.

IMPACT/DISCUSSION: While hypercalcemia in lymphoma is rare, hypercalcemia of malignancy is common. Parathyroid hormone and Vitamin-D can be inappropriately upregulated and overproduced. The production of PTH-rP is the most common paraneoplastic syndrome leading to hypercalcemia in malignancy. Increased osteoclast activity is another cause, specifically relating to multiple myeloma. In this case, the etiology was vitamin D overproduction by macrophages associated with tumor cells in lymphoma, similar to that in sarcoidosis. The mechanism is increased production of 1-alpha-hydroxylase, the enzyme responsible for converting vitamin D to its active form, vitamin D3 1,25 (OH)2. This case highlights the importance of understanding how cancers not typically associated with hypercalcemia are still subject to this phenomenon.

CONCLUSION: Multiple phenomena can lead to hypercalcemia in malignancy, including increased production of 1-alpha-hydroxylase. Ultimately, definitive management of hypercalcemia of malignancy is treatment of the malignancy.

HYPEREOSINOPHILIA - A DIAGNOSTIC DILEMMA

Prarthna V. Bhardwaj¹; Nakul Ravikumar². ¹Baystate Medical Center, Springfield, MA; ²UMMS - Baystate, Springfield, MA. (Control ID #3178615)

LEARNING OBJECTIVE #1: To recognize causes of hypereosinophilia.

LEARNING OBJECTIVE #2: To diagnose eosinophilic granulomatosis with polyangiitis when the presentation is confusing.

CASE: 69yo Caucasian man with severe asthma, chronic sinusitis, nasal polyps presented with parasthesias of b/l lower extremities and hands; and diarrhea found to have eosinophilic leukocytosis (Total WBC - 42,000; Total eosinophil count - 28,700). He had a recent hospitalization flu like symptoms with transient bilateral consolidations on chest CT. He had traveled to Nicaragua 4 months prior. PE revealed subjective numbness in fingers and toes bilaterally; and an erythematous rash on his shoulder with surrounding hyperpigmentation that was grossly itchy. Strongyloides and trypanosoma Ab; blood, sputum and stool cultures were negative. Bone marrow biopsy showed extensive infiltration with mature eosinophils. ABL-BCR, JAK 2, PDGFR, FGFR, CHIC -2, flow cytometry, cANCA, pANCA and ANA were negative with normal tryptase levels. EMG was normal. Skin biopsy of the rash was diagnosed as tinea. RAST was positive for aspergillus fumigatus with positive precipitin panel. Hospital course was complicated by new CHF with significant troponinemia (peak 7.03). Cardiac cath was negative for CAD. ECHO revealed newly reduced LVEF of 30%. Cardiac MRI suggested an infiltrative process. He was put on steroids with improvement in counts and azathioprine later for steroid sparing for suspected eosinophilic granulomatosis with polyangiitis (previously Churg Strauss Syndrome) and is being followed by multiple specialties. He completed oral itraconazole for ABPA. On follow up, his symptoms have improved.

IMPACT/DISCUSSION: Hypereosinophilia is an elevation in eosinophil count above 1,500/ μ L. It is divided into primary, secondary and idiopathic.

Secondary eosinophilia is non-clonal increase caused by infections, allergic conditions, autoimmune diseases and paraneoplastic syndromes. Main differentials were EGPA, allergic bronchopulmonary aspergillosis, clonal malignancy and idiopathic hypereosinophilic syndrome. While APBA can cause eosinophilia, involvement of organs other than the upper respiratory tract is uncommon. EGPA is classified as ANCA-positive and ANCA-negative. About 50-60% of EGPA show ANCA positivity. Based on American College of Rheumatology (ACR), patient met 4 of the 6 criteria for EGPA despite negative ANCA. Cardiac involvement including CHF, myocarditis, pericarditis, myocardial ischemia and arrhythmias are the major cause of death and poor prognosis occurring in 27-47% cases. It is more common in ANCA-negative patients and directly correlates with eosinophilia.

CONCLUSION: ABPA can result in hypereosinophilia but is limited to organs in the upper respiratory tract. Despite ANCA negativity, if patient meets ACR criteria in the right clinical setting, EGPA can be confirmed. It is important to recognize the subtle differences between these entities causing hypereosinophilia in order to clinch the diagnosis and involve appropriate specialties to institute early treatment.

HYPERGLYCEMIA, OBESITY, AND STIGMA: PHYSICIAN WEIGHT-BASED BIAS PREVENTING EARLY RECOGNITION OF RARE MEDICATION SIDE EFFECT.

Pranav Shah¹; Ahmed Yeddi¹; Omnia Awad¹; Diane L. Levine³; ijeoma Nnodim². ¹Detroit Medical Center, Plymouth, MI; ²wayne state university school of medicine, Westland, MI; ³Wayne State University, Detroit, MI. (Control ID #3184572)

LEARNING OBJECTIVE #1: Recognize how weight-based bias regarding obese patients can negatively impact health outcomes and contribute to disparities.

LEARNING OBJECTIVE #2: Recognize iatrogenic causes of poorly controlled "lifestyle" diseases associated with obesity such as medication induced hyperosmolar hyperglycemic non-ketotic syndrome (HHNS).

CASE: 22-Year-old female with medical history of well controlled type 2 diabetes mellitus (HbA1c 6.9%), morbid obesity (BMI 54) and pseudotumor cerebri status post ventriculoatrial shunt presents with worsening headaches for 3 days. A lumbar puncture showed mildly elevated opening pressure with normal cerebrospinal fluid analysis. She was started on acetazolamide 250 mg twice daily with improvement of headaches. However, her blood glucose measurements became very high: 300-500 mg/dL, requiring increasing insulin dosages. By day 4, she was requiring 490 units total dose of insulin, 7 times her home daily dose. We believed the patient was not adhering to a strict hospital ADA diet and was consuming additional carbohydrate-rich meals. However, upon further questioning, she denied this assertion. As her hyperglycemia remained resistant to insulin, multiple providers repeatedly questioned her adherence to the hospital diet. Eventually, a medication re-assessment resulted in the discovery of hyperglycemia as a rare side effect of acetazolamide, which was subsequently discontinued. Within 48 hours of cessation of acetazolamide, blood glucose levels normalized with a fasting glucose 70-120 mg/dL, and post-prandial glucose 80-180 mg/dL and remained stable on her home insulin regimen.

IMPACT/DISCUSSION: Initial consideration for the patient's poorly controlled hyperglycemia was non-adherence to the hospital diabetic diet. Her denial of non-adherence was met with incredulity by the care team. Consequently, she endured a prolonged hospital length of stay, shame, and emotional distress. We learned a lesson about self-awareness of physician bias regarding obesity and how it can negatively impact outcomes and contribute to health disparities. Obesity is escalating in epidemic proportions with rising weight discrimination (>66% over the past decade). Many healthcare providers hold strong negative attitudes and stereotypes about people with obesity. Such attitudes influence interpersonal behavior and decision-making which may negatively impact care. Physicians should be

mindful of their own biases and intentionally consider alternative causes including iatrogenic factors such as medication side-effects. In our case, hyperglycemia related to acetazolamide is a rare side-effect only seen in mouse models and the mechanism has not fully been clarified.

CONCLUSION: Obese patients suffer discrimination in the healthcare setting contributing to health disparities. Physician self-awareness of implicit bias can lead to a behavior change, "outside-the-box" thinking, and improved health outcomes. In rare cases, acetazolamide may induce severe hyperglycemia in patient's with diabetes mellitus

HYPOCOMPLEMENTEMIC URTICARIAL VASCULITIS SYNDROME - A RARE CASE OF ANGIOEDEMA

Kateryna Fedorov¹; Chrisanna Dobrowolski²; Clement Tagoe².

¹Montefiore Medical Center, Bronx, NY; ²Montefiore Medical Center, Bronx, NY. (Control ID #3184919)

LEARNING OBJECTIVE #1: Identify patients with hypocomplementemic urticarial vasculitis syndrome

LEARNING OBJECTIVE #2: Differentiate hypocomplementemic urticarial vasculitis syndrome from allergic reaction

CASE: 37-year-old female with systemic lupus erythematosus (SLE) presented with swelling of the lips and throat for 3 days. The swelling was accompanied by a husky voice, painful erythematous eruptions on her arms, legs, chest, back, as well as dull right knee and ankle pain. Within 48 hours the cutaneous eruptions changed in color to deep blue, and then resolved, leaving hyperpigmented macules. She has been having similar less severe skin eruptions and lip swelling episodes over the past year. Physical examination was significant for swelling over the right side of the upper lip, hyperpigmented macules on the eyebrows, nose, left cheek and ear, as well as bluish, circular macules on the left arm, right shoulder, and left posterior thorax. Leukocyte count was slightly elevated at 12.8k/uL, anti-dsDNA was elevated at 145IU, and both C3 and C4 were low at 40mg/dL and 4.4mg/dL respectively. The patient was treated with for an allergic reaction but responded only briefly and soon developed shortness of breath and pulmonary edema. Further laboratory tests revealed C1 inhibitor >100%, C1 esterase inhibitor 28mg/dL, Trypsinase 2ng/mL, all within normal range. Biopsy of the lesions showed leukocytoclastic vasculitis. Given prior diagnosis of SLE, new angioedema, urticaria, vasculitis, and arthralgias the patient was diagnosed with hypocomplementemic urticarial vasculitis syndrome (HUVS). She was treated with high-dose Solumedrol with complete resolution of all symptoms.

IMPACT/DISCUSSION: HUVS is an autoimmune condition in which IgG antibodies bind to the Fc region of C1q triggering a type III hypersensitivity reaction, ultimately causing widespread endovascular damage. The most common signs and symptoms are reflected in the diagnostic criteria. For diagnosis patient needs to meet both major criteria: urticaria for 6 months and hypocomplementemia, and two of six minor criteria: venulitis of dermis, arthralgias, glomerulonephritis, uveitis or episcleritis, abdominal pain, and presence of C1q precipitin. Angioedema is an initial presentation in 50% of cases and is frequently mistaken for anaphylactic reaction. Urticarial rash is characterized by deep blue discoloration, pain, with resolution in 48 hours and residual dark skin pigmentation. Biopsy of the lesions classically reveal of leukocytoclastic changes. Many affected patients have other rheumatologic conditions, such as SLE. As awareness of HUVS in the medical community is low it is important to recognize patients who fail traditional treatment for allergic reactions and to broaden the differential diagnosis to include rare diagnoses such as HUVS.

CONCLUSION: HUVS is a rare condition that mimics atopic reactions. It is important to remain open minded when assessing SLE patients and broaden the differential diagnosis when a patient is not responding to standard treatments.

HYPONATREMIA IN MALIGNANCY - IT'S NOT ALWAYS SIADH

Vasilii Bushunow; Amar Kohli; Amar Bansal. UPMC, Pittsburgh, PA. (Control ID #3168584)

LEARNING OBJECTIVE #1: Explain physiology of hyponatremia in states with low effective arterial blood volume (EABV).

LEARNING OBJECTIVE #2: Distinguish low EABV states from SIADH.

CASE: A 60-year-old man presented with several weeks of nausea, anorexia, and leg swelling. He also had several months of headaches with a biopsy negative for temporal arteritis. His PCP noted high liver enzymes. The patient had a forty-year smoking history without alcohol use or occupational exposure. Review of systems was positive for weight loss; negative for jaundice, cough, dyspnea or orthopnea, or seizures. Exam included a pulse of 90, BP of 107/71, no neurological deficits, cachexia, a right occipital nodule, dry mucous membranes, hepatomegaly, and lower extremity edema. Stigmata of chronic liver disease were absent. Labs included a Na of 118, K of 4.2, bicarbonate of 20, Cl of 85, Cr of 0.5, osms of 245, and AST of 650. Urinalysis showed Na less than 10 and osms of 448. Thyroid hormones, cortisol, and aldosterone were normal. Imaging showed lesions concerning for metastatic disease, including the skull, bilateral lungs, and liver. The patient received 0.9% saline with worsening edema but no increase in sodium. Repeat urinalysis showed low sodium and high osmolarity. The patient left the hospital against medical advice but was readmitted after collapsing at home and soon died of lung and liver failure.

IMPACT/DISCUSSION: Hyponatremia requires integration of physical and laboratory findings to determine etiology and guide therapy. This patient's cachexia impeded the assessment of volume status causing diagnostic uncertainty. For me, this case reinforced the value of thorough daily exam to monitor volume status rather than relying solely on lab values. Hyponatremia involves up to 25% of ICU cases and is a sign of poor prognosis regardless of etiology. As the leading cause of hyponatremia in cancer care, SIADH was considered in this patient, but his hyponatremia was better explained by hepatic tumor burden leading to splanchnic vasodilation and low EABV. This term implies preserved or increased intravascular volume but a decreased ratio of blood in the arterial versus the venous circulation. Whether from low cardiac output or arterial vasodilation, low EABV is perceived as hypovolemia, causing sympathetic and reno-humoral activation and non-osmotic ADH release. Increased aldosterone leads to further volume overload, while free water retention causes hyponatremia. In contrast, SIADH requires euvoolemia, with normal urine sodium reflecting suppressed aldosterone. Some studies propose an interval increase of FENa by >0.5% after a 2L saline bolus as a diagnostic test for SIADH, but this was not assessed in this patient. Both SIADH and low EABV share inappropriately concentrated urine indicative of ADH, but low urine sodium should prompt search for pathology decreasing EABV.

CONCLUSION: Differentiating low EABV from SIADH requires assessment of intravascular volume. Low urine sodium is a clue of perceived hypovolemia and excludes SIADH.

IDIOPATHIC CHYLOTHORAX; IS IT A BENIGN OR MALIGNANT DIAGNOSIS?

Sandra Naffouj; Jasmine Omar. Henry Ford Hospital, Detroit, MI. (Control ID #3180494)

LEARNING OBJECTIVE #1: Diagnose idiopathic chylothorax

LEARNING OBJECTIVE #2: Manage chylothorax

CASE: A 29-year-old healthy male presented with acute onset of dyspnea and right-sided pleuritic chest pain. CT scan of the chest showed large right-sided pleural effusion. Thoracentesis was performed, draining 2 liters of turbid white pleural fluid and a chest tube was placed. Fluid

analysis revealed exudative effusion with lymphocytic predominance and triglyceride (TG) of 1,100 mg/dl consistent with chylothorax. Pleural fluid cytology and cultures were negative for malignancy and infection. Patient was made nil per os, total parenteral nutrition (TPN) and IV octreotide were started. High-volume chyle leakage was persistent. Patient underwent lymphangiogram, which showed chyle leak from the thoracic duct (TD) at the level of T7-T8. He underwent embolization, however, output did not improve. Patient underwent video-assisted thoracoscopy (VATS) and TD ligation by thoracic surgery. Pleural biopsy was negative for malignancy. Serum LDH, alpha-fetoprotein, beta-human chorionic gonadotropin, HIV, acid-fast bacilli, fungal, and anaerobic cultures were all negative. Peripheral blood smear was negative for dysplasia and blasts. Full body CT did not show any evidence of malignancy. Output trended down, and chest tube was removed when chest x-ray showed resolution of pleural effusion. Diet was advanced to low-fat, medium chain triglyceride (MCT) diet. There was no leak recurrence at 1-month follow-up.

IMPACT/DISCUSSION: Chylothorax is the presence of chyle in the pleural space with a TG level >110 mg/dl or evidence of chylomicrons in the pleural fluid. Non-traumatic chylothorax is a rare condition and can be due to many disease processes. A thorough evaluation of the most common causes of non-traumatic chylothorax includes malignancy (lymphomas, lung and mediastinal cancers), infections (tuberculosis, fungal infections), and congenital disorders of the lymphatic system, which were negative in our case. Conservative management includes either nothing by mouth or a low-fat diet with MCTs, which are absorbed directly into the portal system, bypassing the TD to reduce chyle flow and promote healing. TPN is used to replace proteins, electrolytes, and deliver lipids directly into the bloodstream, thereby bypassing the lymphatic system and decreasing chyle flow. Octreotide is an adjunct to help reduce chyle absorption from the intestines. When conservative measures fail, there are many interventional modalities to consider, including TD embolization, TD ligation, or pleurodesis. For our patient, a combination of conservative and operative interventions was performed given high-output of chyle and absence of a clear etiology, resulting in leakage resolution.

CONCLUSION: It is crucial to perform a comprehensive assessment in non-traumatic chylothorax to exclude occult underlying etiology. Initial conservative management includes dietary modifications. If there is no improvement, interventions are available to repair TD and reduce chyle output.

IF PSORIASIS ISN'T ENOUGH - A CASE OF ERYTHRODERMIC PSORIASIS

Max Ruge; Jordan Scharping; Michelle Sweet. Rush University Medical Center, Chicago, IL. (Control ID #3184916)

LEARNING OBJECTIVE #1: Describe erythroderma and some of its common etiologies.

LEARNING OBJECTIVE #2: Discuss the potential treatment options for erythrodermic psoriasis.

CASE: A 65-year-old female with a 1-year history of psoriasis presented with a worsening rash and associated chills, arthralgias, weight loss, and diarrhea. Initially the erythematous and scaly rash was localized to her arms and under her breasts, but two months ago, it began spreading and became significantly more erythematous, pruritic, and painful. Due to disease progression, she was enrolled in an experimental randomized double-blinded clinical trial where she was given either secukinumab (Cosentyx) or placebo one month prior to hospitalization. Subsequently, her symptoms continued to worsen to the point where she could not get out of bed. On admission exam, her temperature was 101.3°F, heart rate was 103, and she had diffuse confluent erythema with overlying scale covering her entire body. She was diagnosed with erythroderma due to psoriasis, likely due to medication withdrawal from starting placebo or changing to the study agent. She was prescribed triamcinolone wet wraps

BID and benadryl with significant relief of her symptoms. Infectious workup and assessment for electrolyte derangements were negative. She symptomatically improved and was discharged 5 days later.

IMPACT/DISCUSSION: Erythroderma is typically defined as erythema of over 75% of the body surface area and has multiple causes including psoriasis, atopic dermatitis, drug reactions, and numerous malignancies such as Sezary syndrome and other lymphomas. Erythrodermic psoriasis is the rarest subtype of psoriasis, yet it is critical to recognize given its significant mortality (9 to 64%). Key triggers include infection or an abrupt change in steroids or anti-psoriatic agents. The severity of erythroderma is highly variable but potentially lethal as the degree of scaling and inflammation can lead to superinfection, electrolyte abnormalities, shock, or even ARDS. In cases with persistent severe symptoms or with hemodynamic or thermoregulatory instability, first-line treatment consists of either cyclosporin or infliximab along with topical steroids. In general, systemic corticosteroids should be avoided because steroid withdrawal has been associated with erythrodermic flares, although this is controversial. Supportive therapy is also critical given the risk for electrolyte and fluid abnormalities. In addition to basic labs, skin culture from open or crusted sites and blood cultures are also warranted in unstable cases. Our patient significantly improved after a 12-hour trial of topical therapy. However, if she had not improved or if her symptoms progressed, cyclosporin would have been started.

CONCLUSION: This case highlights an atypical and potentially lethal complication of psoriasis. While our patient improved with triamcinolone wraps and supportive care, severe cases that are refractory to topical therapies should be treated with cyclosporin or infliximab.

IGA VASCULITIS ASSOCIATED WITH ACTIVE MESOTHELIOMA

Bradley F. Woodman¹; Ami DeWaters². ¹Penn State Health/Milton S Hershey Medical Center, Hershey, PA; ²Penn State Hershey Medical Center, Hershey, PA. (Control ID #3185856)

LEARNING OBJECTIVE #1: Describe the diagnostic signs and symptoms of adult-onset IgA vasculitis.

LEARNING OBJECTIVE #2: Discuss the evaluation and management of adult-onset IgA vasculitis.

CASE: A 74 year old man with a recent diagnosis of desmoplastic-type malignant mesothelioma with recurrent pleural effusions presented prior to starting mesothelioma treatment with a one week history of painless purple lesions on his bilateral lower extremities and hand swelling leading to an inability to make a fist. The patient endorsed loss of appetite, but he denied abdominal pain or arthralgias. On physical exam, the patient had fine inspiratory crackles on auscultation, a non-tender abdomen, bilateral pitting edema of his upper extremities, and palpable purpura extending from his feet to his thighs bilaterally. Initial laboratory results were significant for a creatinine of 1.72 mg/dL from a previous baseline of 0.86 mg/dL one week prior. His erythrocyte sedimentation rate was 9.3 mg/dL, and his c-reactive protein was 75 mm/hr. He was admitted and treated with steroids, and a skin biopsy was diagnostic for IgA vasculitis. His renal function improved and he was discharged home on a steroid taper with topical steroids.

IMPACT/DISCUSSION: IgA vasculitis is rare in adults with only ten percent of cases occurring in adult patients. The tetrad of clinical features characteristic of IgA vasculitis is acute onset abdominal pain, arthritis or arthralgias, purpura, and renal involvement in the form of hematuria or proteinuria. The causes of IgA vasculitis are poorly understood, but it has been hypothesized that it could present as a paraneoplastic syndrome. In this case, it is possible that it presented as a paraneoplastic syndrome associated with mesothelioma. To evaluate and diagnose IgA vasculitis, a skin biopsy is necessary. A positive biopsy for IgA vasculitis has either a leukoclastic vasculitis or proliferative glomerulonephritis with predominantly IgA deposition. Treatment is mainly supportive, as it is a self-

limiting disease in the majority of cases. Glucocorticoids are not routinely recommended for treatment. However, in patients with severe abdominal pain or significant renal dysfunction, glucocorticoids are used to reduce inflammation.

CONCLUSION: IgA vasculitis is a rarely seen disease in adults, and is characterized by purpura, abdominal pain, arthralgias, and kidney injury. Clinicians should consider IgA vasculitis with these symptoms and obtain a skin biopsy of the purpura to confirm the diagnosis. Treatment is mainly supportive.

ILEAL NEOBLADDER, AN OFTEN OVERLOOKED CAUSE OF NON-ANION GAP METABOLIC ACIDOSIS.

Henry C. Zheng; Christopher Chen; Katherine Timmins. Baylor College of Medicine, Houston, TX. (Control ID #3186071)

LEARNING OBJECTIVE #1: Recognize metabolic disturbances of ileal neobladders by understanding its physiology.

LEARNING OBJECTIVE #2: Manage severe hyperchloremic non-gap metabolic acidosis in patients with ileal neobladders.

CASE: A 75-year-old man with a history of bladder cancer status post radical cystoprostatectomy and ileal neobladder reconstruction 2 years prior presented with 2 weeks of malaise, and decreased urine output. He also notes a bug bite of the left hip which has now developed into a small, superficial abscess. He denies fevers, chest pain, shortness of breath, abdominal pain, nausea or vomiting. He was afebrile, normotensive, breathing 23 breaths/min, sating 98% on room air. He appeared lethargic but was without acute distress. A small 1x2cm superficial abscess of the left hip was seen without significant surrounding erythema, fluctuance or purulent discharge. Suprapubic discomfort on palpation was also noted. Workup was notable for Na 137 mEq/L, K 4.0 mEq/L, Cl 117 mEq/mL, bicarbonate 7 mEq/L, creatinine 4.19 mg/dL, glucose 98 mg/dL, ABG pH 7.19, PCO₂ 11 mmHg, PO₂ 98 mmHg and lactate 1.3 mmol/L. His anion gap is 13. A rapid response was called for acidemia with concerns of sepsis, however, given non-anion gap acidosis, a benign appearance of abscess, lack of fevers and normal lactate, suspicion for infection as primary etiology was low. A Foley catheter was placed for concerns of urinary obstruction and 1 liter of urine was collected immediately. An isotonic sodium bicarbonate infusion was started to treat the acidemia. Over the next 3 days, his non-gap acidosis resolved and creatinine downtrended. Blood cultures remained negative. He was discharged with plans to follow up in primary care clinic to determine the necessity of chronic bicarbonate replacement therapy in the future.

IMPACT/DISCUSSION: Mild metabolic derangements can occur in up to 15% of patients with ileal neobladder and severe acidosis occurs in <1% of these patients overall. As the urine sits in the neobladder, the gastrointestinal mucosal sodium-hydrogen antiporter secretes sodium in exchange for hydrogen ions, and bicarbonate is excreted in exchange for hydrogen ion and chloride ion resulting in a hyperchloremic non-anion gap metabolic acidosis. Urinary retention results in severe acidosis due to prolonged absorption time of the urinary constituents. Treatment is focused on minimizing urine contact time with the reservoir mucosa. A Foley catheter should be placed to enhance urinary drainage. Though intravenous bicarbonate administration is generally not indicated for most types of anion-gap metabolic acidosis, it is reasonable to consider isotonic sodium bicarbonate infusion for these patients as they have chronic bicarbonate deficiency. Lastly, hypokalemia in the setting of severe acidosis requires close monitoring and repletion.

CONCLUSION: As neobladder surgeries become more common, it's increasingly important to understand the physiology and recognize the metabolic complications in order to initiate therapy in a timely manner.

IMMUNE CHECKPOINT INHIBITOR-INDUCED MYOCARDITIS PRESENTING AS COMPLETE HEART BLOCK

Tyler Mehegan¹; Aarti Asnani². ¹Beth Israel Deaconess Medical Center, Brookline, MA; ²Beth Israel Deaconess Medical Center, Boston, MA. (Control ID #3171120)

LEARNING OBJECTIVE #1: Recognize fulminant myocarditis as an adverse effect of immune checkpoint inhibitors (ICIs).

LEARNING OBJECTIVE #2: Manage complete heart block caused by ICIs.

CASE: The patient is a 79-year-old man with a history of high-grade pleomorphic bladder cancer status post cystoprostatectomy, recently started on adjuvant atezolizumab, who presented to the Emergency Department with one hour of lightheadedness, nausea, and pallor. His review of systems was otherwise negative. In the ED, he was noted to have a heart rate of 24 and a blood pressure of 80/40. An electrocardiogram (ECG) showed complete heart block with a ventricular escape rhythm. Laboratory testing was notable for a troponin T level of 1.09 ng/ml. A temporary transvenous pacemaker was placed, followed by placement of a permanent dual-chamber pacemaker. Coronary angiography, transthoracic echocardiography, and an infectious workup including Lyme IgG and IgM were all unremarkable. He was discharged with a diagnosis of senile conduction disease and a type II non-ST elevation myocardial infarction. Forty-eight hours later, he was readmitted with chest pain and an increased troponin T of 2.06 ng/ml. In discussion with his oncologist, treatment was initiated for presumed atezolizumab-induced myocarditis with methylprednisolone 1g IV Q24 hours and ultimately myco phenolate, resulting in improvement in his symptoms and cardiac biomarkers. Notably, repeat ECGs following immunosuppression demonstrated stable native conduction without pacemaker dependence.

IMPACT/DISCUSSION: Over the last decade, ICIs have drastically improved survival for patients with a variety of malignancies. Although generally well-tolerated compared to cytotoxic chemotherapy, immune-related adverse events are common, including colitis, pneumonitis and hepatitis. ICI-induced myocarditis occurs less frequently, in less than 1% of patients treated with ICIs, but is often fatal. Despite aggressive immunosuppression, progression to fulminant myocarditis, multiorgan system failure, and death is common. As clinical presentations are variable and can be non-specific, a high index of suspicion for myocarditis in patients on ICI therapy is paramount. While complete heart block has been reported in the setting of ICI-induced myocarditis, there are no published data or guidelines regarding the need for permanent pacemaker implantation in this patient population. As demonstrated by this case, it is possible for native conduction to recover with immunosuppressive therapy in patients suspected to have ICI-induced myocarditis. A trial of temporary pacing may therefore be a reasonable approach while implementing an immunosuppressive strategy.

CONCLUSION: In patients on ICI therapy presenting with any new cardiac abnormality, a diagnosis of ICI-induced myocarditis should be considered. In ICI-induced myocarditis presenting as an advanced cardiac conduction disorder, a trial of aggressive immunosuppression may result in recovery of native conduction and obviate the need for a permanent pacemaker.

IMMUNE THROMBOCYTOPENIC PURPURA: AN UNCOMMON INITIAL PRESENTATION OF HUMAN IMMUNODEFICIENCY VIRUS

Ariana Mooradian; Gretchen Grosch. Saint Louis University, St Louis, MO. (Control ID #3183925)

LEARNING OBJECTIVE #1: Explore an unusual presentation of a common disease (HIV)

LEARNING OBJECTIVE #2: Identify risk factors that increase likelihood of poor response to therapy in HIV patients with ITP

CASE: A 49-year-old transgender female presented to the emergency department after a syncopal episode and reported weakness, shortness of breath, gingival bleeding, epistaxis, small red lesions and bruises on shins, and melena. She developed myalgias and foot pain three weeks prior and was taking naproxen 1-2g daily. Patient denied change in weight, upper respiratory tract symptoms, headache, vision change, diarrhea, dysuria, and hematuria. Laboratory results revealed hemoglobin of 4.9 g/dL, schistocytes 2+, and platelets of $4 \times 10^3/\mu\text{L}$. The patient was admitted to the intensive care unit where she was given 1 unit of packed red blood cells, 4 units of fresh frozen plasma and underwent plasmapheresis. She completed a 5 day course of dexamethasone and counts increased. Bone marrow biopsy performed revealed hyper cellular marrow with trilineage hematopoiesis without evidence of lymphoma and she was diagnosed with immune thrombocytopenic purpura (ITP). Human Immunodeficiency Virus (HIV) screening returned positive and CD4 count was found to be 493 cells/mm³ (21%) with a viral load of 4,390,000 copies. The patient was maintained on oral steroids until follow up with infectious disease clinic at which point highly active anti-retroviral therapy (HAART) was initiated.

IMPACT/DISCUSSION: The incidence of thrombocytopenia in HIV patients has been estimated at 6-15% though early estimates were twice as high. Estimates of thrombocytopenia at diagnosis are much lower. The clinical entity of HIV-related thrombocytopenia usually presents during chronic infection or advanced immunosuppression (CD4 <200) thus treatment of choice for this entity is antiretroviral therapy. Indeed, reports of thrombocytopenia after successful and sustained viral response is relatively uncommon. A retrospective analysis by Ambler et al. found that treatment of HIV alone was insufficient treatment of thrombocytopenia and nearly all patients treated for ITP required additional secondary treatment. Advanced age, anemia, intravenous drug use, and hepatitis infection have been indicated as risk factors for poor treatment response. Studies have found that there is no difference in risk between genders or ethnicities. Thrombocytopenia presenting early in HIV most resembles classic ITP, whereas presentation later in disease course may present more complicated. At this time, there has not been a consensus on HAART that is most effective for HIV-associated ITP.

CONCLUSION: HIV screening is part of standard preventative medicine. With advances in medication, early detection and initiation of antiviral therapy is paramount to best possible prognosis. Clinicians should consider HIV infection in any patient that presents with thrombocytopenia. Given current uncertainties as to optimal therapy, more research is warranted to establish a standard of care for HIV-associated ITP.

IMPORTANCE OF RAPID DIAGNOSIS IN RAPIDLY PROGRESSIVE DEMENTIAS: A CASE OF VITAMIN B12 DEFICIENCY

Aradhana Verma²; Benjamin Li³; Michael Conte³; Katie Raffel¹. ¹University of California San Francisco, San Francisco, CA; ²California Northstate University, Elk Grove, CA; ³St. Mary's Medical Center, San Francisco, CA. (Control ID #3185041)

LEARNING OBJECTIVE #1: Review initial assessment for reversible causes of rapidly progressive dementia

LEARNING OBJECTIVE #2: Recognize the neurologic sequelae and treatment trajectory of vitamin B12 deficiency

CASE: An independent 80 year-old man with well-controlled diabetes was brought in by family with a two-month history of progressively declining cognitive function, worsening vision, and visual and auditory hallucinations. The patient was no longer able to navigate city busses nor participate in basic self-care. The patient was afebrile, BP 126/48 and HR 54. On neurologic exam, he was oriented only to self, inattentive, and with deficits in all cognitive domains: executive function, abstraction, recall. He had impaired visual acuity. There were no strength or light touch sensory deficits. Reflexes were intact, and no myoclonus, rigidity, tremor, or cerebellar findings were noted. Complete blood count, chemistry panel, liver function tests, thyroid and coagulation profile were within normal

limits. HIV, RPR, urine toxicology and heavy metal toxicology were negative. Infectious workup including urinalysis, blood cultures and CXR were unrevealing. MRI brain with contrast demonstrated small chronic microvascular ischemic changes. Cerebrospinal fluid analysis demonstrated protein of 49.2 mg/dL, 1 WBC/mm³, glucose 83 mg/dL, absent oligoclonal bands and normal IgG index. HSV and CMV PCR and bacterial culture were negative. Vitamin B12 was 126 pg/mL.

IMPACT/DISCUSSION: This clinical presentation constitutes a subacute rapidly progressive dementia that may have been caused by vitamin B12 deficiency. Cobalamin is required for the development and maintenance of myelination of the central nervous system. Deficiency leads to demyelination of the spinal cord, cranial and peripheral nerves, and white matter. While the most common neurologic complaints of vitamin B12 deficiency are paresthesia, numbness, and gait problems, our patient exhibited less common but known advanced symptoms including dementia, visual disturbances and psychosis. Notably, neurologic symptoms can occur in the absence of anemia. In adults with neurologic sequelae, parenteral administration of vitamin B12 is indicated. In contrast to relatively quick hematologic response to B12 repletion, neuropsychiatric improvement can take months to a year or even worsen transiently after treatment. Rarely, patients are reported to have residual long-term moderate to severe neurologic disability.

CONCLUSION: After sedation for lumbar puncture and MRI, the patient developed an acute or subacute encephalopathy, and the family chose to pursue comfort care. Prompt diagnosis of vitamin B12 deficiency as cause of subacute rapidly progressive dementia is critical as it is reversible and neurologic recovery is strongly associated with the severity and duration of symptoms prior to treatment. If index of suspicion for B12 deficiency is high, methylmalonic acid and homocysteine should also be sent to detect early disease.

IMPROVING MEDICATION RECONCILIATION

April Ehrlich; Esther Oh. Johns Hopkins University, Baltimore, MD. (Control ID #3185680)

LEARNING OBJECTIVE #1: Recognize potential for error in medication reconciliation

LEARNING OBJECTIVE #2: Identify ways to improve accuracy of medication reconciliation

CASE: Patient is a 79 year old woman with history of hypertension, stroke, asthma, chronic obstructive pulmonary disease, rheumatoid arthritis, myelomalacia of the cervical cord, lumbar stenosis, osteoporosis, and vitamin D deficiency who presented to a General Internal Medicine clinic for GI complaint. Her visit note mentions that she brought in her medications and a reconciliation was completed with a total of 14 medications. However, given concern for memory impairment a home visit was made. During the home visit, she presented a different list from another PCP with 12 medications and had difficulty presenting her medication bottles as there was no organization. She later came in for a dedicated medication reconciliation appointment, with her medications, and was found to have only 9 medications, was taking pills from 3 separate bottles of a single medication, and had incorrect pill counts. Further discussion revealed she frequently did not fill medications due to finances. Thus many of her medications were discontinued with the final medication list consisting of 4 medications in order to avoid polypharmacy and improve compliance.

IMPACT/DISCUSSION: According to the Institute for Healthcare Improvement adverse drug events remain a top patient safety priority. However, accurate medication reconciliation, especially in the geriatric population can be challenging. This challenge is highlighted by Project RED, a discharge intervention program at Boston Medical Center, that showed improvement in readmissions with comprehensive discharge planning including a medication reconciliation. Yet even in this structured environment, follow up phone calls by a pharmacist revealed that over 50% of those with completed reconciliations needed corrective action by a pharmacist.¹ This

indicates the need to determine ways to improve the accuracy of medication reconciliation in order to improve patient safety. This patient highlights the difficulty in obtaining an accurate medication list, especially in the geriatric population with concern for cognitive impairment, and shows how home visits and dedicated appointments can assist in this endeavor.

CONCLUSION: This case shows how the typical processes of doing a medication reconciliation in a general internal medicine clinic can lead to significant error, especially in the geriatric population. It also points to potential useful tools for addressing this challenge including home visits and dedicated clinic appointments for the purpose of medication reconciliation. Sources 1. Jack BW, Chetty VK, Anthony D, et al. A reengineered hospital discharge program to decrease rehospitalization: a randomized trial. *Ann Intern Med.* 2009;150(3):178-187.

IN "LUE" OF OTHER SYMPTOMS: A CASE OF LUES MALIGNA IN A PATIENT WITH HUMAN IMMUNODEFICIENCY VIRUS

Sherry Zhang¹; Jeremy Chang²; Sindalisa Hean¹; Eric Daar¹. ¹Harbor-UCLA Medical Center, Wilmington, CA; ²LAC+USC, Wilmington, CA. (Control ID #3180886)

LEARNING OBJECTIVE #1: Recognize that secondary syphilis may present as lues maligna with numerous manifestations, especially in patients with human immunodeficiency virus (HIV)

CASE: A 48-year-old male presented with 2 months of painful skin lesions, weight loss and fevers. The skin lesions initially appeared as small erythematous papules on his feet and lower shins, but became larger and spread to other sites on his body, including his arms, hands, trunk and face. In addition, the patient reported a 40-pound weight loss over the past year and fevers for several months. Vitals were notable for a temperature of 39.3 degrees. Physical exam was notable for multiple papular lesions with associated crusting and eschar throughout his bilateral upper and lower extremities, including the palms and soles, chest, back and face. An HIV antibody/antigen screen and confirmatory antibody test both returned positive, with CD4 count of 264. Rapid plasma reagin (RPR) titer was 1:64 with a positive fluorescent treponemal antibody absorption (FTA-ABS) test. Biopsy of one of the cutaneous lesions showed nonspecific ulceration and fibrosis as well as perivascular lymphocyte and neutrophil infiltration with negative stains for spirochetes, fungi and mycobacteria. The patient's clinical picture including physical exam, serologic testing, and biopsy results were consistent with lues maligna and secondary syphilis. The patient was given a single intramuscular injection of 2.4 million units of penicillin G benzathine. Within a few days following this treatment, he experienced resolution of his fevers and shrinking of his skin lesions. The patient was subsequently started on anti-retroviral therapy with emtricitabine-tenofovir and dolutegravir for management of his HIV infection.

IMPACT/DISCUSSION: Lues maligna - also known as malignant syphilis - is a rare manifestation of secondary syphilis that predominantly presents in patients with HIV as well as in other immunocompromised individuals. It is characterized by ulcerative papular lesions and can also be associated with nonspecific symptoms such as fever, weight loss, joint pain, and malaise as seen in our patient. The cutaneous lesions may mimic viral exanthems or disseminated fungal infections, making visual diagnosis challenging. Although no spirochetes were seen on biopsy of our patient's skin lesion, this finding has low sensitivity in the diagnosis of lues maligna as pathology most often shows lymphocyte and neutrophil infiltration like in this case. The diagnosis of lues maligna was further supported by the prompt resolution of his fevers and skin lesions after a single dose of penicillin G benzathine.

CONCLUSION: As syphilis can have a myriad of clinical manifestations and mimic other conditions - therefore possibly clouding the diagnosis - clinicians should consider lues maligna as a rare presentation of a common condition when in evaluating patients with ulceronodular skin lesions, in order to provide prompt diagnosis and treatment.

IN-N-OUT: AN UNCOMMON CAUSE OF CHRONIC ABDOMINAL PAIN.

Bradley N. Tun; Ricardo Cruz. Boston Medical Center, Boston, MA. (Control ID #3180852)

LEARNING OBJECTIVE #1: Review differential diagnosis and evaluation of chronic abdominal pain.

LEARNING OBJECTIVE #2: Recognize internal hernia as a potential etiology of chronic abdominal pain and its potential complications.

CASE: 51 year old male with history of gastric adenocarcinoma who underwent subtotal gastrectomy with retrocolic Roux-en-Y reconstruction presented to the ED with acute on chronic abdominal pain. Prior to this visit he had been experiencing intermittent abdominal pain episodes since his surgery. Initially the pain was attributed to GERD. However, these episodes persisted and he underwent extensive evaluation including a referral to gastroenterology. He had an EGD that was positive for H. pylori which was eradicated with quadruple therapy. He also had a colonoscopy and several CT scans during multiple ER visits that were all unremarkable. Leading diagnosis at the time was a functional abdominal pain syndrome. On this presentation, he described the abdominal pain as sharp, constant and associated with nausea, emesis and anorexia. His physical exam was concerning for peritonitis with lab studies notable for WBC of 15.4 and lactate of 2.7. CT abdomen pelvis showed swirling of vessels and mesentery in the abdomen with significant mesenteric edema concerning for mesenteric ischemia. He underwent an urgent laparotomy which showed an internal hernia with entire small bowel up to intracecal valve herniated through jejunal mesenteric defect. The internal hernia had caused a 15cm segment of small bowel necrosis that required resection. He tolerated the surgery and was discharged home a week later.

IMPACT/DISCUSSION: Chronic abdominal pain is a common complaint in the outpatient setting; differential is broad and includes common causes such as peptic ulcer disease, GERD, gastritis and irritable bowel syndrome. Based on the history, physical and laboratory studies, imaging can be indicated such as an abdominal ultrasound, CT scan, MRI, endoscopy and ERCP. One uncommon cause of abdominal pain is an internal hernia. Causes of internal hernias include congenital anomalies due to improper intestinal rotation, atrophy of the omentum, inflammatory and ischemic processes of the peritoneal cavity and prior abdominal surgeries, Roux-en-Y being most common. Radiologic diagnosis of internal hernias is challenging since characteristic findings on CT scan are often missed as hernias can spontaneously reduce on their own. Complications of internal hernias include small bowel obstruction, intestinal ischemia from incarceration and strangulation of intestinal contents, and bowel perforation. Management of internal hernia is surgery to reduce hernia and to close the defect. In our patient, his internal hernia, as a result of his prior Roux-en-Y reconstruction surgery, had been causing his chronic abdominal pain.

CONCLUSION: Suspect internal hernia as a cause of chronic abdominal pain in a patient with a history of abdominal surgery, specifically Roux-en-Y gastric bypass.

INCIDENTAL FINDING OF LEFT VENTRICULAR TRABECULATION IN THE SETTING OF CEREBROVASCULAR ACCIDENT

Dolly Nam; Lillian Niakan; Brent Herndon; Jaison John. University of Texas at Austin Dell Medical School, Austin, TX. (Control ID #3186357)

LEARNING OBJECTIVE #1: To recognize how congenital persistence of deep trabeculae can lead to increased risk of thromboembolic events.

CASE: A 37-year-old man with past medical history significant for hypertension, hyperlipidemia, and bipolar disorder presented to the emergency department with a two week history of right hand weakness and numbness and difficulty speaking. An MRI brain showed a left middle cerebral artery infarction. A CT angiography of his head and neck showed

a subacute left middle cerebral artery distribution infarct and occluded intracranial left middle cerebral artery at the M1 segment. Subsequently, a TTE showed trabeculations in the left ventricle in the apex that were concerning for possible left ventricular non-compaction (LVNC). For definitive diagnosis, a cardiac MRI was performed and showed a non-compacted: compacted myocardium ratio of <2.2, and trabeculated mass <20% of the total myocardial mass. A cerebral angiogram showed left M1 segment middle cerebral artery occlusion with good collateral circulation from anterior and posterior cerebral arteries. The cardiologist recommended a repeat cardiac MRI in two to three years to track progression of trabeculations. The patient was started on lifelong anticoagulation to prevent further embolic events.

IMPACT/DISCUSSION: Though guidelines vary based upon imaging modality, for cardiac MRI a ratio of non-compacted:compacted myocardium must be 2.3 and LV trabeculated mass must be 20% of global LV myocardial mass to meet the definition of LVNC (2). Although the patient does not meet the imaging criteria for LVNC, he is still at significantly higher risk for thromboembolic events than the general population. Involvement of the cardiologist, lifelong anticoagulation, and close outpatient follow up are three key points in this case that can potentially prevent and minimize the serious complications of this condition.

CONCLUSION: - LVNC is a congenital disorder that increases risk of thromboembolic events such as CVA - Deep trabeculations can likewise increase risk of thromboembolic events even in absence of diagnostic criteria for LVNC

INCREASING DIVERSITY UNCOVERS TUBERCULOSIS RARITY

Marshall Meier¹; Kanapa Kornsawad². ¹University of Texas Health San Antonio, San Antonio, TX; ²University of Texas Health Science Center, San Antonio, TX. (Control ID #3184438)

LEARNING OBJECTIVE #1: Recognize clinical features of pancreatic tuberculosis

LEARNING OBJECTIVE #2: Assess need of invasive procedures for diagnosis

CASE: A 25-year-old man with no past medical history presented with five days of rapidly enlarging neck mass. He recently moved from India to San Antonio and noticed an unintentional weight loss of 20 pounds over the past month with a non-productive cough, nausea and vomiting. Denies neck pain, dysphagia and fever. Physical exam revealed a diffusely enlarged, non-tender anterior 5 cm neck mass without axillary or inguinal lymphadenopathy. The exam was negative for exophthalmos or abdominal tenderness. Laboratory studies showed TSH of 0.009 with free T4 of 1.4 and negative thyroglobulin, TSH receptor, and thyroperoxidase antibodies. Also found to have an elevated alkaline phosphatase to 135. Computed tomography (CT) of the thyroid characterized multilobulated, complex cystic lesions with extension into the right thoracic inlet. CT abdomen revealed a 2.5cm multilobulated complex cystic lesion in the head of the pancreas. Fine needle aspiration of the thyroid and paratracheal lymph nodes revealed +AFB with granulomatous inflammation and necrosis consistent with extrapulmonary tuberculosis (TB). The patient was treated with RIPE therapy and an MRI of the abdomen revealed complete resolution of both the paratracheal swelling and pancreatic mass at three months.

IMPACT/DISCUSSION: Pancreatic TB was first described in 1944, but little data exists regarding incidence within the United States. Abdominal TB, which encompasses multiple organs and peritonitis, accounts for only about five to twelve percent of new cases per year. In India, a region with much higher overall prevalence, the incidence of pancreatic involvement is 8% of all abdominal cases. TB thyroiditis accounts for only 0.6% of all thyroid masses making this a unique presentation of extrapulmonary TB with both pancreas and thyroid involved. There is no universally accepted diagnostic or treatment strategy for pancreatic TB. For management of

this patient, we followed an algorithm first suggested by Sharma et al. It utilizes imaging characteristics of the abdominal mass as well as biopsy proven TB in other non-pancreatic sites in order to avoid further unnecessary invasive tests. The use of fine needle aspiration for direct diagnosis of pancreatic TB has yielded variable results of 43-80%. Based on this information and taking into account the patient's young age as well as no other risk factors, he was spared an invasive and potentially harmful procedure. This diagnosis requires a high index of suspicion but ultimately leads to appropriate treatment and sub-specialty follow up.

CONCLUSION: Tuberculosis can manifest within a multitude of different organs leading to puzzling symptoms and clinical presentations. By thoroughly investigating each abnormality, clinical context can guide a thorough workup while avoiding unnecessary and invasive procedures but still achieving favorable outcome and appropriate sub-specialty follow up.

INDECISION BEFORE THE INCISION: DIFFICULT CHOICES BEFORE A WHIPPLE PROCEDURE

Richard Pham, UPMC, Pittsburgh, PA. (Control ID #3185842)

LEARNING OBJECTIVE #1: Examine the variables affecting stable decision-making in advanced illness

LEARNING OBJECTIVE #2: Identify social disparities among a minority group during end-of-life care

CASE: A 64-year-old African American woman is admitted with altered mental status and bacteremia while on total parenteral nutrition. On chart review, it was noted she was diagnosed with a benign pancreatic cystadenoma years ago and declined a curative Whipple due to her hesitancy regarding the operative risks. Over several years she had suffered functional decline, with multiple admissions for pancreatitis and difficulties with maintaining nutrition. Documented discussions revealed frequent uncertainty about her desires for artificial nutrition and invasive procedures going forward. The team notes this is her third admission for bacteremia this year, but this time the patient is unable to discuss her care preferences due to her mental status. A goals of care discussion is held with family, and her sister expresses concerns about the patient's worsening functional decline and reiterates her desires for no additional invasive procedures. Hospice planning is initiated. A few days later, the surgical team revisits the possibility of Whipple and a sudden change in treatment course is made. The patient and family decide to ultimately pursue Whipple and TPN is resumed. The patient is hospitalized for a total of two months and discharged without definite plans for surgery.

IMPACT/DISCUSSION: The patient expressed conflicting preferences through her disease course and as providers, we must be cognizant that preferences may be shaped by how we present treatment options. The way the surgery and medicine team communicated the illness course clearly resonated with the patient and family in opposite ways. Poor communication between providers resulted in poor communication with the patient. Poor communication is also a factor often cited as a possible source of health disparity in end-of-life planning. African Americans are statistically less likely to engage in hospice planning than white counterparts. In 2015, 50.5% of Medicare white Americans engaged in hospice at the end of life while only 38% of African Americans did. African Americans are cited to undergo intubation and CPR more frequently than whites prior to death. Even among African Americans in hospice who have end of life preferences, 90% received care consistent with their wishes, while 95% of white Americans did.

CONCLUSION: -Making advanced decisions about an unknown future is a time of great stress and anxiety for patients. -Providers must communicate among each other to better ensure consistent communication to prevent inconsistent patient preferences -Health disparities among African Americans exist also in end-of-life care, and the onus is on physicians to recognize poor communication as a contributing factor.

INFERIOR MESENTERIC VEIN THROMBOSIS SECONDARY TO ACUTE SIGMOID DIVERTICULITIS A RARE COMPLICATION.

Muqsita Nashat; Saba Mushtaq. Mercy Nazareth Hospital, Philadelphia, PA. (Control ID #3178637)

LEARNING OBJECTIVE #1: Diagnose and treat septic thrombophlebitis of inferior mesenteric vein secondary to acute diverticulitis.

CASE: A 50-year-old male presented to the emergency room with worsening left lower quadrant abdominal pain of two days duration associated with subjective fever and diarrhea. Three weeks prior to his presentation, he was diagnosed with acute diverticulitis confirmed by abdominal CT scan and completed a seven-day course of Ciprofloxacin and Metronidazole. Physical exam revealed a temperature of 36.4C, pulse 136/min, BP 140/85, tenderness in the left lower quadrant without any peritoneal signs. There was no leukocytosis and a repeat CT of the abdomen showed worsening sigmoid diverticulitis with new septic thrombophlebitis of the inferior mesenteric vein extending to the Porto splenic confluence. Patient was admitted, placed on bowel rest, treated with intravenous Piperacillin/Tazobactam, fluids, Heparin drip and oral Vancomycin as his stool for C. diff toxin gene by PCR was positive. His blood cultures were negative and flow cytometry showed no evidence for a lympho or myeloproliferative disorder. Due to persistent abdominal pain, he underwent hemicolectomy and a coloproctostomy. Pathology of colon showed acute diverticulitis with pericolonic abscess. The patient was discharged home and advised to complete the remaining 14 days of oral Vancomycin and six-month course of Coumadin

IMPACT/DISCUSSION: Clinical cases of Inferior Mesenteric Vein thrombosis (IMV) complicating acute diverticulitis is rare and comprises of 4-11% of cases but carries a 15-23% risk of mortality. Acute diverticulitis can cause inflammation of IMV by peri colonic abscess and thrombosis occurs by inflammatory mediators causing endothelial injury and activation of coagulation cascade. Sigmoid diverticulitis is the most common causative etiology of thrombophlebitis of IMV accounting for 30% of cases, the remaining other causes are appendicitis (19%), IBD (6%), pancreatitis (5%), infectious enteritis (4%), bowel perforation and malignancies (6%). There is high mortality in cases complicated by hepatic abscess or bowel ischemia. The clinical presentation of septic thrombophlebitis of IMV is insidious with vague symptoms delaying early diagnosis and therefore requires a high index of suspicion. CT scan of the abdomen with contrast is generally the first test of choice with direct visualization of endoluminal thrombus. Bacteremia is typically polymicrobial with E. coli, Bacteroides, Streptococcus Viridans, Proteus Mirabilis and Klebsiella Pneumonia being the most common pathogens. Sterile blood cultures in our patient can be explained by the prior use of antibiotics. Treatment with broad spectrum antibiotics and systemic anticoagulation often has a favorable outcome when compared to treatment with antibiotics alone

CONCLUSION: This case illustrates the fact that IMV thrombosis though a rare complication of acute diverticulitis requires a high index of suspicion for a prompt diagnosis and to prevent complications.

INFILIXIMAB-INDUCED PULMONARY EMBOLISM.

Areeg Bala^{1, 2}; Mahmoud Barbarawi^{1, 2}; Hoda Daher^{1, 2}; Ashok K. Kanugula^{1, 2}; Ghassan Bachuwa^{3, 2}. ¹Hurley Medical Center, Grand blanc, MI; ²Michigan State University, Flint, MI; ³hurley medical center, Flint, MI. (Control ID #3186505)

LEARNING OBJECTIVE #1: Recognize infliximab (Remicade) as a cause of pulmonary embolism.

CASE: A 20 years old African American male with a past medical history of diabetes type 1 and recently diagnosed Crohn disease 6 months prior presentation actively on mesalamine and infliximab infusions. His last infusion was shortly before the presentation. He presented to the emergency

department with chest pain and back pain. On examination, he was tachycardic with a heart rate of 139. Laboratory investigations showed elevated D-dimer, EKG showed sinus tachycardia, and CT of the chest with contrast showed pulmonary embolism involving the left lower lobe segmental and subsegmental vessels. He denied any history of smoking, recent immobilization, surgery, travel, or any personal or family history of clotting disorders. He was diagnosed with provoked pulmonary embolism and started on IV heparin infusion. He showed improvement and was sent home with a subcutaneous anticoagulant for a period of 3 months.

IMPACT/DISCUSSION: Impact and Discussion: This case demonstrates the potential pulmonary embolism side effect of a commonly prescribed anti-TNF infliximab. Remicade, trade name for Infliximab, a chimerical monoclonal antibody that works against tumor necrosis factor TNF. It's used for a different array of autoimmune disease. It can't be given by mouth because the digestive system will destroy the drug, and hence, it's given in intravenous infusions. Although most patients treated with infliximab experience side effects related to suppression of the immune system, thromboembolic side effects are very low. The most common side effects are serious infections (fungal, bacterial, or viral), reactivation of tuberculosis, reactivation of hepatitis, drug-induced lupus, and increase the risk for certain types of cancer. A case report has identified the occurrence of pulmonary embolism during infliximab treatment. The mechanism by which infliximab causes pulmonary embolism is still not very clear and hence further research is warranted.

CONCLUSION: Although infliximab is associated with multiple common side effects, we should be aware of its thromboembolic aptitude. Close attention should be given to IBD patients started on infliximab infusion for any symptoms of pulmonary embolism or deep vein thrombosis DVT.

INFLUENZA-A, A RARE CAUSE OF DIFFUSE ALVEOLAR HEMORRHAGE.

Deep Patel. Brookwood Baptist Health, Birmingham, AL. (Control ID #3186005)

LEARNING OBJECTIVE #1: Recognize that Influenza A is a rare but important cause of diffuse alveolar hemorrhage.

LEARNING OBJECTIVE #2: Recognize the important aspects of diagnosis and treatment of Influenza A.

CASE: A 59-year-old African American male with a past medical history of hypertension, hemolytic anemia, thrombocytosis, and DVT presented with 1 day of fever up to 102F, shortness of breath, congestion, and palpitations. No prior surgical history. Family history significant for myocardial infarction in brother in his 60's. Social history significant for prior tobacco use. Physical exam revealed increased work of breathing, bilateral wheezing, crackles, and tachycardia. Pertinent Lab findings included WBC of 12.1, H&H 7.6/25.3, platelet count 93, Creatinine 1.58, lactic acid 4.0, troponin 0.141, Procalcitonin 23.53.. Chest X-ray was concerning for bilateral pneumonia vs. pulmonary edema. Rapid Flu test was negative. Cultures were obtained and IV fluids, Azithromycin, and Piperacillin/tazobactam were started. Repeat X-ray was concerning for ARDS, so pulmonary service was consulted. Overnight his respiratory distress worsened and he was intubated. The next morning, he had bloody respiratory secretions and bronchoscopy revealed diffuse alveolar hemorrhage. Vasculitis labs were sent. Respiratory virus panel for Influenza A was positive and Tamiflu was initiated. Vasculitis work-up including ANA, ANCA, and Anti GBM was negative. Influenza was considered the cause of the diffuse alveolar hemorrhage.

IMPACT/DISCUSSION: Influenza-A - particularly H1N1 - is a viral illness associated with potential serious complications. One complication is diffuse alveolar hemorrhage. The first case of H1N1 was reported in March 2009 and by June 2009 it was a pandemic. It affected all ages, however death mostly occurred in those between 30-50 years of age. Although a rapid flu test and respiratory virus panel may be positive, real time reverse transcriptase polymerase chain reaction is the diagnostic

method of choice. Even with a high index of suspicion, clinical diagnosis is difficult because confirmatory testing may take up to a week. Oseltamivir is the treatment of choice. If started within 48 hours of symptom onset it reduces mortality and duration of hospitalization. If initial testing of influenza is negative in patients with alveolar hemorrhage then Influenza can be easily overlooked. In patients with alveolar hemorrhage H1N1 should be considered a differential as prompt empiric treatment is required.

CONCLUSION: This case highlights the importance of suspecting Influenza-A infection in a patient with diffuse alveolar hemorrhage, particularly when vasculitis work-up is negative. Although it is rare for influenza to cause diffuse alveolar hemorrhage, it certainly is possible. The physician should have a high index of suspicion as rapid flu tests may be falsely negative. Treatment with oseltamivir should be initiated promptly.

INTESTINAL TUBERCULOSIS MIMICKING CROHN'S DISEASE

Anira Iqbal¹; David T. Broome²; Rishi Rikhi²; Roop Kaw². ¹Chirayu Medical College and Hospital, Bhopal, India; ²Cleveland Clinic Foundation, Cleveland, OH. (Control ID #3184017)

LEARNING OBJECTIVE #1: Recognize and diagnose Intestinal tuberculosis(TB) mimicking Crohn's disease(CD), particularly in immigrants from TB-endemic countries.

CASE: A 73-year-old female Pakistani immigrant(1988) presented with 2 week history of bloody bowel movements, abdominal pain, fatigue, low grade fevers while on Tacrolimus and Prednisone, which she had been taking for 5 years post renal transplant. Colonoscopy showed terminal ileal inflammation with erosions, granularity, and ulcerations characterized as Crohn's disease and oral steroids were started. However, tissue biopsy demonstrated caseous granulomas consistent with TB. Steroids were discontinued after 5 days of initiation and she was switched to RIPE(Rifampin, Isoniazid, Pyrazinamide, Ethambutol), while continuing immunosuppressants, and discharged. A month later, she presented with recurrent symptoms. Pertinent findings were a fever of 39.3°C and right lower quadrant tenderness to deep palpation without signs of peritoneal irritation. Imaging displayed acute ileal inflammation of 8-10cm with progressive ulceration. Fecal testing for acid fast bacilli(AFB) was positive. Serum RIPE levels were checked to ensure proper absorption. She was instructed to continue RIPE for 9 months and to follow up closely.

IMPACT/DISCUSSION: Intestinal TB and CD are chronic granulomatous diseases presenting similarly. With the reemergence of TB in the West due to the AIDS epidemic, differentiating them is of great importance. At-risk population for TB includes immigrants from endemic regions(Asian and African countries), alcoholics, prisoners and immunocompromised. Both conditions present with abdominal pain, fever, lethargy, bowel habit alteration and loss of appetite. CT scan in CD shows prominent ileal vasculature("comb sign"). In TB, the ileocaecal wall is asymmetrically thickened, with large nodes forming a mass. On colonoscopy, hypertrophic lesions with transverse ulcers suggest TB. CD has a cobblestone appearance with longitudinal deep ulcers and skip lesions. Fistulae are suggestive of CD. Histopathologically, caseation necrosis with large granulomas ($>400\mu$) and AFB support TB, as compared to small granulomas ($<200\mu$) in CD. Additional testing by stool AFB, Interferon gamma release assay for TB or Anti-Saccharomyces cerevisiae antibody for CD might corroborate diagnosis.

CONCLUSION: Physicians should be cognizant of Intestinal TB mimicking CD in at-risk population including immigrants from endemic regions, alcoholics, immunocompromised and prisoners. A combination of lab testing, imaging, colonoscopy and histopathology should be used to differentiate the two. Steroid therapy for a presumed diagnosis of CD will do more harm than good in individuals with Intestinal TB. References Sharma R, Madhusudhan KS, Ahuja V. Intestinal tuberculosis versus crohn's disease: Clinical and radiological recommendations. Indian J Radiol Imaging. 2016;26(2):161-72. Tandon HD, Prakash A. Pathology of intestinal tuberculosis and its distinction from Crohn's disease. Gut. 1972;13:260-9.

INTRAVASCULAR LARGE B-CELL LYMPHOMA PRESENTING AS HEMOPHAGOCYTIC LYMPHOHISTOCYTOSIS

Suheil Albert Atallah-Yunes¹; Arthi Sridhar¹; Riffat Sabir². ¹UMASS-Baystate, Springfield, MA; ²Baystate Medical Center, Longmeadow, MA. (Control ID #3186537)

LEARNING OBJECTIVE #1: Recognize that intravascular lymphoma is very rare and mainly presents with non specific signs and symptoms

LEARNING OBJECTIVE #2: Recognize HLH as a presentation of lymphoma which could make treatment with chemotherapy more challenging

CASE: A 66-year-old male with a past medical history of hypertension who was admitted to the hospital after being referred by his hematologist due to worsening of fever, chills and rigors. Prior to admission patient had an extensive work up for anemia, thrombocytopenia, fatigue and 15 pounds weight loss in 5 months duration. Outpatient work up ruled out an infectious etiology. CT scan showed hepatosplenomegaly and splenic lesions. Bone marrow biopsy was performed as an outpatient and preliminary findings were highly suggestive of large B-cell lymphoma within the sinusoids of the blood vessels pointing towards intravascular large B-cell lymphoma (IVBL). Upon admission, his vital signs revealed a high grade fever of 103 F. Physical exam was positive for hepatosplenomegaly with no palpable lymph nodes. Blood work revealed a white cell count of 10.9 k/uL, hemoglobin of 8.8 gm/dL and a platelet count of 37s k/uL. Given the high suspicion for intravascular large B-cell lymphoma, transjugular hepatic biopsy was performed and biopsy results confirmed large B-cells in the hepatic sinusoids. He was started on R-CHOP therapy. His ferritin level was elevated at 2000 ng/ml while IL-2 receptor levels were elevated at 18 K raising the suspicion for HLH in the setting of his worsening anemia, thrombocytopenia and hepatosplenomegaly. Patient was started on Dexamethasone for treatment of HLH and continued receiving chemotherapy for treatment of his IVBL.

IMPACT/DISCUSSION: IVL is a rare subtype of extranodal lymphoma and results from lymphocytic cell proliferation in the luminal vessels with minimal to no involvement of the surrounding parenchyma. Intravascular diffuse large B-cell lymphoma (IVBL) is the most common subtype. IVBL is classified into two: Classical IVBL and Asian Variant IVBL. The most common is the classical IVBL which usually occurs in western countries and mainly involves the CNS and the cutaneous tissue. Thus, patients present with CNS and cutaneous manifestation. Asian Variant (AV) IVBL is rare and tends to spare the CNS and the skin. These patients present with fever, malaise, anemia, thrombocytopenia, hepatosplenomegaly, hemophagocytosis, elevated liver function tests, elevated ferritin and hence HLH as it was seen in our patient. Theories support the release of macrophage stimulating factor and inflammatory markers mainly IL-6 causing overactivation of the macrophages and so HLH. IVL is treated with the RCHOP therapy, if HLH is suspected then prednisone could be replaced with dexamethasone for treatment of HLH.

CONCLUSION: Patients with IVL tend to present with nonspecific signs and symptoms in the usual absence of palpable lymph nodes. HLH is a rare presentation of IVL and could make treatment with chemotherapy more challenging due to the commonly seen cytopenias.

IRON CLAD FEVERS OF UNKNOWN ORIGIN (FUO) IN A PATIENT WITH SICKLE CELL DISEASE

Tessa Henry¹; Steven G. McKee². ¹University of Arkansas for Medical Sciences, Little Rock, AR; ²University of Arkansas, Little Rock, AR. (Control ID #3184536)

LEARNING OBJECTIVE #1: Diagnose a rare cause of FUO in patients with sickle cell disease and iron excess.

CASE: A 32 year-old with sickle cell disease presented with fever and shortness of breath after multiple recent hospitalizations for pneumonia. Instead of several bouts of acute episodes, she divulged several months of

intermittent fevers and productive cough. On examination she appeared ill and had tender, massive hepatomegaly. She had normal heart sounds, decreased breath sounds, and bilateral inspiratory crackles. White blood cell count was 15K/uL, hemoglobin was 7.2g/dL, liver function tests were elevated in a cholestatic pattern with alkaline phosphatase 721IU/L and ferritin level was greater than 15,000ng/mL. She received a short course of broad-spectrum antibiotics without abatement of fever. Infectious workup for atypical and typical bacteria, fungi, *Mycobacterium tuberculosis* (MTB) and viral pathogens was negative. Computed-tomography (CT) displayed bilateral ground-glass opacities. The patient declined bronchoscopy. Hemophagocytic lymphohistiocytosis was entertained but she did not meet criteria. By hospital day 14, she remained febrile but had improvement of her respiratory status so she was discharged with plans for outpatient liver biopsy. The working diagnosis was adult onset Still's disease. Two weeks later she returned with shortness of breath and persistent fevers with exam unchanged apart from pitting edema to her knees. Evaluations for venous thrombus and embolism were negative and echocardiogram was non-diagnostic. Chest CT showed new pleural nodules with cavitation. Bone marrow, liver, and lung biopsies revealed non-caseating granulomas. Rare organisms were seen on acid-fast stain of the lung tissue. Standard testing for MTB plus PCR was again negative. Fever persisted despite antibacterial therapy so she was transitioned to azithromycin, ethambutol, and rifabutin. Blood transfusion was minimized and she received deferasirox for iron chelation. Lung biopsy cultures grew *Mycobacterium intracellulare* confirming disseminated infection and mandating one year of treatment.

IMPACT/DISCUSSION: *Mycobacterium intracellulare* is one species within the *M. avium* complex (MAC). MAC infections are a known complication of sickle cell disease in African populations with iron excess yet on review of the literature we found only four similar cases in North America.

CONCLUSION: This case highlights MAC as an important cause of FUO in a North American sickle cell patient with iron overload. The prevalence of nontuberculous mycobacterial infections is increasing in North America and all five cases of MAC infection in patients with sickle cell disease and iron overload have been reported since 2010. Thus MAC infection may be a growing risk for transfusion-dependent sickle cell patients on this continent. Recognizing the possibility of MAC infection in sickle cell patients with iron excess, despite locale, may lead to earlier diagnosis and treatment.

IRON REPLACEMENT: A CAUTIONARY TALE

Joy Tang; Gareth Hattersley. Medical College of Wisconsin, Milwaukee, WI. (Control ID #3185220)

LEARNING OBJECTIVE #1: Learn the symptoms, diagnosis and treatment for polycythemia vera.

CASE: A 68-year-old healthy male was found to have progressively decreasing mean corpuscular volume (MCV) on routine labs. Patient was asymptomatic. Vitals were unremarkable. Labs revealed a low MCV of 68.9 fL (from 90.6 fL three years ago), hemoglobin (hgb) of 15.8 g/dL, platelets (plt) of 445 K/ μ L, white blood cell (WBC) count of 12.8 k/ μ L. Electrolytes and creatinine were unremarkable. Iron studies were consistent with pure iron deficiency. He was referred to gastroenterology given his progressive microcytosis and iron deficiency, concerning for occult bleed. EGD and colonoscopy were unremarkable, but did reveal a Billroth II anatomy, which was initially thought to be the etiology of his low iron. He was transfused with twelve doses of IV ferric gluconate 125mg. Post-transfusions, he was noted to have elevated hgb of 18.8 g/dL. WBC and plt remained unchanged. Repeat iron level decreased to 37 μ g/dL. Patient was then referred to hematology. Serum erythropoietin was low at 1.0 mU/mL. Ultrasound revealed splenomegaly and he was found to be positive for the JAK2 mutation. He was diagnosed with polycythemia vera (PV) and started on aspirin for prevention. Treatment was initiated with phlebotomies and hydrea.

IMPACT/DISCUSSION: PV is a rare, chronic myeloproliferative disease characterized by clonal proliferation of myeloid cells causing increased red cell mass. Symptoms include pruritus, headache, paresthesia, dizziness, visual disturbance and bleeding. Serum erythropoietin (epo) can be obtained to differentiate between primary and secondary polycythemia, with low epo pointing towards PV. Diagnosis can be made by fulfilling all major criteria or two major and the minor criteria. Major criteria include hemoglobin >16.5 g/dL in men and 16.0 g/dL in women, bone marrow biopsy demonstrating hypercellularity with trilineage growth and presence of JAK2 V617F mutation or other functionally similar mutations. The minor criteria is subnormal serum erythropoietin. Currently there is no cure for PV. Management is based on risk stratification and can include starting aspirin for primary prevention, phlebotomy to maintain hematocrit <45% and use of cytoreductive agents. PV can be difficult to diagnose due to confounding factors. Our patient had a classic presentation of PV that was initially mistreated due to concern for occult bleed based on his age, microcytosis and iron deficiency. Platelets are also frequently elevated in iron deficiency, making his diagnosis less apparent. Physicians should consider PV as a differential for patients who present with iron deficiency and inappropriately normal or elevated hemoglobin. Patients with PV should be carefully monitored as life-threatening complications can develop from vaso-occlusive causes or progression to myelofibrosis or leukemia.

CONCLUSION: Consider PV as a differential for patients who present with iron deficiency and inappropriately normal or elevated hemoglobin

IS IGNORANCE BLISS? THE BIOPSY DILEMMA IN CIRRHTIC PATIENTS WITH GLOMERULONEPHRITIS

Max Ruge; Jeffrey Bulger; Michelle Sweet. Rush University Medical Center, Chicago, IL. (Control ID #3184888)

LEARNING OBJECTIVE #1: Discuss the most common glomerular disorders seen in cirrhosis with a particular focus on IgA nephropathy.

LEARNING OBJECTIVE #2: Describe two common methods of renal biopsy and the preferred method in a patient with decompensated cirrhosis.

CASE: A 54-year-old male with history of alcoholic cirrhosis (MELD 18 on admission) presented from an outside hospital with decompensated cirrhosis and worsening acute kidney injury (AKI) likely from either hepatorenal syndrome or overdiuresis (FeUrea = 27.2%). His diuretics were initially held at our hospital, and he received a 5% albumin infusion, which lowered his creatinine from 1.6 to his baseline of 0.85. During his AKI workup, he was incidentally found to have nephrotic-range proteinuria with an estimated 24-hour protein excretion of 4.2 g/day and >200 RBCs on urinalysis. Some degree of proteinuria and hematuria had also been noted on all urine studies from prior admits dating back 2 months. Transjugular kidney biopsy was performed due to concern for underlying glomerular disease, and additional liver samples were obtained to re-evaluate the stage of cirrhosis. The renal biopsy revealed findings consistent with IgA nephropathy, and he was started on losartan. Shortly after the procedure, he was found to have the complications of a ruptured gallbladder and a slow bleed from the cystic artery that required Gelfoam embolization. He spent about 1 week in the MICU for treatment of his decompensated cirrhosis and complications of the biopsy and was ultimately discharged 20 days later.

IMPACT/DISCUSSION: Only a very small percentage of renal pathology in cirrhosis patients is the result of glomerular disease such as nephritic (3.4%) or nephrotic syndrome (2.2%), which most frequently includes IgA nephropathy, type I membranoproliferative glomerulonephritis, and mesangial proliferative glomerulonephritis. There is a well-documented association between IgA nephropathy and liver cirrhosis likely because the damaged liver is not able to clear IgA complexes in circulation resulting in deposition in the kidneys. Furthermore, portal hypertension also appears to play a critical role in the development of IgA nephropathy in patients with cirrhosis. Both ACE inhibitors and

ARBs are renal-protective in IgA nephropathy and have been shown to decrease proteinuria from this mechanism. Renal biopsy is difficult in this population due to the numerous clotting dysfunctions associated with cirrhosis leading to the elevated risk of complications such as perirenal hematoma. Transjugular biopsies are typically preferred over the traditional percutaneous route to mitigate some of these risks, even though adequate tissue is obtained only 78.6% of the time versus 90-95% for percutaneous route.

CONCLUSION: Given the risk of complications and the well-established relationship with IgA nephropathy, renal biopsy should be only obtained in cases of nephrotic-range proteinuria and hematuria if it may influence treatment such as evaluation for liver transplant or for rapidly progressive renal disease.

IS THE HIGH WORTH THE TORSADES? A CASE OF LOPERAMIDE-INDUCED TORSADES DE POINTES

Jaime de la Fuente; Jared Bird; Korosh Sharain; Vasken Keleshian; Nandan Anavekar. Mayo Clinic, Rochester, MN. (Control ID #3161490)

LEARNING OBJECTIVE #1: Identify loperamide as an important over-the-counter medication with abuse potential that can cause prolonged QT interval

LEARNING OBJECTIVE #2: Recognize life threatening ventricular arrhythmias and their treatment

CASE: A 29-year-old female with a history of bile acid diarrhea and chronic abdominal pain presented for an outpatient esophagogastroduodenoscopy. Prior to the procedure, she developed severe nausea, vomiting, and dizziness, prompting direct admission to the general medicine service. Initial negative work up included: complete blood count, extended electrolytes, pregnancy test, urinalysis, urine drug screen, and serial troponins. ECG demonstrated a prolonged QTc interval of 549 msec. Upon further history, she revealed she had been consuming more than 200 mg (100 pills) of loperamide daily, for over a year, to relieve her abdominal pain and diarrhea. Her last dose of loperamide was 48 hours prior to presentation. During hospital day one she developed palpitations and had a pre-syncopal episode. Review of her cardiac monitor revealed polymorphic ventricular tachycardia (PVT). She was promptly started on IV magnesium and isoproterenol to decrease the QTc interval and reduce the probability of further PVT. This initially abated further PVTs. However, while weaning down the isoproterenol she had recurrence of runs of PVT. Thus, IV lidocaine was added to her regimen. Significant QT interval prolongation continued despite loperamide discontinuation, raising the teams suspicion for an underlying congenital long QT2 syndrome. Thus, she was transitioned to nadolol without further occurrence of PVT. Nine days later patient was discharged from the hospital with a QTc of 460 msec on nadolol. Further outpatient work up two months later, including electrocardiogram, stress test, and genetic testing, was negative for congenital long QT syndrome. QTc at that time was 430 msec. Patient's nadolol was discontinued.

IMPACT/DISCUSSION: This case illustrates the importance of being familiar with over the counter QT interval prolonging agents, the possibility of loperamide being used as a drug of abuse, and the treatment of acquired PVT. It is believed that the mechanism of the prolonged QT by loperamide involves the inhibition of cardiac sodium and potassium channels. As demonstrated by this case, it is also critical to understand that the cardiac effects of loperamide, especially when abused and consumed for an extended period of time, will last much longer than the reported half-life of 11 hours. Additionally, congenital QT syndrome can potentially be unmasked when taking these agents, and as such should be maintained on the differential, and treated with beta blockade therapy in the outpatient setting.

CONCLUSION: Polymorphic ventricular tachycardia (PVT) is a life threatening arrhythmia resulting from a variety of mechanisms. For the general internist, it is important to recognize its initial management and over the counter medications with abuse potential, like loperamide, which can lead to this serious arrhythmia.

IS THERE A LAWYER IN THE HOUSE? THE PHYSICIAN ROLE IN LEGAL ADVOCACY

Aliza Norwood; Alejandro Moreno. UT Dell Medical School, Austin, TX. (Control ID #3184396)

LEARNING OBJECTIVE #1: Recognize symptoms of panic disorder in an immigrant patient

LEARNING OBJECTIVE #2: Apply the concept of the extended care team to legal services

CASE: A 27 year-old woman with a history of preeclampsia and depression presented with worsening paroxysmal left-sided chest pain for 3 years. Multiple prior visits that included CBC, CMP, TSH, and EKGs revealed no cause for her symptoms. She described the pain as sharp and non-radiating, usually lasting 15 minutes, and associated with lightheadedness and shortness of breath. She also reported occasional headaches, tremors, nausea, and cold sweats. Her vitals, including orthostatics, were stable. The exam was notable only for a heart rate of 50 beats/min, and EKG confirmed sinus bradycardia. Labs were normal as in prior visits. A Holter monitor showed sinus bradycardia with rare supraventricular ectopic beats. Her PHQ9 score was 9. Further questioning revealed a long history of persecution that included child and sexual abuse. She fled from her country to the US while pregnant to escape growing threats against her life and that of her unborn child. She began to have flashbacks and nightmares and became socially withdrawn. She was diagnosed with panic disorder and referred to behavioral health; over the next 2 months she noted improvement in symptoms with counseling and mindful breathing exercises. Multiple attempts were made to contact her immigration lawyer by phone and email, with no response. The patient returned to clinic with worsening symptoms 3 months later after receiving a final deportation order. With the patient's permission she was referred to a non-profit immigration advocacy firm and a pro-bono lawyer to explore possible avenues of relief. The immigration lawyer proposed a course of action which was limited to an extraordinary legal recourse given the time elapsed and the existing deportation order. The patient declined because immigration authorities would have detained her for several months until the trial proceedings were over.

IMPACT/DISCUSSION: Anti-immigration policies have been linked directly to negative mental health effects on immigrants including depression, anxiety, and PTSD. Evidence exists that threat of deportation increases the risk of mental illness. Physicians are increasingly relying on social workers and others in the extended care team to address the social determinants of health. There are already precedents to screen patients for abuse or domestic violence which can lead to social and legal referrals. While not a part of routine practice, we propose that doctors are under a similar obligation to ensure patients are referred to competent legal aid for immigration services if needed to protect physical and/or emotional health. If referred early, the negative consequences of inadequate legal counsel may be prevented.

CONCLUSION: Physicians should have a low threshold to screen for physical and mental effects of trauma in immigrant patients. Medicolegal partnerships can be a tool to aid patients who seek asylum.

IS THIS BECAUSE I'M PREGNANT OR DID I JUST CUT MY TOE?

Camille R. Bourgeois; M. Matias Iberico. Tulane University School of Medicine, New Orleans, LA. (Control ID #3184152)

LEARNING OBJECTIVE #1: Recognize the rising rate of invasive Group B streptococci (GBS) infections in non-pregnant adults

LEARNING OBJECTIVE #2: Identify appropriate antimicrobial coverage for GBS infection

CASE: A 74-year-old woman presented with exertional dyspnea, orthopnea, chills, and rigors worsening over the preceding 24 hours. No

cough or sputum production was reported. She was visiting from out of town and was inconsistently taking home medications for hypertension, diabetes, and atrial fibrillation. She had been walking more than usual and did not report chest pain but did develop a small toe laceration. Her blood pressure was found to be 210/110 mmHg on arrival and temperature of 101.1F. Elevated JVP, bibasilar crackles, and bilateral lower extremity edema were present. The right great toe had a small superficial laceration without evidence of drainage or surrounding infection. She was treated for decompensated heart failure and suspected sepsis. Broad spectrum antibiotics were initiated. Blood culture reports returned 6 hours after the draw with group B streptococcus. Antibiotics were transitioned to IV ceftriaxone and she was discharged on cefadroxil. No other source of infection was identified, and bacteremia was attributed to the small toe laceration.

IMPACT/DISCUSSION: The CDC Active Bacterial Core surveillance estimates that 28,000 cases of invasive GBS occurred in 2014 and 93% occurred in non-pregnant adults. It is emerging as a frequent cause of invasive infection in non-pregnant adults with underlying chronic medical conditions. The main clinical presentations were bacteremias without apparent focus and soft tissue infections. One study reported that osteoarticular, skin and soft tissue infections account for 31% of manifestations and 45% of all patients studied experienced a complicating bacteremia. In about a quarter of the episodes of bacteremia studied, no source of infection identified. The most frequent risk factors associated were chronic kidney disease, cardiac failure, neoplasia history, ischemic heart disease, and diabetes mellitus. The high proportion of episodes of bacteremia indicates that blood cultures should be obtained in any elderly patient presenting with a skin and soft tissue infection or osteoarticular infection. GBS is susceptible to penicillin and amoxicillin, but these medications are only used for treatment about 29% of the time. Microbiology labs do not routinely test for sensitivities to GBS considering its consistent susceptibility to these antibiotics. It is important for internists to recognize the value of antibiotic stewardship and deescalate antimicrobial coverage accordingly when GBS is identified.

CONCLUSION: The incidence of invasive GBS infection is rising in the non-pregnant adult population. Penicillin is first line treatment for GBS infection and given the near uniform susceptibility, microbiology labs do not routinely run sensitivity testing on GBS species.

IS THIS MUNDANE WORK? REFLECTIVE WRITING TO EMOTIONAL WELL BEING.

Manisha Bhide. University of Colorado Denver, Aurora, CO. (Control ID #3167939)

LEARNING OBJECTIVE #1: Reflect on daily work.

LEARNING OBJECTIVE #2: Realize the importance of networking at regional and national level. Reflective writing and mentoring relationships play an important role in work satisfaction and emotional well being.

CASE: Boom ! Boom" The shots rang out, about to claim a life, but Ricky survived. "Rosie, why did you save me?" He croaked. "I want to die. I have nothing left to live for. Whatever mattered is all gone". "Ricky, He has given you a chance to lead a human life and you have to make the most of it. Until now you lived for yourself. Now, may be you can live for the society. There is so much to do. It is ultimately your relationship to Him that really matters." "In my busy clinic, I was running late again! I glanced at the paper in the door. "Paul P- BP followup." "This should be quick. It is just BP follow up. That should allow me to catch up" I thought erroneously. Paul unfolded his handkerchief from pocket and dabbed his eyes and unfolded his life story with it. He belonged to the era that still carried his handkerchief and ironed his jeans. Paul's wife of 40 years, Clara had a stroke. He spent every waking moment in the nursing home with Clara. He took it upon himself to clean her, dress her and take care of her personal hygiene every day for 18 years. She passed away in the middle of the night. I secretly felt relieved for Paul, thinking that his suffering was over. He could lead a new, near normal life. But, that aphasic expression, that contracted numb hand,

that incontinent, sacral decubitus relationship with Clara meant more to Paul than anything else in this world

IMPACT/DISCUSSION: I met "Dr. Young", my SGIM mentor 10 years ago when I was an eager junior faculty. He encouraged me to participate in National clinical content subcommittee and gave me a letter of recommendation for promotion. He was there with me in the reflective writing workshop. He has played a key role as a mentor and a guide in my professional development. I like the opening greeting that he uses in every mentor-mentee meeting "Are you enjoying what you are doing?" Our residents do a reflective writing as a part of the continuity clinic didactics. These have served as a baseline for peer reviewed publication in JGIM, Annals, JAMA etc. Medical students are doing reflective writing as a part of hidden curriculum and learning professionalism. This helps them share their emotions like about the first death they encountered. Research has shown that this helps mental well being of trainees and professionals and gives them resilience.

CONCLUSION: Reflecting on each of these instances, every one of us needs to pour our heart and soul and passionately cherish our daily work like a prayer. Even in this world of electronic medical records, smart phones and virtual lives in social media, it is the human relationships that matter the most. It is through our routine, daily work that we are realizing our relationship with Him every moment of our lives and rising from mundane work to higher spiritual level.

IT GETS WORSE BEFORE IT GETS BETTER: DELAYED POST HYPOXIC LEUKOENCEPHALOPATHY

Stephen M. Stuart¹; Maddie Bender¹; Starr Steinhilber². ¹UAB, Birmingham, AL; ²University of Alabama at Birmingham, Birmingham, AL. (Control ID #3185883)

LEARNING OBJECTIVE #1: Define the clinical pattern of Diffuse Post-Hypoxic Leukoencephalopathy (DPHL)

CASE: A 58-year-old woman presents from a rehab facility for acute change in mental status. During a recent admission she was found down with profound hypoxia due to medication overdose, intubated, and experienced cardiac arrest during the hospitalization. She improved after one week in the intensive care unit and was verbal, mobile, and interactive at the time of discharge to the rehab facility. She then functionally declined within days and on admission to our facility was aphasic and encephalopathic. Exam notable normal vitals, minimal interaction, clonus with upgoing Babinski, diffuse rigidity with flexion of elbows, wrists, and hands, as well as mutism. Work up included a CT Head notable for subacute infarct that had been seen previously. Labs were unremarkable and infectious causes of encephalopathy were unrevealing other than a UA suggestive of UTI for which she was treated without improvement. EEG had generalized slowing with no seizure activity. Brain MRI revealed multiple white matter lesions consistent with demyelination. CSF fluid was normal. Given her imaging suggestive of demyelination, her clinical course of a hypoxic event with initial mental improvement followed by decompensation, exam findings, and otherwise negative work-up, the patient was diagnosed with DPHL. She slowly improved throughout her admission and became more alert, less confused and three months later she was independent on her ADLs with minimal neurologic deficits.

IMPACT/DISCUSSION: DPHL is a rare diagnosis that requires both clinical suspicion, specific imaging findings, and appropriate exclusion of other plausible diagnoses (1). The illness script includes a hypoxic insult to the brain followed by a lucid period with subsequent worsening of mentation. Lucid period reported at 2-40 days following recovery from initial hypoxic event (1). Subsequent clinical features include mutism, parkinsonism, bizarre behavior, frontal release signs, pathologic laughing, and hyperlexia. Radiographical findings include demyelination of the cerebral white matter. MRI is the best modality to visualize demyelination of white matter in the brain thought to be specific for DPHL (1). After a thorough work up, our team was without a diagnosis that could explain

the patient's deficits. As we searched we learned about DPHL as a post-hypoxic syndrome. We realized that the timing of her symptoms as well as clinical symptoms, EEG findings, and imaging findings matched the diagnosis. We watched as she recovered over time with supportive care. We hope this case helps recognize this rare entity as a potential diagnosis following hypoxic brain injury. Retrospectively detecting an initial recovery followed by a sudden deterioration in neurologic status will help move DPHL on clinician's differential.

CONCLUSION: Consider DPHL in patients with hypoxic brain injury followed by initial recovery and then delayed neurologic deficits.

IT IS NOT COMMON COLD, IT IS AN UNCOMMON COLD IN AN ARIZONAN

Alvaro J. Altamirano; Roshanak Habibi. Banner university medical center, Tucson, AZ. (Control ID #3179495)

LEARNING OBJECTIVE #1: To recognize an uncommon cause of pericardial effusion in a patient who failed outpatient treatment of upper respiratory tract infection.

CASE: 28 year-old male with no past medical history presented to emergency department in Tucson, Arizona with productive cough and progressive shortness of breath of one month. He was treated in urgent cares for upper respiratory tract infection with courses of levofloxacin, doxycycline, azithromycin, prednisone, fluticasone and ventolin; which did not improve his symptoms. Associated symptoms were nausea, fever, chills and night sweats. He was a nonsmoker, with no recent travel history, no sick contact and no tuberculosis (TB) exposure. He was from Korean descent, raised in Tucson. Social and family history were unremarkable. Abnormal laboratory data were white blood cell of 16, erythrocyte sedimentation rate of 52, C-reactive protein of 78 and a positive serology for coccidioidomycosis (positive enzyme immunoassay for immunoglobulin M and G antibody with reflex confirmation). Coccidioides complement fixation titer was 1:32. Sputum culture, QuantiFERON TB gold, respiratory viral panel and human immunodeficiency virus testing were all negative. His chest x ray and commuted tomographic scan of chest and abdomen showed bilateral pulmonary infiltrates, hepatosplenomegaly, generalized lymphadenopathy and a moderate pericardial effusion. Echocardiogram also confirmed pericardial effusion with no signs of tamponade. EKG was normal. He was rehydrated and started on Fluconazole 400 milligram daily and 5 day course of Colchicine. He did not require pericardiocentesis or tissue biopsy, since the diagnosis seemed straight forward. His symptoms gradually resolved in course of few weeks and in Valley fever clinic follow up in Tucson his antifungal treatment continued for total of 6months.

IMPACT/DISCUSSION: Coccidioidomycosis, an infection with fungi Coccidioides immitis and C. posadasii, endemic of southwestern US is a rare disease, usually presented as community acquired pneumonia. Extrapulmonary manifestations are reported less than 1% in different studies. Pericardial involvement is unique presentation with less than thirty cases reported in literature. Presenting symptoms are usually non-specific and resemble upper respiratory illness and pneumonia. Male sex and ethnicities such as Asians are more likely to develop disseminated disease. Any organ can be involved, with skin, lymph nodes, bones, and central nervous system being the most common extrapulmonary sites. Complement fixation titer ranges from 1:2 to >1:32 in disseminated disease. Amphotericin B and fluconazole are treatment options. Misdiagnosis may lead to continued morbidity and in our case disseminated disease with potentially fatal cardiac involvement.

CONCLUSION: Pericardial effusion in our case could be life threatening if eventual Coccidioides screening was not sent. Pattern recognition of this infection in endemic areas should prompt an internist to send diagnostic studies early.

IT IS WHAT IT IS (UNTIL IT ISN'T): POLYMYALGIA RHEUMATICA AS A SUBSET OF GIANT CELL ARTERITIS

Mahmuda Khan¹; Sara Abrahams⁴; Diane Horowitz³; Eun Ji Kim²; Nancy A. LaVine¹. ¹Northwell Health, New Hyde Park, NY; ²Northwell Hofstra School of Medicine, Lake Success, NY; ³Northwell Health, Manhasset, NY; ⁴Zucker School of Medicine at Hofstra/Northwell, Hempstead, NY. (Control ID #3170068)

LEARNING OBJECTIVE #1: Review diagnostic criteria for polymyalgia rheumatica (PMR) and giant cell arteritis (GCA).

LEARNING OBJECTIVE #2: Assess for GCA in patients with PMR refractory to initial treatment.

CASE: 82 y/o man with coronary artery disease presented with abrupt right shoulder pain for 3 days. Abduction precipitated the pain, but it was improving. He returned 10 days later c/o of bilateral leg/shoulder pain, leg weakness, and fatigue. His ambulation was limited; he could not climb stairs. He denied fever, small joint pain, headache, jaw pain or visual changes. Exam noted pain with shoulder abduction >90 degrees and hip flexion, and upper/lower proximal muscle weakness. Being suspicious of polymyalgia rheumatica (PMR), ESR was obtained and was elevated at 49 (normal <20), ANA and anti CCP were negative. A diagnosis of PMR was made and prednisone 10mg/day was started. His pain improved slightly, but symptoms continued even with 20mg. Despite absence of headaches/visual symptoms, the lack of improvement raised the concern for giant cell arteritis (GCA). Transcranial Doppler revealed concentric wall thickening of the right temporal artery, confirming a diagnosis of GCA. Prednisone was increased to 30mg daily with complete resolution of symptoms.

IMPACT/DISCUSSION: PMR is an inflammatory condition commonly diagnosed in older patients with proximal body aches, morning stiffness, and elevated ESR, which rapidly responds to low dose glucocorticoids (10-20 mg prednisone/daily). GCA, another inflammatory condition of older adults, is associated with headaches, vision changes, jaw pain and elevated ESR, requiring higher dose prednisone (40-60mg/day) with a goal of preventing vision loss. 40-60% of GCA patients can have PMR like symptoms, and GCA should be suspected in patients with PMR who have an inadequate response to initial therapy. The gold standard for GCA diagnosis is temporal artery biopsy, thought with a significant false negative rate. Doppler US of the artery is an increasingly recognized noninvasive diagnostic tool; the "halo sign" (a hypoechoogenic area of edema) is highly specific (80-97%) for GCA. Although our patient lacked GCA symptoms (headaches, blurry vision, scalp tenderness, jaw pain), the lack of clinical improvement with appropriate steroids prompted further evaluation and diagnosis of GCA with treatment and clinical response.

CONCLUSION: This case is an important example of an atypical presentation of GCA, a "do not miss" diagnosis. The typical clinical picture of GCA includes headache, visual changes, or jaw pain, in addition to elevated inflammatory markers. Our patient presented with achiness, fatigue, and elevated ESR. Take Home Points: PMR can be the first presentation of GCA, which should be suspected in patients who do not respond to low-dose glucocorticoids. Doppler US showing concentric wall thickening of the temporal arteries ("halo sign") should be considered as an alternative diagnostic test to the gold standard of temporal artery biopsy for suspected subclinical GCA in patients with PMR.

IT'S HAMMER TIME

Ashley Kang; Chaya Abelow. Montefiore Medical Center, Bronx, NY. (Control ID #3181268)

LEARNING OBJECTIVE #1: Recognize signs and symptoms of hypothernar hammer syndrome

CASE: A 55-year old male smoker presented with left hand pain and dusky finger discoloration for one month. On exam he had distal dry gangrene of the left fourth and fifth digits with an absent ulnar pulse. Labs

included ESR 42, CRP 6.6, normal complement levels, negative cryoglobulins, negative anti-phospholipid screen, normal urinalysis, and negative blood cultures. Echocardiogram showed no vegetations or thrombi. Upper extremity duplex revealed no flow in the distal ulnar artery. Angiogram showed distal ulnar occlusion, poor palmar arch filling, but with flow to all five digits. Upon further review of his occupational history, the patient stated that he is a construction worker and often uses drilling machinery. He was diagnosed with hypothenar hammer syndrome. He was initially treated with nifedipine and clopidogrel, but ultimately underwent amputation and botox injection.

IMPACT/DISCUSSION: Hypothenar hammer syndrome is a rare clinical entity that results from repeated trauma to the ulnar artery. It is typically described in middle-aged men whose occupation involves repetitive use of the hand. Metal workers, carpenters, auto mechanics, and construction workers are some examples of those at increased risk. The ulnar artery branches off to the deep and superficial palmar arch at Guyon's canal. The superficial branch is the main blood supply for most fingers and crosses over the hypothenar muscles before penetrating the palmar aponeurosis. At this segment it is very susceptible to injury. Repetitive trauma can cause intimal damage and induce vasospasms, encouraging platelet aggregation and thrombus formation. Aneurysm may also form with damage to the arterial wall, limiting blood flow to the hand. Clinical presentation varies depending on the severity of damage. Patients may complain of a palpable mass, vasospasm, paresthesias, hypothenar pain, or coolness and discoloration of the fingertips. Generally, symptoms are unilateral and the thumb is spared. Severe disease presents as gangrene or eschar formation at the fingertips. Similar symptoms may be seen in Raynaud's disease, thromboangiitis obliterans, and connective tissue disorders, however, these patients typically have bilateral upper extremity involvement. Initial workup includes a thorough physical exam and Doppler ultrasound, but the gold standard test for diagnosis is angiography. Treatment may include lifestyle modifications, calcium channel blockers, antiplatelet agents, and Botox injection. Severe cases warrant vascular surgery.

CONCLUSION: Hand pain is a very common complaint in the outpatient population. Usually the underlying origin is musculoskeletal, but vascular injury should remain on the differential. A detailed review of occupational history and thorough physical examination are crucial. Physicians should be prudent to consider hypothenar hammer syndrome especially in patients that report occupational or recreational trauma to the hypothenar region.

IT'S NOT A TUMOR! A CASE OF NECROTIZING SARCOID GRANULOMATOSIS

Zachary G. Jacobs; James Clements. Oregon Health & Science University, Portland, OR. (Control ID #3171776)

LEARNING OBJECTIVE #1: Recognize the clinical features of necrotizing sarcoid granulomatosis

LEARNING OBJECTIVE #2: Describe the differential diagnosis for pulmonary granulomatous diseases

CASE: A 71-year-old female retired veterinarian with a history of seasonal allergies presented to the hospital with 5 weeks of worsening dyspnea on exertion, which now confined her to a recliner. She also reported a dry cough, orthopnea, anorexia, and a 40-lb weight loss over 3 months. She lived on a farm with numerous animals and vacationed in Mexico every year. She required 3L oxygen at rest, and her O₂ saturation fell to 74% with minimal activity. On lung exam she had diminished breath sounds and inspiratory crackles at the bilateral bases. Initial labs were notable only for mild anemia, hyponatremia, and low albumin. Chest CT revealed innumerable ill-defined pulmonary nodules diffusely as well as irregular intralobular septal thickening, bilateral pleural effusions, and mediastinal lymphadenopathy, which was thought to be consistent with lymphatic spread of tumor. Thoracentesis revealed an

exudative effusion with negative culture and cytology. A bronchoscopy with endo- and trans-bronchial biopsies showed non-caseating granulomas with negative cultures (including acid-fast bacilli) and cytology. Additional laboratory testing included interferon-gamma release assay, anti-nuclear antibody, anti-neutrophil cytoplasmic antibody, and serologic studies for multiple fungal organisms, all of which were negative. A video-assisted thoracoscopic surgery (VATS) with wedge biopsy was performed, which revealed sarcoid-like granulomas with focal central necrosis and accompanying granulomatous inflammation involving pulmonary vasculature and lymphatics. The patient was diagnosed with necrotizing sarcoid granulomatosis (NSG). She was treated with high-dose corticosteroids with marked symptomatic and radiographic improvement in less than one month.

IMPACT/DISCUSSION: NSG is a rare and poorly understood form of pulmonary granulomatous disease that was first described in 1973. Approximately 130 cases have been reported. It may present with fever, cough, dyspnea, chest pain, and weight loss, though patients are asymptomatic in as many as 25% of cases. Based on its tumor-like appearance, NSG is often mistaken for malignancy. Diagnoses such as sarcoidosis, granulomatosis with polyangiitis (GPA), tuberculosis (TB), and fungal infections are also on the differential, among others. NSG is characterized on histopathology by sarcoid-like granulomas, vasculitis, and a variable degree of necrosis. While no consensus guidelines for treatment exist, corticosteroids, lung resection, and watchful waiting have been employed. Prognosis is typically good.

CONCLUSION: 1. NSG is a rare disease characterized by sarcoid-like granulomas, vasculitis, and necrosis. 2. It presents with diffuse lung nodularity and is often mistaken for malignancy. 3. The differential diagnosis includes sarcoidosis, GPA, TB, and fungal infections.

IT'S NOT ALWAYS CANCER: ISCHEMIC COLITIS MASQUERADE AS COLONIC MASS

SeQuoya Killebrew¹; Michele D. Lewis²; Jonathan Lam¹; Neema Patel¹; Nancy Dawson¹. ¹Mayo Clinic, Jacksonville, FL; ²Mayo Clinic Florida, Jacksonville, FL. (Control ID #3167686)

LEARNING OBJECTIVE #1: Recognize risk factors associated with ischemic colitis.

CASE: A 72-year-old gentleman with past medical history significant for end-stage renal disease on intermittent hemodialysis, heart failure with reduced ejection fraction of 30-35%, atrial fibrillation, and hypotension presented with one day of new lower abdominal pain. The day prior to onset of symptoms he had an episode of hypotension during dialysis. He reported a history of recurrent hypotension resulting in chronic use of midodrine. The patient stated the abdominal pain awoke him from his sleep, describing it as a severe pressure-like sensation. He had a history of chronic constipation, otherwise denied any episodes of nausea, vomiting, diarrhea, melena, or hematochezia. The patient had no history of nonsteroidal anti-inflammatory drug (NSAID) use. His last colonoscopy and EGD approximately 3 years ago reported normal. On admission, labs significant for hemoglobin 12.9, white blood cell count 13.9, platelets 126, and lactate 1.9. CT abdomen and pelvis without contrast revealed uncomplicated cecal colitis without evidence of obstruction and normal mesenteric vasculature. The patient was empirically started on antibiotics and placed on bowel rest. However, despite conservative management the patient's symptoms persisted and repeat CT abdomen and pelvis with contrast 3 days later revealed an eccentric, irregular cecal wall thickening concerning for malignancy with surrounding inflammatory stranding and edema. Subsequently the patient underwent colonoscopy the next day revealing an ulcerated partially obstructing large cecal mass that involved the entire cecum and the wall across from the ileocecal valve. Biopsies were collected during colonoscopy and colorectal surgery was consulted thereafter for presumed malignancy. However, there was no evidence of malignancy on histopathology. Repeat colonoscopy was completed for

confirmation of the diagnosis, but final pathology revealed no evidence of malignancy. Ultimately, the patient continued to have severe right lower quadrant abdominal pain and underwent robotic ileocolic resection. Surgical pathology confirmed ischemic colitis.

IMPACT/DISCUSSION: This case represents a unique presentation of ischemic colitis presenting as a large colonic mass. Colonic ischemia may have a variable presentation ranging from mild to severe lower abdominal pain with or without hematochezia. Risk factors include elderly age, recent cardiovascular procedure, myocardial infarction, hemodialysis, hypercoagulable state, and medications. High suspicion and prompt diagnosis with appropriate imaging is crucial. Evaluation with colonoscopy can be a vital tool in confirming the diagnosis and determining ultimate therapy.

CONCLUSION: Ischemic colitis is the result of decrease blood flow to the colon that can be acute or chronic in onset and can have a nonspecific presentation. Providers should have high suspicion for the diagnosis when patients present with increased risk factors.

IT'S NOT JUST A TEST QUESTION: VIBRIO VULNIFICUS NECROTIZING MYOFASCIITES

Debapria Das; Andrea Ramirez Gomez; Rachna Rawal. Saint Louis University, St. Louis, MO. (Control ID #3185996)

LEARNING OBJECTIVE #1: Recognize the clinical features of primary bacteremia due to *Vibrio vulnificus*.

CASE: A 51-year-old male with a past medical history of cirrhosis due to sarcoidosis, was admitted with worsening left lower extremity pain and swelling for two days. He remembered a pop in his left leg two days ago followed by severe left lower extremity pain the morning after. Additionally, he was unable to bear weight. On arrival, he was hemodynamically unstable requiring pressor support and broad spectrum antibiotics. His physical exam was notable for an obese male with swelling, tenderness to palpation, and crepitus in the left lower extremity. His abdomen was distended and he was not altered. His labs were remarkable for a leukocytosis of 35.7, lactic acidosis 8.48, and Cr 1.98 (baseline 1). A CT of his left lower extremity revealed nonspecific soft tissue edema without subcutaneous emphysema or fluid collection. Blood cultures were positive for *Vibrio vulnificus*. The patient had consumed oysters for dinner 10 days ago. He was started on piperacillin and doxycycline but continued to clinically decline. He required multiple debridements and ultimately due to severe myonecrosis needed an above-knee-amputation. He clinically improved after the amputation and his antibiotics were narrowed to minocycline and doxycycline. His hospital course was complicated by kidney failure due to acute tubular necrosis. He did not have complete renal recovery by time of discharge and required dialysis.

IMPACT/DISCUSSION: This case is an example of the presentation of primary *V. vulnificus* bacteremia complicated by necrotizing myofasciites associated with the consumption of oysters in cirrhotic patients. Over 90% of patients with primary septicemia report a recent history of consuming raw oysters, which have increased concentrations of *V. vulnificus*, especially in warm temperatures or with drops in salinity. When compared to other foodborne illnesses in the United States, *V. vulnificus* has the highest fatality at 51.6% of cases. 86% of diagnosed cases are male. Interestingly, 75% of infected patients present with bulbous lesions, which this patient did not have. However, *V. vulnificus* acutely leads to shock in one-third of patients with primary septicemia with mortality up to 90%, requiring urgent diagnosis. Patients with MELD scores greater than 20 are associated with higher mortality compared to other cirrhotic patients. Although yearly reported cases are around 100, the CDC reports a 78% increase in incidence since 1992, which may be due to an increasing vulnerable population and climate change.

CONCLUSION: Cirrhotic patients are well-known to suffer from unique medical complications. Additionally, one that is readily well-known but may not be as recognized due to a low prevalence is a severe infection from *Vibrio vulnificus*. We need to be cognizant of exposure in this

population as prompt diagnosis could potentially be life-saving. Early diagnosis is crucial due to high risk of amputations and multiorgan failure.

ITS ALL ON YOUR HEAD

Alan J. Spanel; Michael P. Smith. University of Nebraska Medical Center, Omaha, NE. (Control ID #3186139)

LEARNING OBJECTIVE #1: Recognize the importance of source control in MRSA blood stream infections

LEARNING OBJECTIVE #2: Review the treatment options when MRSA bacteremia fails to clear

CASE: A 38-year-old woman presented with a 3-day history of fevers and severe retro-orbital pain with diplopia. She was febrile to 104, had left eye proptosis, severe periorbital edema, and inability to abduct the left eye. Multiple dry, non-purulent frontal scalp lesions without associated fluctuance were noted. The patient's medical history was significant for Sjogren's syndrome and autoimmune sensory ganglionopathy on chronic immunosuppression. She had recently received a scalp steroid injection for alopecia. Orbital MRI revealed bilateral cavernous sinus thrombosis. Her initial blood cultures were positive for MRSA and she was initiated on IV vancomycin. She became hemodynamically unstable despite sensitivity of her infection to vancomycin. Her antibiotic therapy was transitioned to IV daptomycin, again without clinical improvement and persistent bacteremia. She then became tachypneic with increased oxygen requirement and was found to have bilateral septic pulmonary emboli and pleural effusions. Linezolid was added. She then experienced worsening of her cranial nerve palsy and right arm weakness. A repeat orbital MRI demonstrated multiple acute infarcts of the cerebral hemispheres and internal capsule consistent with septic embolic stroke. Her treatment was broadened to three anti-staphylococcal drugs: IV daptomycin and ceftazidime with high dose oral Bactrim DS. Her bacteremia and daily fevers persisted. A PET CT scan was performed, demonstrating multiple scalp abscesses that were subsequently drained, leading to her bacteremia finally clearing. She was continued on a prolonged course of IV daptomycin and ceftazidime.

IMPACT/DISCUSSION: MRSA bloodstream infections often may take days or even weeks to resolve. In the setting of persistently positive blood cultures, antimicrobials are often adjusted based on susceptibility data to better target therapy. In this case, even multiple anti-staphylococcal agents were utilized. There are limited randomized controlled trial data regarding treatment of persistent MRSA bacteremia. Multiple case series and reports support the use of various regimens. A preferred regimen has not yet been identified. Regardless of the agents selected, the importance of source control cannot be overstated. This patient's blood cultures finally cleared only when her benign-appearing scalp lesions were drained surgically. A meticulous search for a persistent focus of infection can sometimes be the only solution.

CONCLUSION: MRSA infection is commonly seen by the general internist and its complications are numerous. Severe MRSA infections unresponsive to initial antimicrobial therapy carry a significant morbidity and mortality and treatment plans can be difficult to formulate.

JAK2 V617F MUTATION: UNUSUAL CAUSE OF ACUTE PORTAL VEIN THROMBOSIS.

Hasan Mahbub; Nikita Fernandes; Yelena Averbukh. Montefiore Medical Center, Bronx, NY. (Control ID #3186253)

LEARNING OBJECTIVE #1: Learn manifestations and management of Portal Vein Thrombosis (PVT)

LEARNING OBJECTIVE #2: Identify risk factors associated with PVT.

CASE: A 29-year-old man admitted for abdominal pain for 7 days, severe generalized pain radiating to the back associated with vomiting and constipation alternating with diarrhea. Past medical history significant

for Portal vein thrombosis (PVT) and superior mesenteric vein thrombosis, JAK2 V617F mutation and Protein S deficiency. Physical examination remarkable for tenderness over right and left lumbar regions. Lab tests revealed Hemoglobin 15.7 g/dL, WBC 11.9 k/ μ L, Platelet 402 k/ μ L, Lactic acid 3.4 mmol/L, Coagulation studies within normal limits. Computed tomography (CT) of abdomen revealed portal venous thrombosis, diffusely thickened colon and mild splenomegaly. Anticoagulation therapy was initiated with enoxaparin. Patient showed clinical improvement. Outpatient follow up with Hematology and Hepatology was arranged.

IMPACT/DISCUSSION: Prevalence of PVT is estimated to be 1% with 0.6%-16% occurring in asymptomatic liver disease and 35% in the setting of cirrhosis with hepatocellular carcinoma. PVT can present acutely with symptoms of acute abdominal pain, fever, ascites, or splenomegaly, while chronic PVT can be asymptomatic. Laboratory studies for evaluating PVT include liver function testing, CBC for erythrocytosis and testing for prothrombotic risk factors. Ultrasound is recommended as first-line imaging with an accuracy of 88%-98% and a specificity of 60%-100%. CT and MRI additionally provide advantages of better visualization of anatomy and extension of occlusion, visualizing bowel ischemia, presence of malignancy, or cirrhosis. Treatment of PVT is directed towards reducing the advancement of thrombosis and preventing development of portal hypertension or intestinal infarction. Restoring portal venous flow in both partial and complete occlusion is achieved with anticoagulation (AC) in patients with prothrombotic states without contraindications to therapy. Because recanalization occurs between 4 to 6 months, it is recommended that anticoagulation be continued for at least 6 months, regardless of initial response to AC therapy. Choice of AC is low molecular weight heparin followed by long-term use of vitamin K antagonists with targeted INR of 2-3. Treatment beyond 6 months is dependent on patients with high recurrence risk. Endovascular interventions to restore portal flow have been utilized in patients that fail conservative management or demonstrate signs of bowel ischemia. Follow-up imaging is recommended every 6 months with ultrasound or contrast enhanced CT or magnetic resonance imaging (MRI).

CONCLUSION: • PVT should be considered as one of the differential diagnosis of abdominal pain in patients with risk factors like JAK2 mutations for developing a prothrombotic state. • If AC is not initiated, PVT can potentially lead to fatal complications like bowel ischemia.

JUXTAPAPILLARY DUODENAL DIVERTICULITIS MASQUERADE AS A COMMON BILE DUCT MASS

Leonard Walsh¹; Andrew Groff²; Abraham Mathew³; Manpreet Singh¹; Rohit Jain¹. ¹Hershey Medical Center, Hershey, PA; ²Penn State Hershey College of Medicine, Hershey, PA; ³Penn State Hershey Medical Center, Hershey, PA. (Control ID #3184595)

LEARNING OBJECTIVE #1: Recognize duodenal diverticulitis as a differential diagnosis in patients presenting with abdominal pain, nausea, and vomiting who meet SIRS criteria and have indeterminate cross-sectional imaging since delayed treatment can lead to severe complications.

LEARNING OBJECTIVE #2: Recognize that duodenal diverticulitis in the absence of a leak should be treated with broad-spectrum antibiotics and endoscopic therapy in appropriately selected patients.

CASE: An 82-year-old Caucasian female with a past medical history of hypertension and coronary artery disease presented to the ED with a seven-day history of nausea, intermittent vomiting, and abdominal pain. She denied fevers, chills, or change in bowel habits. Vitals were significant for mild tachycardia and tachypnea. Physical exam revealed mild diffuse abdominal pain with normoactive bowel sounds and no rebound tenderness or guarding. Labs were notable for a mild leukocytosis of 12.0 WBC/ μ L. Computed tomography (CT) scan of the abdomen showed a thickened common bile duct (CBD) and 2.2 cm foci of gas in the distal CBD region that was concerning for a mass or abscess. The patient was

started on IV levofloxacin and metronidazole. Gastroenterology performed an endoscopic ultrasound (EUS) and upper endoscopy, which showed a non-bleeding juxtapapillary duodenal diverticulum with purulent discharge and normal EUS findings. Disimpaction with an extraction balloon was performed followed by irrigation with normal saline. After endoscopy, the patient was transitioned to oral ciprofloxacin and metronidazole to complete a fourteen-day course of antibiotics. The patient was seen for follow-up 4 weeks after hospital discharge and was doing well with complete resolution of symptoms. Follow up abdominal CT showed an interval decrease in the size of the duodenal diverticulum with no inflammatory changes.

IMPACT/DISCUSSION: Duodenal diverticulae are relatively common incidental findings in adult patients between the ages of 50-70 however rarely become symptomatic. The associated complications such as infection and free perforation have the potential to be severe and thus early management is important. Diagnosis of diverticulitis based on presentation and imaging alone is often unclear since symptoms can be nonspecific and cross-sectional imaging can mimic other disease processes such as biliary or pancreatic pathologies. In such cases that are equivocal or fail conservative management, an upper endoscopic approach in the absence of free perforation is indicated for diagnosis and allows for therapies including debridement, irrigation with normal saline, and stent placement in select cases.

CONCLUSION: Duodenal diverticulitis is a rare complication of juxtapapillary diverticulae however it is important to promptly recognize and treat due to the risk of developing complications including a free perforation. Oftentimes diagnosis cannot be made by clinical presentation and cross-sectional imaging alone, and in such cases, upper endoscopy is indicated for diagnosis and treatment.

KEEP AN EYE ON YOUR BONES

Mahmuda Khan¹; Eileen Kim¹; Robin Koshy². ¹Northwell Health, New Hyde Park, NY; ²Northwell Health, Manhasset, NY. (Control ID #3180211)

LEARNING OBJECTIVE #1: Recognize ocular adverse effects of bisphosphonate use

LEARNING OBJECTIVE #2: Manage bisphosphonate induced ocular disease with steroids

CASE: This is a 64 year-old woman with a past medical history of asthma, chronic urticaria, osteoporosis on risedronic acid who presented with acute right eye pain worsened with extraocular movements. Associated symptoms included fevers. On physical exam, she had right periorbital edema with erythema, episcleral injection with chemosis but no proptosis or resistance to retropulsion. She had leukocytosis (14.9), thrombocytosis (572k), and elevated CRP (1.9). Infectious and rheumatologic workup was negative. CT Maxillofacial revealed minimal preseptal soft tissue swelling with thickening of the conjunctiva, consistent with acute right conjunctivitis. MR of Head and Orbit showed no evidence for venous sinus or cortical vein thrombosis. She was started on ampicillin/sulbactam and linezolid without much improvement, which prompted concerns for bisphosphonate induced orbital inflammation. Only after the initiation of prednisone, she reported a significant improvement in the symptoms as well as objective examination findings of improving periorbital swelling, episcleral injection, and chemosis. Patient was discharged on a prednisone taper.

IMPACT/DISCUSSION: It is important to note that the differential diagnosis of patient's presenting with fevers and orbital erythema and swelling is not limited to infectious sources. Other etiologies include vascular, trauma, autoimmune, metabolic, neoplastic, and most importantly, medication induced inflammatory response. This case has taught me to have a higher level of suspicion for medication, specifically, bisphosphonate induced ocular manifestations. Common reactions to bisphosphonates include conjunctivitis, uveitis, episcleritis, scleritis, and keratitis. The mechanism of bisphosphonate-induced inflammatory events

is unknown; however, alendronate and risedronate are nitrogen based aminobisphosphonates, which play a role in tumor necrosis factor and cytokine release. Increase in inflammatory mediators may increase risk of inflammatory disorders such as acute conjunctivitis. A retrospective cohort study showed patients who use oral bisphosphonates for the first time may be at higher risk of scleritis and uveitis compared to patients with no bisphosphonate use. Treatment includes discontinuation of bisphosphonates, depending on severity of ocular symptoms. A case report presented a patient whose diffuse conjunctival erythema did not respond to common first line topical agents- erythromycin, tobramycin, and dexamethasone. Severe cases with uveitis, scleritis, or global inflammation require systemic steroids and steroid eye drops, such as in our patient.

CONCLUSION: This case highlights the importance of accurate medication reconciliation both inpatient and outpatient settings. Internal physicians need to be aware of the potential ocular side effects of bisphosphonates. Treatment in severe cases include topical and systemic steroids.

KEEP YOUR EYE ON THROMBI IN RENAL CELL CARCINOMA PATIENTS

Kanishka G. Patel; David Yin; Sheira Schlair. Albert Einstein College of Medicine/Montefiore Medical Center, Bronx, NY. (Control ID #3184717)

LEARNING OBJECTIVE #1: Outline the differential diagnosis of an intracardiac mass in renal cell carcinoma

LEARNING OBJECTIVE #2: Discuss differentiation and management of bland versus tumor thrombi

CASE: A 66 year old man with stage IV renal cell carcinoma (RCC), a non-occlusive IVC tumor thrombus and end-stage renal disease on hemodialysis via a right internal jugular permacath was admitted with a 5-day history of fever and weakness. He had a temperature of 99.3, a WBC count of 17.2 and was found to have Klebsiella bacteremia. Physical exam revealed a new systolic murmur, which prompted echocardiogram, showing a large, mobile, multi-lobed structure in the right atrium likely attached to the permacath, suggestive of thrombus (could not rule out vegetation). Antibiotics and heparin were started. CT showed a chronic IVC tumor thrombus that did not extend into the SVC or right atrium, suggesting the right atrial mass was not tumor thrombus. Permocath was removed and to definitively rule out embolization of the right atrial thrombus, CTPE was performed, revealing a right lower lobe pulmonary embolism and warfarin was initiated.

IMPACT/DISCUSSION: RCC is a highly vascular tumor that can invade through the renal vein and into the IVC, with 10-15% of cases resulting in tumor thrombus formation. Less commonly (1%), the tumor may extend into the right cardiac chamber. Accurate differentiation of bland from tumor thrombus is crucial for proper management. While both bland and tumor thrombi present as vessel filling defects, a malignant thrombus has continuity with the primary tumor, enhancement and vessel expansion on CT or MRI. Because a bland thrombus results from IVC compression by a renal mass, it presents as vessel narrowing on imaging. While nephrectomy and thrombectomy treat tumor thrombi, anticoagulation is used for bland thrombi. Though tumor thrombus dislodgement is a known complication of thrombectomy, the development of tumor emboli outside the lung in the absence of such manipulation is unclear. The differential diagnosis of an intracardiac mass in a septic RCC patient can span different etiologies including infectious (vegetation), malignant (primary tumor, metastases, tumor thrombus) and hematologic (bland thrombus). As imaging was strongly suggestive of a thrombus, several key details pointed to bland over tumor thrombus. Risk factors for thrombosis, including a hypercoagulable state due to malignancy as well as foreign body effect from the IVC tumor thrombus and permacath, and attachment of the mass to the permacath raised our suspicion for a bland thrombus. Moreover, lack of IVC thrombus extension into the SVC and right atrium suggested the mass was more likely bland thrombus. Thus, anticoagulation and antibiotics were given empirically.

CONCLUSION: This case demonstrates the importance of reviewing all clinical data when narrowing the differential diagnosis for an intracardiac mass. Moreover, identification of thrombi in RCC patients warrants subsequent differentiation of bland from tumor thrombus for effective management.

KIKUCHI FUJIMOTO DISEASE: A RARE BUT IMPORTANT CAUSE OF LYMPHADENOPATHY

Melanie Parikh¹; Christina Thoonkuzhy². ¹Case Western Reserve University, Cleveland, OH; ²University Hospitals Cleveland Medical Center, Cleveland, OH. (Control ID #3184869)

LEARNING OBJECTIVE #1: Recognize the clinical features of Kikuchi Fujimoto Disease (KFD)

LEARNING OBJECTIVE #2: Distinguish KFD from other causes of lymphadenopathy

CASE: A 30-year-old African American female with past medical history of asthma and Epstein-Barr virus, presented to the ED with an acutely worsened headache with associated fevers and chills, which were no longer responding to OTC ibuprofen. The patient reported a two-month history of chills, nausea, diffuse muscle pain, neck pain, throbbing headache, and morning joint stiffness, which would last for more than an hour. She had visited multiple emergency departments, but no definitive diagnosis had been made. Physical exam on admission was significant for tender posterior chain, preauricular, and anterior cervical chain lymphadenopathy, especially on the right side of the neck, severe headache and fevers reaching a Tmax of 104. Previous autoimmune workup showed positive ANA with a titer of 1:320, but all other specific autoimmune markers, including complement, ACE and ANCA were negative. Lumbar puncture did not show evidence of an infectious process, CT head and MRI brain were normal. A MRV was done to rule out cerebral thromboembolism, but evidence of benign intracranial HTN was seen. Patient was started on topiramate, with clinical improvement. Excisional biopsy was conducted which showed an infiltrate composed of immunoblasts, crescentic histiocytes and abundant apoptotic or karyohectic debris, thus making the diagnosis of Kikuchi-Fujimoto Disease.

IMPACT/DISCUSSION: Kikuchi-Fujimoto disease (KFD), or histiocytic necrotizing lymphadenitis, is a benign and self-limited disease that mainly affects young women, especially those of East Asian heritage. Patients typically present with localized lymphadenopathy, fever, and leukopenia in about 50% of cases. Although KFD is not very common, it should be included in the differential diagnosis of lymphadenopathy because its natural history and treatment differ dramatically from those of lymphoma, tuberculosis, and systemic lupus erythematosus (SLE). The lymphadenopathy in KFD usually resolves spontaneously in 1-4 months without any treatment. The distinguishing factor is karyohectic debris on lymph node biopsy or aspiration. Without appropriate histologic diagnosis, a patient with KFD may undergo unnecessary testing and treatment for malignant lymphoma or tuberculosis. Once the diagnosis is made, it is important to maintain close follow-up with these patients to monitor for the development of SLE. KFD is known to occur in conjunction with SLE and some experts say that KFD can be an unusual presentation of SLE.

CONCLUSION: KFD should be considered in young patients presenting with unilateral cervical lymphadenopathy. Excisional biopsy is the key to diagnosis in these cases. Patients should be managed conservatively with close follow-up.

KRATOM: A SO-CALLED LEGAL OPIOID

David R. Henkin; Brendan Sullivan; Joshua S. Smith. Henry Ford Hospital, Detroit, MI. (Control ID #3162271)

LEARNING OBJECTIVE #1: Familiarize the reader of the substance called kratom

LEARNING OBJECTIVE #2: Assessment and management of intoxication, withdrawal and detoxification of kratom. Recognize the legality and regulation of kratom in the U.S.

CASE: We present a case of a 25 year old male who presented to an inpatient rehabilitation and detoxification center requesting help for an addiction to kratom. He disclosed a history of IV heroin use 2 years earlier, which he stated he was able to wean himself from using kratom. He endorsed ingesting kratom powder up to 40 grams twice daily for the last 2 years. The patient recognized his tolerance and ultimately his addiction, but attempting to quit "cold turkey" caused him to develop symptoms of myalgias, chills, diarrhea, rhinorrhea, arthralgias and fatigue. Given his apparent tolerance and withdrawal symptoms similar to that of a true opioid withdrawal, he was managed with a buprenorphine taper, which adequately allowed him to successfully complete detoxification.

IMPACT/DISCUSSION: The substance called kratom has recently gained more recognition on the streets and in admissions to detoxification centers. Kratom (*Mitragyna speciosa*) is a plant indigenous to Southeast Asia and Thailand. At different concentrations of its leaves, ingestion will produce both stimulant and opioid-like effects, with studies showing its mode of action by binding mu opioid receptors. One online "Kratom User Guide" suggests that 1-5 grams elicit a stimulant effect and higher doses of 5-15 grams cause opioid-like effects. Intoxication at higher doses in long-term users or in acute toxicity has been reported to cause seizures and hepatotoxicity. The CDC has even traced kratom to a multi-state outbreak of salmonella. There is a noticeable increase in the number of articles referencing kratom, as well as an increasing amount of vendors and general information websites for kratom in the past few years which may suggest a greater overall demand.

CONCLUSION: Kratom is an addictive substance whose use has actually been outlawed in many Southeast Asian countries. In the US, kratom is legally regulated as an herbal product under US law, FDA and DEA policies, and is therefore considered a legal substance in the United States. That being said, the Drugs and Chemicals of Concern list states, "There is no legitimate medical use for kratom in the U.S." In 2016, the DEA planned to classify kratom as a schedule I drug; however the DEA received significant challenges from the public and ended up releasing a withdrawal of notice of intent. In the time of writing this, kratom is still not a scheduled drug. As it remains easily accessible in local tobacco shops and online, we must be aware of its existence and use pattern as well as its effects, abuse potential and addictive properties.

LACTIC ACIDOSIS: WHO IS TO BLAME?

Mohamed Gabr; Isaac Leader. Montefiore Medical Center (Wakefield Campus), Bronx, NY. (Control ID #3183342)

LEARNING OBJECTIVE #1: Recognize lactic acidosis as a common finding in inpatient settings

LEARNING OBJECTIVE #2: Identify causes of lactic acidosis and rule out serious etiologies

CASE: A 68 year-old man presenting with chest pain was found incidentally to have lactic acidosis. His past history included diabetes mellitus, ischemic heart disease, chronic hepatitis C, alcohol abuse, and cocaine abuse. His last reported cocaine use was two days prior to presentation and last alcohol use was the morning of presentation. Physical examination was unremarkable except for mild abdominal tenderness. Myocardial infarction was ruled out with negative troponins. Lactic acid level was 13.2 mmol/L (normal <2), with a pH of 7.2 and a sodium bicarbonate level of 15 mmol/L (normal 22-28). Blood glucose level was normal and the anion gap was 36. Liver function tests revealed an AST of 76 U/L (normal <50) and ALT of 50 U/L (normal <40). Urine drug screen was positive for cocaine and blood ethanol level was normal. Computed tomography scan revealed no evidence of bowel ischemia. Review of systems and bloodwork were not suggestive of any infectious processes,

and vital signs were normal except for elevated blood pressure. Home medications were aspirin, atorvastatin, amlodipine, famotidine, and metformin; metformin was held at admission. His symptoms gradually improved and lactic acid levels returned to normal. He was counseled regarding alcohol and cocaine cessation and metformin was discontinued.

IMPACT/DISCUSSION: Lactic acidosis is defined as serum pH of less than 7.35 with a lactate level greater than 4 mmol/L. It is commonly classified into type A acidosis, occurring as a result of tissue hypoxia with overproduction of lactic acid, or type B acidosis due to causes unrelated to hypoxia. Causes of type A acidosis include sepsis, shock, cardiac failure, hypovolemia, and other causes of hypoperfusion. Physical examination, vital signs, and other signs of tissue perfusion such as urine output and mental status may provide hint. Type B acidosis may be present in ethanol intoxication, hepatic dysfunction due to chronic alcoholism, malignancy, mitochondrial dysfunction, or due to medications (e.g. beta agonists, antiretrovirals, linezolid, and propofol). It may also occur in diabetes mellitus, whether in the setting of diabetic ketoacidosis or due to medications such as biguanides. D-lactic acidosis is another rare cause that occurs as a result of fermentation of carbohydrates by gut bacteria in cases of malabsorption or short bowel syndrome. In our patient's case, it appeared that several factors might have contributed to his type B acidosis, including alcohol use, drug use, liver disease, and metformin.

CONCLUSION: Physicians should promptly aim to identify the etiology of lactic acidosis. Type A lactic acidosis may indicate the presence of a more serious process that warrants urgent treatment. After confidently ruling out Type A, Type B acidosis can be considered through a careful review of patients' medical histories, habits, and medications.

LAMBL'S EXCRESENCES MASQUERADE AS ENDOCARDITIS

Navid Berenji¹; Abdulrahman S. Museedi¹; Ermias Sori¹; Omar Sheikh¹; Rushit Kanakia². ¹UT Health San Antonio, San Antonio, TX; ²UTHSCSA, San Antonio, TX. (Control ID #3186025)

LEARNING OBJECTIVE #1: Recognize importance of anticoagulation in Lambl's excrescences

LEARNING OBJECTIVE #2: Assess role of Positron Emission Tomography scans in complex cases of infective endocarditis

CASE: A 58-year-old woman with hypertension and multiple cerebrovascular accidents presented with fever and headache. Patient had recently presented with left upper extremity weakness, headache and blurry vision for which evaluation led to revealing several foci involving bilateral hemispheres on brain MRI. As part of the work up, trans-esophageal echocardiography (TEE) revealed small echodensities on aortic and mitral valves concerning for vegetations in setting of septic emboli. Thorough work up for infectious endocarditis, including blood cultures and serology, as well as autoimmune work up was negative. Diagnosis of culture-negative endocarditis was given and patient was started on broad-spectrum antibiotics with termination of anticoagulation therapy, as she was previously on Apixaban. She continued to have episodic fevers and a new rash, which biopsy revealed to be due to medication reaction secondary to antibiotics. Repeat TEE one month later revealed stabilized sub-centimeter echodensities in aortic and mitral valves, suspecting Lambl's excrescences (LE) over septic or thrombotic emboli. Positron emission tomography (PET) scan was negative on the vegetation and potential metastatic sites to include brain lesions. Patient was started on warfarin.

IMPACT/DISCUSSION: Lambl's excrescences are small filamentous strands, which extend from the margins of the valves, especially mitral and aortic valves. LE, previously thought to be benign due to degenerative process, have been associated with few cases of embolic strokes. Given risks associated with surgery and obtaining a biopsy of these lesions, echocardiography remains a valuable tool in distinguishing LE. LE is a diagnosis of exclusion thus thorough work up is granted for every patient. In our patient, nonbacterial thrombotic endocarditis such as marantic

vegetations and Libman-Sacks endocarditis, antiphospholipid syndrome, and other connective tissue disorders were ruled out. Additionally, PET scan was used in addition to Dukes criteria to exclude distant septic emboli and infective endocarditis. This can be an additional tool in the diagnosis of infective endocarditis in complex cases.

CONCLUSION: Currently, there are no definitive guidelines regarding management of LE. There are different reports of management for LE with anticoagulation therapy, dual antiplatelet therapy, and neither of antiplatelet nor anticoagulation therapy altogether. Given our patient with cerebrovascular events secondary to LE and other reported cases with similar presentations, we recommend anticoagulation with Warfarin due to lack of sufficient data on non-vitamin K antagonist oral anticoagulants. Surgical extraction is typically reserved for patients with recurrent cerebrovascular accidents while on anticoagulation therapy.

LATE COMPLICATIONS AFTER AORTIC ROOT REPLACEMENT IN A PATIENT WITH MARFAN SYNDROME - AN EMERGENT DIAGNOSIS.

VenkataSivaKumar Pajjuru. Creighton University, Omaha, NE. (Control ID #3186451)

LEARNING OBJECTIVE #1: Recognize the complications of aortic root replacement in patients with Marfan syndrome.

LEARNING OBJECTIVE #2: Assess the risk by Careful follow up studies after the surgical procedure to diagnose such complications.

CASE: A 62-year-old female with Marfan syndrome who previously had an aortic root replacement with Bentall valve procedure and the mechanical valve conduit at the age of 34 presented with chest pain. One week before she underwent elective ureteroscopy and bilateral ureteral stent placement for bilateral hydronephrosis. Three days after the procedure she developed chest pain with nausea and diaphoresis. Patient denies fevers, chills, cough; pain is not radiating to back/shoulders. She is not a smoker or drinks alcohol. Her past medical history includes CVA at the age of 38, hyperlipidemia, recurrent nephrolithiasis, UTI's. Family history includes hypertension, type ii dm in mother and father, Marfan syndrome in her son. She is on warfarin for life long anticoagulation for the mechanical aortic valve. Pulses is symmetrical over both extremities, hemoglobin is stable at 8 mg/dl, Initial EKG was negative for ischemic changes, but Troponin was elevated. Echocardiogram showed normal EF and mechanical aortic valve. CTA chest showed leaking pseudoaneurysm with peri-graft hemorrhage involving the ascending aorta, could originate from the right coronary ostium. Anticoagulation was held, increased beta-blocker dose to control heart rate (as the patient developed Atrial Fibrillation with RVR during inpatient) and to decrease shearing stress on the aorta. Cardiothoracic surgery recommended urgent surgical repair of aortic pseudoaneurysm.

IMPACT/DISCUSSION: The Bentall procedure is considered the gold standard in the treatment of patients requiring aortic root replacement. The vast majority of Bentall procedures involve the replacement of the aortic root with a mechanical valve conduit. Pseudoaneurysm formation at the coronary ostia or at the distal aortic suture line is a frequently reported sequela of the Bentall procedure. Pseudoaneurysms of the ascending aorta occur in from 7% to 25% of patients in whom the original inclusion/wrap technique of the Bentall procedure has been applied. The main causes of pseudoaneurysm formation are tension on suture lines, particularly those involving the coronary ostia. These pseudoaneurysms tend to remain small and asymptomatic, although they on occasions enlarge, cause compression of vital neighboring structures, can rupture, as in our patient, mandating urgent surgical intervention.

CONCLUSION: Elective aortic root replacement or repair in patients with Marfan syndrome is of paramount importance in order to prevent aortic dissections. Lifelong imaging of the entire aorta, using MRI or computed tomography, is needed to prevent devastating complications. Timely diagnosis and management of these complications

(Pseudoaneurysm rupture, Aortic dissections, Aorto-atrial fistula) are warranted as they are life-threatening.

LEGAL DRUGS WITH ILL EFFECTS: A CASE OF KRATOM AND PHENIBUT USE

Christine Soran¹; Shin-Yu Lee²; Soraya Azari³. ¹University of California San Francisco, San Francisco, CA; ²San Francisco General Hospital & Trauma Center, San Francisco, CA; ³University of California, San Francisco, San Francisco, CA. (Control ID #3187163)

LEARNING OBJECTIVE #1: Recognize patient perceptions and reasons for use of Kratom and Phenibut

LEARNING OBJECTIVE #2: Utilize familiar medications for treatment of Kratom and Phenibut Use

CASE: The patient is a 30 year old male with a history of anxiety who presented to primary care asking for help stopping Kratom. The patient used 12 grams of powder Kratom 3 times daily for the 5 years for anxiety symptoms. Two years ago, the patient stopped utilizing an internet protocol hydrocodone taper but resumed use 2 weeks later. With cessation he experiences insomnia, restlessness, and nausea. He also reports taking daily Phenibut purchased on the internet for anxiety and low energy. His only prescribed medication was Citalopram. Physical exam was unremarkable and urine drug screen was negative for all illicit substances. The patient started on buprenorphine/naloxone (BNX) for Kratom use with resolution of his withdrawal symptoms. For Phenibut, he declined baclofen treatment. High resolution mass spectrometry on week 2 of treatment showed no active metabolites of Kratom but did show Phenibut. He has completely stopped using Kratom and tapered Phenibut use to 1-2 times weekly.

IMPACT/DISCUSSION: Kratom is a plant native to Southeast Asia with dose dependent actions on the monoaminergic system and at the mu-opioid receptors (Hassan, Neuro & Bio Reviews, 2013). Recreational use of Kratom in the United States has increased; its purchase is legal in most states. Kratom is promoted on the internet for chronic pain, energy, and detox off opioids. Case reports describe the efficacy of BNX for kratom dependency (Khazeli, J Addict Med. 2018). Patients describe symptoms of anxiety and depression following cessation (Singh, J Psychotropic Drugs. 2018). This patient had prominent anxiety symptoms, likely due to his chronic condition made worse by kratom withdrawal, driving his co-consumption of phenibut. Phenibut is a gamma-aminobutyric acid type B agonist that is legally available from online retailers (Owen, Drug Al Rev. 2016). It has anxiolytic and euphoric effects and has been implicated overdose cases (O'Connell, Amer J of Med. 2014). Case reports describe syndromes of dependence and withdrawal characterized by anxiety, agitation, insomnia, and tremors (Ahuja et al. Case Rep Psychiatry, 2018) and can be treated with Baclofen. There are no case reports that we are aware of describing patients with misuse of both substances simultaneously. These medicines are not detected by traditional testing and providers are unaware of patients' use of herbal medicines (Lee, J of Clin Onc, 2014). This case illustrates the importance of taking a thorough history for use of licit and illicit substances. This case illustrates low perceived risk in the public domain of legal substances. Providers and patients will need education about these products to help influence policy.

CONCLUSION: Patients using Kratom or Phenibut perceive low risks but experience dependence and withdrawal. Successful treatment of Kratom use with BNX and Phenibut with Baclofen is possible

LESS IS MORE: REVERSAL OF VALVULAR DISEASE USING PATIENT-CENTERED CARE WITHOUT DEVICE THERAPY

LU CHEN¹; Uta Guo³; PARAG MEHTA². ¹NEW YORK PRESBYTERIAN - BROOKLYN METHODIST HOSPITAL, Brooklyn, NY;

²NewYork-Presbyterian BMH Hospital, Brooklyn, NY; ³SUNRISE GME CONSORTIUM, LAS VEGAS, NV. (Control ID #3186255)

LEARNING OBJECTIVE #1: Recognize and treat functional mitral regurgitation (MR) complicated by heart failure (HF) without valve replacement

CASE: A 71-year-old African American female with a past medical history of diabetes mellitus and hypertension presented to the Emergency Department with progressively worsening dyspnea at rest for two weeks. Admission blood pressure was 185/107 mmHg, heart rate was 120, and respiratory rate was 37. Physical examination was significant for volume overload with elevated jugular venous pressure, bibasilar crackles, and lower extremity edema bilaterally. Laboratory studies showed a Brain Natriuretic Peptide level of 1023 pg/mL. Diuresis was initiated with intravenous furosemide. During her hospitalization, a transthoracic echocardiogram (TTE) revealed an LV ejection fraction (LVEF) of 25%, enlargement of LV internal diameter (LVID) and severe eccentric MR. Findings were confirmed with transesophageal echocardiogram and coronary angiography. Angiography also revealed normal coronary vessels. Metoprolol and Lisinopril were initiated following diagnostic studies. Over the next few months, the patient was followed closely at our HF clinic and medications were optimized according to guideline directed therapy. Communication and encouragement were provided using secured exchanges via patient portal in our Electronic Health Record. This allowed home blood pressure monitoring as well as functional assessment between clinic visits. At four months follow-up, the patient reports exertional dyspnea after walking three blocks. TTE showed similar LVEF, but the reduction in both MR severity and LVID. Cardiac Resynchronization Therapy was deferred at this time. In nine months, the patient can ambulate symptom-free for six long blocks. TTE showed LVEF of 69%, trace MR, and normalization of LVID. Patient continues to follow up at our clinic with no exacerbation or readmission.

IMPACT/DISCUSSION: As Internal Medicine residents, we frequently encounter hospitalized patients with poorly controlled comorbidities. Often, we attempt to optimize patient care by offering the latest innovation. The art of patient-centered care is lost in the whirlwind of technological advancement. Time and effort from both physician and patient should be allocated to optimize guideline-directed medical therapy fully. This approach resulted in a success story of patient engagement and encouragement to achieve quality, cost-effective and patient-centered care.

CONCLUSION: Patient-centered care is a cost-effective therapy that resulted in near complete reversal of MR and LV remodeling using medication optimization without device therapy.

LET SLEEPING NODES LIE: A RARE CAUSE OF MASSIVE HEMOPTYSIS

Kyle M. Koster; Zachary Sherman; Shira A. Sachs. Weill Cornell Medicine, New York, NY. (Control ID #3181479)

LEARNING OBJECTIVE #1: Recognize the varied clinical presentations of broncholithiasis

LEARNING OBJECTIVE #2: Review treatment modalities for broncholithiasis

CASE: A previously healthy 27 year-old man from Tennessee presented with massive hemoptysis. He experienced sudden onset dyspnea and non-productive cough, followed by large volume hemoptysis requiring intubation in the field. Computed tomography angiography of the chest revealed scattered ground glass opacities, bibasilar consolidations, and a 3.0 by 2.1 centimeter calcified, subcarinal lymph node. The lymph node was attributed to prior histoplasma exposure found on laboratory workup. Multiple bronchoscopies were notable for dark blood in the trachea extending into the right main stem bronchus and old clots in lower airways, without a clear bleeding source. The patient was ultimately extubated without subsequent episodes of hemoptysis. A final bronchoscopy was performed, revealing a round, white lesion protruding from the wall of the right main stem bronchus, consistent with broncholithiasis. However, a pulmonary Dieulafoy's lesion could not be excluded. The patient was discharged with outpatient follow-up and underwent bronchial artery embolization.

IMPACT/DISCUSSION: Broncholithiasis occurs when calcified lesions are present within the bronchus, usually due to erosion of a calcified lymph node into the airway. Calcified lymph nodes are typically the result of a prior inflammatory or infectious process; tuberculosis is the most common cause worldwide, but histoplasmosis is the most common cause in endemic areas. Potential complications of broncholithiasis include hemoptysis and airway obstruction. Computed tomography can be used to identify calcified lesions in the chest, though diagnostic bronchoscopy should be performed to directly visualize suspected broncholithiasis. However, bronchoscopy may be limited in the setting of active inflammation or bleeding. Definitive treatment should be pursued to prevent repeat decompensation. Options include bronchial artery embolization, endobronchial resection, or lobectomy. In our patient, a Dieulafoy's lesion, a vascular anomaly characterized by a tortuous, dysplastic arteriole in the submucosa, remained a consideration, and therefore bronchial artery embolization was performed.

CONCLUSION: Broncholithiasis is a rare cause of hemoptysis, usually due to calcified lymph nodes eroding into the airway. Patients may present acutely with hemoptysis or airway obstruction. Prior histoplasmosis infection is the most common cause in North America. Internists should consider this diagnosis in patients with unexplained hemoptysis or airway obstruction and an appropriate exposure history.

LIFE IN A SHELTER: HEART FAILURE READMISSIONS IN THE HOMELESS

Christina Elzahaby¹; Dharmarajan S. Thiruvinvamalai². ¹Montefiore Medical Center, Bronx, NY; ²Montefiore Medical Center (Wakefield Campus), Bronx, NY. (Control ID #3183676)

LEARNING OBJECTIVE #1: Identify barriers for outpatient health care access in homeless patients.

LEARNING OBJECTIVE #2: Propose a plan to reduce hospital readmissions and improve healthcare access in such patients

CASE: A 57-year-old homeless man living in a shelter with history of uncontrolled hypertension, heart failure (HF), cocaine and alcohol addiction and schizophrenia presented with dyspnea, exercise intolerance and bilateral edema. He had difficulty maintaining access for outpatient care and adherence to diet, fluid restrictions and medications, depending on emergency visits for health-care needs. Examination: Blood pressure was 190/70 mm Hg, basal rales; 2+ bilateral pitting edema; proBNP elevated; chest x-ray revealed heart failure. Echocardiogram confirmed dilated cardiomyopathy, left ventricular hypokinesis and ejection fraction of 28%. Cardiac cath was advised, but was refused. Intravenous diuretics, metoprolol and lisinopril helped treat acute heart failure. He was educated utilizing the HF re-admission prevention program. On discharge, he was lost to follow up, failing to keep outpatient appointments. Attempts to reach the patient or his shelter supervisor were futile. Four weeks later, he was readmitted for another episode of acute HF.

IMPACT/DISCUSSION: The US Department of Housing and Urban Development (HUD) estimates 63,559 homeless people live in NYC (2018). A majority of homeless live in a shelter that provides a temporary residence and sometimes a gateway for permanent housing after long waiting list; these shelters often lack facilities and services to help patients receive appropriate outpatient care. Cardiovascular disease is a major cause of death in homeless adults, who may be smokers, at risk for uncontrolled hypertension and diabetes, psycho social stress and substance use, and medication non-adherence. Homeless patients have higher rates of using acute care resources like ED visits and hospitalizations, and often sign out against medical advice; they have higher 30 day readmissions to hospital impacting costs and quality of life. These patients need close follow up, education, communication with shelter services, and social support, to fulfill transportation and other needs. Medical respite programs can offer medical, nursing and accommodation for homeless persons discharged from acute hospital stays, who are sick to take care of themselves in a shelter, to help reduce hospital re-admissions.

CONCLUSION: - Homeless patients in a shelter have poor access to health care and fulfill their needs through acute care facilities, increasing costs of care. - Once hospitalized, efforts should target outpatient community integration to reduce re-admissions rate, including support, telephone calls, appointment reminders and transportation, in collaboration with social worker or case managers. - Simplify medication and dietary regimens to improve adherence.

LIMITATIONS OF BISAP SCORE IN PREDICTING SEVERE ACUTE PANCREATITIS (SAP)

Eshandeep S. Boparai; Nishant J. Trivedi. Kaiser Permanente Medical Center - San Francisco, San Francisco, CA. (Control ID #3183756)

LEARNING OBJECTIVE #1: Predict Severe Acute Pancreatitis when BISAP Score (Bedside Index for Severity in Acute Pancreatitis) is reassuring, less than or equal to 2

LEARNING OBJECTIVE #2: Recognize utility of imaging in diagnosis of necrotizing pancreatitis

CASE: A 43-year-old male with a history of chronic alcohol use presented to the clinic for acute, severe nausea and epigastric pain. Labs showed transaminitis: with aspartate aminotransferase (AST) 226 U/L, alanine aminotransferase (ALT) 514 U/L and total bilirubin at 1.7 mg/dl. Lipase was within normal limits at 58 U/L and a gallbladder ultrasound was unremarkable. Two days later, the patient presented to the Emergency Department after an episode of non-bloody, non-bilious emesis at work and severe abdominal pain. The patient reported waves of crippling epigastric pain radiating posteriorly, that were worsened by oral intake. Physical exam was notable for severe distress, sinus tachycardia to 110, and an abdominal exam significant for guarding and diffuse tenderness. Lab values were notable for White Blood Cell count elevation to 33,200 and a Hemoglobin of 16.5 g/dl, suggestive of hemoconcentration. Elevation in AST to 318 U/L, ALT to 644 U/L, alkaline phosphatase to 278 U/L, and total bilirubin to 2.4 mg/dl was noted, with lipase now elevated to 20,297 U/L. The abdominal ultrasound remained unremarkable. However, a CT scan of the abdomen and pelvis with IV and PO contrast revealed large amounts of peripancreatic fat stranding, enlarged edematous pancreas with poor enhancement of majority of parenchyma consistent with necrotizing pancreatitis. Despite significantly abnormal lab and CT scan findings, the BISAP score was 2, indicating a lower rate of complications and mortality. However, the patient went on to develop septic shock requiring antibiotics and vasopressors for blood pressure support, with a prolonged ICU hospitalization complicated by pancreatic fluid collections and abscesses needing multiple surgical drainage procedures and necrosectomies.

IMPACT/DISCUSSION: In the past decade, the BISAP score has offered internists prognostic insight for predicting severe acute pancreatitis, particularly in the first 24 hours. A score of 2 or lower is associated with a lower rate of mortality (2% and lower) and complications whereas a BISAP score of 3 and greater has been associated with a steep rise in mortality (5-20%), organ failure, and necrosis. Despite BISAP's clinical utility, a patient who presents with acute, necrotizing pancreatitis in its earliest stages may have a reassuring BISAP score and be subsequently mismanaged.

CONCLUSION: Though the BISAP score has very good predictive performance for SAP, this case reiterates the potential danger of overreliance on a single predictive scoring system. A thorough clinical assessment - history, physical exam, lab-work and imaging modalities, especially a CT scan - should be utilized for appropriate triage and management of a patient with acute pancreatitis

LINEZOLID INDUCED INTERSTITIAL LUNG DISEASE

Tanaz Salimnia¹; Daymon Peterson¹; Neeharika Ralh¹; Leonard Johnson². ¹Wayne State University, Rochester, MI; ²Ascension St. John, Detroit, MI. (Control ID #3185839)

LEARNING OBJECTIVE #1: Linezolid is a newer class of medication with this being the first reported case of it causing interstitial lung disease as a side effect.

LEARNING OBJECTIVE #2: The mechanism of linezolid induced lung injury is believed to be due to the reduction in antioxidation ability and the subsequent formation of free radicals.

CASE: A 34-year-old male with a prior history of injection drug use, hepatitis C, chronic tobacco use and seizures presented to the emergency department for a syncopal episode with associated urinary incontinence thought to be due to seizure. The patient reported that he had developed a nonproductive cough and dyspnea two weeks prior with no associated fever, chills or sick contacts. He had been taking linezolid for three weeks for a right lower extremity infection. At presentation, he was tachypneic, tachycardic and hypoxic. Upon examination, he appeared dyspneic, his lungs were clear and his right lower extremity demonstrated excoriations without active soft tissue infection. His WBC was 13.9 with predominant neutrophils and chest X-ray demonstrated diffuse interstitial changes bilaterally. His linezolid was held and two days later, the patient's cough, hypoxia and dyspnea had resolved, WBC had normalized and repeat CXR showed significant improvement. The patient was readmitted 2 months later for an acute exacerbation of chronic lung disease and his CXR continued to be clear.

IMPACT/DISCUSSION: Linezolid has a wide side effect profile but has not been reported as a cause of DILD. The proposed etiology of DILD is based on free radical damage which is the same mechanism as bleomycin induced pneumonitis. Linezolid induces a reduction in antioxidation ability and the subsequent formation of free radicals. Levels of superoxide dismutase (SOD) and catalase (CAT) in the plasma were decreased after linezolid treatment, which provided the first clinical evidence that linezolid can regulate antioxidant enzyme release. This would in turn cause alveolar cell destruction resulting in pulmonary inflammation. The diagnosis of DILD is made clinically and is mainly based on excluding other causes. Eosinophilia may or may not be present. Treatment involves discontinuation of the offending agent and in acute cases, symptoms tend to resolve within 24 to 48 hours. Patients should also be cautioned to avoid repeat exposure to the offending agent.

CONCLUSION: Linezolid is a newer class of antibiotic in the oxazolidinone class with advantageous pharmacokinetics making it quite potent for numerous infections. However, as a newer drug class, unrecognized side effects are being discovered. This is the first reported case of linezolid causing DILD and clinicians should be aware of this potential side effect.

LITHIUM INDUCED ENCEPHALOPATHY

ejaz shah¹; Saliha Saleem². ¹montefiore medical center, Bronx, NY; ²Montefiore Medical Center, Bronx, NY. (Control ID #3186431)

LEARNING OBJECTIVE #1: Assess lithium induced encephalopathy in elderly

LEARNING OBJECTIVE #2: Recognizing lithium as a controlled substance.

CASE: 65 year old man with Bipolar Disorder (on lithium and valproate) presented with altered mental status (AMS). As reported by family he was progressively lethargic and somnolent since 2 months. At baseline he was well oriented. His last office visit was 2 months back with his Primary care provider (PCP) with blood work showing normal kidney function and was started on lithium. On presentation to hospital he was oriented to self only and rest of neurological examination was non-focal. Pertinent labs were: Creatinine of 1.50 mg/dl (Normal level - 0.5 to 1.1 mg/dl) and Lithium level 2.8 mmol/lit (Normal level 0.6 to 1.2 mmol/lit). On admission CT head was unremarkable. Electroencephalography (EEG) was consistent with diffuse cerebral dysfunction, worse in the left fronto-temporal region. presence of triphasic waves raising the possibility of a metabolic encephalopathy and is a reported finding in lithium toxicity. Lithium was held.

Nephrology recommended aggressive intravenous hydration. Lithium levels trended down, $2.8 \rightarrow 1.8 \rightarrow 1.3 \rightarrow 0.8$ mmol/lit, with subsequent improvement of renal function and mental status to baseline. Lithium was taken off from his psychiatry medication list and was discharged home.

IMPACT/DISCUSSION: Lithium has many medical and psychiatric uses. Common uses include but are not limited to migraine headaches, alcoholism and bipolar disorder. Toxicity from lithium can occur by overdose especially from alteration in its clearance by the kidney. Known presentation with lithium overdose include ataxia, lethargy and tremors. Risk factors associated with toxicity include age > 60 years, derranged kidney function and drug-drug interaction. Our patient was otherwise healthy elderly male with new onset derranged kidney functions that led him to have encephopathy. Lithium prescriptions usually comes from psychiatrist, and once started lithium levels should be monitored monthly along with creatinine levels. Unfortunately, our patient had a controlled substance prescribed by a PCP and was not monitored. We as physicians should be cautious in prescribing such medications, and once prescribed regular neurological exams, drug levels and creatinine should be monitored.

CONCLUSION: Lithium is associated with serious but reversible side effects. As a physician extra care should be implemented after prescribing it. Patient physical examination and blood tests should be monitored strictly.

LOOKING BACKWARDS: A 1940S HERBAL REMEDY FOR OPIOID WITHDRAWAL IN 2018

Maximillian Bourdillon¹; Nathan Pham¹; Andrea Alonso²; Nicolette Oleng¹. ¹Boston Medical Center, Boston, MA; ²Boston University School of Medicine, Boston, MA. (Control ID #3183661)

LEARNING OBJECTIVE #1: Highlight the abuse potential of unregulated homeopathic substances

LEARNING OBJECTIVE #2: Educate providers on the identification and management of kratom withdrawal

CASE: A 37-year-old woman with a history of polysubstance use disorder (alcohol, opiates without intravenous drug use in the last year) presented to the emergency department for right hand cellulitis and alcohol withdrawal. She reported drinking 5-10 beers daily; last drink on the morning of admission. She reported tremors, diaphoresis, and nausea. She received multiple doses of benzodiazepines using the CIWA (Clinical Institute Withdrawal Assessment) tool for alcohol withdrawal with initial improvement of her symptoms. However on the floor, symptoms of diaphoresis and tremulousness persisted while her exam was notable for dilated pupils and frequent yawning. Given this presentation and prior history of opiate dependence and treatment with suboxone, the patient was placed on COWS (Clinical Opiate Withdrawal Scale) for which she scored for moderate withdrawal. A urine drug screen showed trace amounts of buprenorphine. On admission, patient denied opiate use in the six months prior to admission. However, she disclosed a 6-month daily use of an herbal tea with kratom as a home remedy for depression and anxiety. Kratom has pharmacological interaction with the opioid system and opioid withdrawal was precipitated with abrupt cessation during this admission. With the help of addiction medicine consult team, she was treated for opioid withdrawal with suboxone, with symptomatic improvement.

IMPACT/DISCUSSION: Kratom (*Mitragyna speciosa*) is an herb indigenous to Southeast Asia with dose-dependent stimulant and opiate-like properties. It has been used as an over the counter treatment of opioid withdrawal dating to the 1940s. It is traditionally chewed but can be powdered and mixed in liquid. There is scant literature demonstrating its efficacy in treating opiate dependence. While there are increasing reports of lethal overdose and other adverse effects, our understanding of kratom is limited to a few case reports or series. The DEA has even considered scheduling kratom. While kratom's popularity has been rising via internet vendors and smoke shops in the US, it has remained relatively unknown in healthcare thus rendering providers ill equipped to screen and manage the overdose or withdrawal from this substance. The active

ingredient in kratom is mitragynine. At low doses of 1-5 grams of raw leaves, mitragynine has stimulant effects and can cause increased alertness, physical energy, and euphoria. At high doses of 5-15 grams it is an agonist on the Mu and Kappa receptors resulting in analgesia and relief from opioid withdrawal, which explains how cessation can precipitate opioid withdrawal, as described in this case.

CONCLUSION: -Kratom has abuse potential as an anxiolytic and analgesic agent -The potential of kratom in the treatment of opioid withdrawal or as maintenance therapy requires further inquiry, particularly in the current opiate use crisis

LOOKING BENEATH THE SURFACE - DIFFERENTIAL DIAGNOSES FOR SKIN FINDINGS IN A PATIENT WITH HIV

Angela O. Suen; Eliana Bonifacino. UPMC, Pittsburgh, PA. (Control ID #3163108)

LEARNING OBJECTIVE #1: Understand how framing bias can limit the differential for patients with HIV.

LEARNING OBJECTIVE #2: Recognize a common noninfectious dermatologic complication of HIV.

CASE: A 55-year-old man with substance use disorder and untreated HIV presents with a chronic diffuse hyperkeratotic crusting rash. Patient reports a recent history of not taking his antiretrovirals due to increased cocaine use and instability of his living situation. His rash started several months ago on his bilateral lower extremities and spread to his hands, feet, trunk, extremities, and face. It is a highly pruritic and painful rash. On examination, there were diffuse hyperkeratotic plaques distributed on the palms, soles, and extremities with areas of hyperpigmented nodules. His CD4 count was measured at 4. Given a clinical picture concerning for Norwegian scabies, patient was started on ivermectin. The patient underwent skin scraping which was negative for scabies mites. He subsequently underwent biopsy which showed psoriasisiform dermatitis. HHV-8 was negative. Patient was treated with daily moisturization and wrapping, and experienced improvement in symptoms. Patient was eventually started on darunavir/cobicistat and tenofovir alafenamide/emtricitabine prior to discharge.

IMPACT/DISCUSSION: The skin is tightly connected to the immune system and a compromised immune system (especially in T-cell function) leads to clinically apparent skin disease. This patient has psoriasis in the setting of untreated HIV, which is an extreme presentation of a relatively common illness. His CD4 count, and homelessness, may have caused framing bias and limited the differential to infectious etiologies commonly seen in HIV: viral pathogens such as HSV, molluscum contagiosum, HPV, VZV; bacterial pathogens such as bacillary angiomatosis, syphilis; fungal pathogens such as Cryptococcus, mycobacterial infection of the skin, or infection by microorganism (such as bedbugs, parasites, scabies, lice). Psoriasis is a common complication of HIV which is not frequently discussed. One proposed mechanism is that the relative decrease in CD4 T-cells causes a relative increase in CD8 memory T-cells which are associated with onset and exacerbation of psoriasis. Patients with HIV tend to have severe psoriasis seen with low CD4 counts. There are no curative therapies for psoriasis and treatment is largely supportive. It is thought that optimizing HIV/AIDS with anti-retroviral therapy can lead to a significant reduction in symptoms.

CONCLUSION: Many illnesses commonly treated by internists have dermatologic manifestations. In the setting of HIV/AIDS, though appropriately, infectious etiologies of rashes should be considered, it is important for generalists to know that non-infectious rashes like psoriasis are also common. This case also highlights how framing bias can influence the approach to patients with HIV/AIDS by limiting the diagnosis to infectious etiologies.

LOOKING BEYOND THE VIRUS: SOCIAL DETERMINANTS OF HEALTH AND HEPATITIS B

Ilana Prior, Weill Cornell Medical College/New York Presbyterian, New York, NY. (Control ID #3185377)

LEARNING OBJECTIVE #1: Using one patient's story, identify social factors that contribute to poor outcomes in HBV

CASE: 54M with chronic hepatitis B (HBV) infection (HBeAg neg) presented with abdominal distension. He was found to have AST/ALT 1000s, INR 3.9, and hep B viral load >170,000,000 IU/mL. PMH: He was diagnosed with HBV in 2009 and started on entecavir. He subsequently lost his Medicaid, including prescription coverage, due to his income exceeding the state maximum. He had stopped his antivirals 2 years prior due to cost. Social history: Born in Taiwan, he immigrated to the US in 1995. He was a naturalized citizen. He spoke no English; his wife was conversational. He was paid under the table for his 60+ hours/week working at a restaurant. He did not have insurance. Hospital course: Despite treatment with NAC and tenofovir, he developed progressive liver failure with altered mental status and renal failure requiring the ICU, intubation, and CVVH. He underwent orthotopic liver transplant on hospital day 8. His family applied for emergency Medicaid; he received post-transplant immunosuppressives via pharmaceutical assistance programs. He was eventually discharged to rehab. His Medicaid application was approved post-discharge.

IMPACT/DISCUSSION: As outcomes in patients with liver disease improve, focus has shifted towards identifying the social determinants that contribute to their health. Our patient had three notable factors which played a role in his need for transplant. First, his ethnicity: HBV disproportionately affect minorities, specifically Asians, in the US. Despite efforts to target Asians for HBV screening and treatment, mortality from HBV remains 8 times higher in Asians than whites in America. Second, language barriers: although his wife could not understand complex medical discussions in English, she often found herself acting as his interpreter for these conversations. Patients with limited English proficiency are more likely than English speaking patients to experience adverse events that are the result of communication errors. Many of these patients feel that their doctors do not explain things clearly. Finally, losing prescription benefits and access to his antivirals resulted in viral reactivation and acute liver failure. Public insurance coverage (vs private) has been associated with increased mortality post-liver transplant. This patient required a transplant organ for a disease that is both preventable and manageable once contracted, and is at higher risk for post-transplant mortality given his current insurance status. His highly morbid outcome was largely the result of his ethnicity, language, and insurance status. These are all areas that should both be acknowledged when caring for patients with similar socioeconomic factors, and targeted for improvement as we attempt to achieve universal health equity.

CONCLUSION: Ethnicity, language barriers, and insurance status can be significant contributors to morbidity in hepatitis B patients

LOST AT C: THE MYSTERIOUS CASE OF RECURRENT BLEEDING

Laya Reddy, Scripps Clinic, San Diego, CA. (Control ID #3185145)

LEARNING OBJECTIVE #1: Recognize signs and symptoms of vitamin C deficiency

LEARNING OBJECTIVE #2: Identify those at risk of vitamin C deficiency

CASE: This is a 25-year-old man with autism spectrum disorder who presented with 1-day of generalized weakness and left knee swelling. This patient had two recent hospitalizations in the month prior to presentation. Initial hospitalization was due to traumatic left knee hemarthrosis. The second admission was due to recurrent hemarthrosis with a hemoglobin

drop from 8.1 to 6.8. Orthopedic surgery did not feel the patient's anemia could be attributed solely to blood loss in left knee joint. Further workup was consistent with mixed picture of iron deficiency and anemia of chronic disease. He presented for a third admission with similar presentation. Past medical history was significant for autism. He also had protein-calorie malnutrition with a body mass index of 13 and had been eating 21 eggs per day for the past four months with no additional form of nutrition. He had no significant family history of bleeding disorders. Physical exam was significant for an ill-appearing cachectic male with a sallow appearance. Patient's left knee was with mild swelling and ecchymosis to lateral thigh as well as decreased range of motion due to pain. The anterior aspects of his bilateral upper and lower extremities with scattered perifollicular papules. Initial labs significant for anemia with hemoglobin of 6.7. Given that bleeding diathesis workup was unrevealing, further investigation was done in conjunction with patient's skin findings and diet devoid of vitamin C, which is non-existent in eggs. This patient's vitamin C level was found to be undetectable and patient was diagnosed with scurvy. He was initiated on vitamin C supplementation with 500 milligrams daily for 3 months. With supplementation, patient's symptoms and anemia improved to baseline within 2 months.

IMPACT/DISCUSSION: Scurvy can mimic an acquired coagulopathy. Though scurvy is more common in underdeveloped countries, prevalence in the United States has been as high as 7.1% in the past few years. At risk populations include children with autism spectrum disorder who habitually eat a highly selective diet devoid of fruits and vegetables along with drug abusers, impoverished, and the elderly. Symptoms of scurvy generally occur within months of a vitamin C deficient diet. The disease is characterized by pronounced cutaneous signs such as petechiae, perifollicular hemorrhage, and bruising. Hemarthrosis and anemia can occur as seen in this patient. The mechanism of anemia is thought to be due to inappropriate folate and iron absorption and utilization and in some cases hemolysis and gastrointestinal bleeding.

CONCLUSION: In the high-risk populations of some developed nations, an estimated 25% of men and 16% of women are deficient in vitamin C. It is vital to keep scurvy on the differential in high-risk, nutritionally deficient patients presenting with hemarthrosis. Distinct cutaneous findings can give clues to diagnosis.

LUSH LASHES AND LYMPHEDEMA: A RARE HERITABLE DISORDER UNDERLYING A COMMON COMPLAINT

Matthew T. Brown; Laura Ragmanauskaite; Chengcheng Ye; Robin Klein. Emory University School of Medicine, Atlanta, GA. (Control ID #3186110)

LEARNING OBJECTIVE #1: Emphasize lymphedema distichiasis as a rare cause of bilateral lower extremity edema

LEARNING OBJECTIVE #2: Recognize hereditary syndromes as etiologies for presenting illnesses if the classic work-up is unrevealing

CASE: A 59 year old female presents with four months of progressive swelling associated with dyspnea and generalized weakness. She first noticed bilateral leg swelling following a pedicure and was treated for a lower extremity cellulitis. However, her symptoms did not resolve, and her edema progressed proximally to involve her thighs and lower abdomen. Past medical history was notable for obesity and gastric sleeve surgery in 2014. Exam revealed smooth, pitting edema in her bilateral lower extremities extending to her lower abdominal wall. In addition to a circular left ankle plaque, a dimpling pattern similar to peau d'orange induration was noted at both thighs with brawny discolored. There was no JVD, S3, or displaced PMI. Her lungs were clear to auscultation. No organomegaly or fluid wave on abdominal exam. Laboratory revealed normal creatinine and albumin. Urine protein was negative at 15 mg/dL. Echo revealed an EF of 65%, normal cardiac anatomy and no diastolic dysfunction. Ultrasound was negative for lower extremity thrombosis. CT abdomen showed only reactive inguinal lymphadenopathy without

masses, liver abnormalities, or ascites. Trial of diuresis did not change her edema. Given her lower extremity plaque and skin changes, dermatology was consulted. Detailed exam revealed a double row of eyelashes or distichiasis. With further inquiry, she endorsed frequent conjunctivitis. She was presumptively diagnosed with Lymphedema distichiasis and referred for further testing.

IMPACT/DISCUSSION: Lymphedema distichiasis is a rare autosomal dominant genetic disorder due to a mutation in the FOXC2 gene. It is characterized by early-onset lymphedema and distichiasis or aberrant eyelashes, present in 94% of patients. Distichiasis ranges from a single aberrant eyelash to a full row of extra lashes along the inner lining of the lid causing corneal irritation or recurrent conjunctivitis in up to 75% of patients. Other associations include ptosis, varicose veins, and even cardiac abnormalities like tetralogy of fallot. Our case illustrates a classic presentation of a rare genetic disease presenting in adulthood. Lower extremity swelling is a relatively common symptom with a broad differential. However, while our initial systems-based evaluation was thorough, it failed to provide a clear clue to a diagnosis. This case illustrates the need to be mindful that hereditary diseases may present in previously well adult patients.

CONCLUSION: Lymphedema distichiasis is a rare genetic disorder for bilateral lower extremity lymphedema. Importantly, as internists, we often do not think of undiagnosed hereditary diseases in evaluating adult patients. Therefore, if the classic work-up is unrevealing, this genetic disease needs to be considered in the differential.

LYMPHOEPITHELIAL CYST: A RARE CASE OF RAPIDLY PROGRESSIVE ABDOMINAL PAIN ASSOCIATED WITH LARGE MULTILOCULATED INTRA-ABDOMINAL CYST

Faith Villanueva; Joydeep Chakraborty; Maryam Sattari. University of Florida, Gainesville, FL. (Control ID #3163324)

LEARNING OBJECTIVE #1: Evaluate and manage large, symptomatic abdominal cysts with uncommon radiographic/pathologic features.

CASE: A 24-year-old man with no significant past medical history presented with left upper quadrant abdominal pain for 3 days. The pain was severe, progressive, non-radiating, increased with movement and eating, associated with subjective fever, and without antecedent abdominal trauma. He denied personal or family history of pancreatitis, pancreatic disease, or neoplasm. His social history was notable for heavy alcohol use and binge drinking. Physical exam was remarkable for severe left lower quadrant abdominal tenderness with palpable mass without peritoneal signs. Serum studies, including lipase and carbohydrate antigen 19-9 (CA 19-9), were unremarkable. Imaging (CT and MRI) revealed normal pancreas and pancreatic duct but showed a 6x12x18 cm multiloculated cystic lesion in the left upper quadrant adjacent to the pancreatic tail. Cytology and histopathology obtained from endoscopic ultrasound-guided fine-needle aspiration (EUS-FNA) showed nonspecific fragments of fibrous tissue without evidence of malignancy. Fluid analysis for amylase and CEA was inconsistent with pseudocyst or mucinous neoplasm. He underwent surgical fenestration of the cyst without complication, and final pathology was consistent with lymphoepithelial cyst. His symptoms significantly improved post-operatively with marked radiographic decrease in mass size.

IMPACT/DISCUSSION: With the recent advent of improved diagnostic and interventional modalities, consensus on evaluation and management of symptomatic abdominal cystic lesions is a continuously evolving field that remains challenging for internists. Lymphoepithelial cysts are benign, rare lesions often found incidentally, and usually require no intervention. However, this patient's cyst was causing severe symptoms and his history of alcohol use as well as size of the mass were concerning for malignancy. Ultimately, complete diagnostic workup including serum tumor markers, cross-sectional imaging, EUS-FNA with fluid analysis, cytology, and pathology was necessary as therapeutic intervention was etiology-dependent. Timely diagnosis and therapeutic intervention required a

multidisciplinary approach and coordination with interventional gastroenterology, hepatobiliary surgery, radiology, and pathology.

CONCLUSION: Lymphoepithelial cysts are benign lesions that can be managed conservatively if asymptomatic. However, due to their rarity and often incidental identification, these lesions can pose a unique diagnostic and therapeutic challenge for internists and be misdiagnosed as neoplasms. Thorough multi-disciplinary evaluation with imaging as well as histologic analysis and correlation are essential to rule out other pathologic etiologies such as malignancy and avoid unnecessary extensive surgical intervention.

MALABSORPTIVE CIRRHOSIS: A RARE COMPLICATION OF DUODENAL SWITCH

Raphael Rabinowitz¹; Tracey Martin²; David M. Feldman^{1, 1}; Benjamin Verplanke¹. ¹New York University Langone Health, New York, NY; ²Weill Cornell Medical Center, New York, NY. (Control ID #3161245)

LEARNING OBJECTIVE #1: Recognize protein malnutrition and cirrhosis as potential complications of biliopancreatic diversion with duodenal switch (BPD-DS).

CASE: A 37-year-old man with a history of severe obesity status post laparoscopic BPD-DS presented with diffuse swelling. The patient was admitted six months previously for severe protein-calorie malnutrition requiring initiation of total parenteral nutrition (TPN). During that admission, he was found to have elevated liver enzymes and ascites. Workup for autoimmune, infectious, and hereditary etiologies of cirrhosis was unremarkable; a liver biopsy showed steatosis without evidence of alcoholic hepatitis or cirrhosis. He now complained of abdominal distension and lower extremity edema that had progressed over several weeks, requiring multiple large-volume paracenteses. He endorsed past heavy alcohol use, but denied recent exposure. On physical examination, he was grossly anasarca with a distended abdomen and appreciable fluid wave, 3+ pitting edema to the hips, and scrotal edema. His admission Model for End-Stage Liver Disease (MELD) score was 14. Repeat biopsy demonstrated prominent portal fibrosis and focal nodularity indicative of advanced-stage cirrhosis, with an interval decrease in steatosis from his previous biopsy. The rapidity of fibrosis and reversal of fatty change suggested the etiology was his bariatric surgery. He was treated with intravenous diuretics with improvement in his anasarca. At one-month follow-up, he had a stable MELD and diuretic-responsive ascites. He has been approved for liver transplant evaluation, with plans to reverse his bypass prior to transplant.

IMPACT/DISCUSSION: BPD-DS is classically associated with improvement in hepatic function due to reversal of nonalcoholic steatohepatitis (NASH). However, case reports of hepatic failure following BPD-DS do exist. Clinicians should be alert to this complication and monitor postsurgical patients closely for signs of hepatic decompensation.

CONCLUSION: BPD-DS is the most effective bariatric surgery technique for sustained weight loss in the super-obese ($BMI > 50 \text{ kg/m}^2$). Nevertheless, its widespread adoption has been limited by technical complexity and concerns over vitamin deficiencies and malnutrition. Loss of hepatotropic factors due to protein malnutrition has been advanced as a mechanism to explain its contribution to the development of cirrhosis. With the increasing prevalence of obesity and the documented effectiveness of BPD-DS for sustained weight loss, this surgery will likely become more commonplace. Awareness of this potential complication and vigilance to ensure adequate protein intake, with aggressive intervention—including the initiation of TPN—to preserve nutritional status is paramount to effective management of BPD-DS patients post-operatively.

MANAGEMENT OF GAMMA-HYDROXYBUTYRATE (GHB) WITHDRAWAL IN A HOSPITALIZED ORTHOPEDIC PATIENT

Hannan Braun; Miriam Harris; Zoe M. Weinstein. Boston Medical Center, Boston, MA. (Control ID #3181804)

LEARNING OBJECTIVE #1: Recognize GHB withdrawal signs and symptoms

LEARNING OBJECTIVE #2: Manage GHB addiction and withdrawal

CASE: A 40-year-old man slipped at home and presented to the ED after feeling his right leg snap. Imaging with X-ray and CT-angiography showed spiral shaft fractures of the distal tibia and fibula complicated by entrapment of the anterior tibial artery. His medical and social history were significant for HIV (CD4 484), bipolar disorder, chronic pain, polysubstance use (reported cocaine, cannabis, MDMA, and crystal methamphetamine use), severe alcohol use disorder in remission for two years, and osteoporosis (of unknown origin). Home medications included alprazolam 0.5mg TID prn, asenapine 10mg, baclofen 20mg BID and hydroxyzine 25-50mg prn. He is sexually active with men. Surgical repair was delayed when he became increasingly hypertensive, tachycardic, and agitated. Despite receiving alprazolam 1.5mg, hydroxyzine 25mg, baclofen 20mg, and lorazepam 1mg, his symptoms persisted, and he developed visual hallucinations. A workup for organic causes of delirium including serum toxicology was negative. Urine toxicology was positive only for medications given and substances reported in the patient's history. During an additional addiction-focused history, he denied alcohol use but reported daily GHB. His agitation required ICU care. He was initiated on a phenobarbital protocol for GHB withdrawal, with additional haldol and dexmedetomidine for his protracted delirium. On hospital day 4, he underwent a successful intramedullary nailing of the femoral and tibial fractures. He received his last dose of phenobarbital on day 7 and was transitioned to home baclofen, a recommendation by the addiction consult service given its potential utility for GHB treatment.

IMPACT/DISCUSSION: GHB is a central nervous system depressant used recreationally (mainly in a liquid oral form) as a party drug for its effects of euphoria, sedation, amnesia, and sex-stimulation. While there is low use (<1%) in the general population, high rates (up to 20%) have been reported among club-going gay and bisexual men. GHB withdrawal includes autonomic nervous system hyperarousal and hallucinations. It remains difficult to treat: GHB is a GABA-B receptor agonist, while alcohol and its withdrawal treatments (benzodiazepines and phenobarbital) are GABA-A agonists. Long-acting benzodiazepines are the mainstay of treatment for GHB withdrawal, with barbiturates considered in withdrawal resistant to benzodiazepines or complicated by psychosis. While originally prescribed to our patient for pain, baclofen—a GABA-B agonist—is currently being studied for its potential to treat GHB use disorder.

CONCLUSION: -GHB withdrawal is similar in presentation to alcohol, presenting with tremor, diaphoresis, and agitation—though with a more rapid onset of neuropsychiatric symptoms. -GHB withdrawal is life-threatening. A thorough addiction history is required for patients with suspected substance use and acute delirium, as GHB is not identified in standard toxicology screening.

MASQUERADE OR MISS? A CASE OF UNDIAGNOSED NEUROSYPHILIS

Justin Nichols¹; Nikita Donti²; Jennifer N. Goldstein³; Ribu Mathew⁴.

¹Christiania Care Health System, Philadelphia, PA; ²Christiania Care Health Systems, Wilmington, DE; ³Christiania Care Health System, Newark, DE; ⁴Sidney Kimmel Medical College, Jefferson University, Philadelphia, PA. (Control ID #3180821)

LEARNING OBJECTIVE #1: Rule out reversible causes of psychosis.

LEARNING OBJECTIVE #2: Diagnose neurosyphilis in individuals with significant risk factors.

CASE: A 35-year-old African American previously healthy male presented with progressive waxing and waning encephalopathy, confusion, delusions, hallucinations, and amnesia. One year prior to presentation, he had been diagnosed with schizophrenia, hospitalized and started on antipsychotics without improvement. The patient developed difficulty with activities of daily living, night sweats, weight loss, ataxia, tremors and visual changes. Social

history was significant for unprotected male sexual encounters, prompting STD testing by his primary care provider. Testing returned positive for HIV (CD4 count of 169), high RPR titers (1:2048 dilutions) and a positive Treponema pallidum particle agglutination assay (TPPA). He was admitted to the hospital for workup and treatment of suspected neurosyphilis. On exam, the patient was alert and oriented only to person with fine hand tremors and a narrow-based shuffling gait. A lumbar puncture revealed elevated protein, leukocytosis, positive Treponema pallidum antibody and elevated VDRL titer (1:16), confirming neurosyphilis. Cryptococcal antigen, JC virus and meningoencephalitis PCR panel were negative. Brain MRI showed cortical atrophy. The patient was treated with a fourteen-day course of IV penicillin G, followed by one dose of IM benzathine penicillin G with improvement in mental status and affect. He was started on antiretroviral therapy and discharged with follow up at the HIV clinic.

IMPACT/DISCUSSION: Neurosyphilis is a great imitator, and early neurological involvement may be seen more frequently in individuals with HIV. Before making a diagnosis of schizophrenia or other psychiatric conditions, reversible causes must be ruled out. A thorough social history is required to assess for risk factors such as HIV status, male gender, and men who have sex with men. Our patient was ultimately diagnosed with AIDS and late-stage neurosyphilis, likely general paresis, after appropriate testing. Since neurosyphilis can occur during any stage of syphilis, a lumbar puncture should be performed when neurological and ophthalmic signs are present or the index of suspicion is high. Elevated protein (>45 mg/dL), white blood cells (>5 cells/microL) and a positive CSF-VDRL confirms the diagnosis of neurosyphilis. Patients should be promptly treated with IV penicillin with test of cure lumbar puncture every six months after treatment until resolution of CSF pleocytosis. Patients with HIV are at increased risk for treatment failure.

CONCLUSION: Strongly consider neurosyphilis on the differential in patients who present with neuropsychiatric symptoms and appropriate risk factors. Confirm the diagnosis of neurosyphilis with a lumbar puncture. Treat neurosyphilis with IV penicillin G for 10-14 days, with subsequent confirmatory testing.

MASQUERADING MYOSITIS

Nirav Antao; Andrea Ramirez Gomez. St.Louis University Hospital, St Louis, MO. (Control ID #3186835)

LEARNING OBJECTIVE #1: Identify the different types of idiopathic inflammatory myositis (IIMs) and diagnostic criteria for the new classification

LEARNING OBJECTIVE #2: Review the clinical presentation of anti-synthetase syndrome

CASE: A 53 year old woman presented with one month of diffuse myalgias, generalized weakness and shortness of breath. She had previously presented to an outside hospital ER on three separate occasions where she was initially treated with multiple antibiotic courses for suspected bronchitis and then briefly admitted for "double pneumonia" due to CT findings of multifocal bilateral reticulonodular pulmonary infiltrates. However, her symptoms never really improved, which prompted evaluation at our institution. Here, physical exam revealed coarse bilateral breath sounds with 3/5 bilateral grip strength and 3/5 strength in proximal and distal bilateral lower extremities. Labs revealed elevated CK 1276, LDH 584, aldolase 34, ESR 91, CRP 11.7 and ANA 1:320 speckled pattern. As her labs, imaging and constellation of symptoms were suggestive of an underlying autoimmune/rheumatologic process, a myositis panel was ordered which revealed +anti Jo-1 and +anti SSA. Due to concomitant persistent shortness of breath and hypoxemia in the setting of above CT, she underwent a bronchoscopy which showed diffuse alveolar hemorrhage. She was thus diagnosed with overlap myositis and more specifically "anti-synthetase syndrome" which is the most representative form of this group. She was started on steroids after which azathioprine was added as an outpatient with significant improvement in her symptoms.

IMPACT/DISCUSSION: Anti-synthethase syndrome is characterized by autoantibodies targeting aminoacyl tRNA synthetases, such as anti-Jo1, and is predominantly associated with interstitial lung disease. Diagnosis is achieved by a combination of clinical manifestations, presence of autoantibodies and biopsy findings. Other studies like EMG and muscle MRI are also useful in diagnosis. Treatment for inflammatory myopathies remains a challenge due to their heterogeneity, thus a multidisciplinary approach is warranted.

CONCLUSION: Inflammatory myopathies are a group of autoimmune disorders characterized by muscle inflammation, but often accompanied by extra-muscular involvement including skin, joints and lung, as seen in our patient. Recent discovery of autoantibodies and advances in pathophysiology have led to the development of a new classification criteria subgrouping IIMs in 5 types. These share some clinical presentations, but also have specific patterns of muscle involvement, distal organ affection or paraneoplastic syndrome association, which makes accurate diagnosis of upmost importance for adequate treatment and prognosis.

MASS EFFECT: A CASE OF BILIARY OBSTRUCTION

Alexander Katz¹; Michael Crawford¹; Deepa Bhatnagar². ¹Tulane University School of Medicine, New Orleans, LA; ²Tulane University, New Orleans, LA. (Control ID #3184480)

LEARNING OBJECTIVE #1: Demonstrate a rare cause of biliary obstruction

LEARNING OBJECTIVE #2: Discuss the clinical spectrum of IgG related disorders

CASE: A 71-year-old man presented with 3 days of intermittent abdominal pain and nausea. His past medical history was pertinent for a recent episode of biliary pancreatitis. He did not report alcohol abuse or a history of gallstones, and his only medications included hydrochlorothiazide, rosuvastatin and losartan. Vitals were normal and epigastrium was tender. Liver enzymes revealed AST 220, ALT 320, alkaline phosphatase of 508 with total bilirubin of 2.8. Lipase was normal. Ultrasound revealed gallstones and common bile duct dilation of 6-7mm but without clear obstruction. CT abdomen/pelvis revealed a 1 cm pancreatic mass and terminal ileum thickening with ileocolic lymph nodes. CA-19 was 264 and IgG was elevated to 1907. MRI and EUS were done to further evaluate pancreatic lesion and showed no evidence of pancreatic mass. Liver biopsy showed no fibrosis or malignancy. Lower endoscopy showed no intraluminal mass in the ileum. Ultimately, the mesenteric nodule biopsy was performed along with cholecystectomy which revealed IgG related sclerosing disease of both the gallbladder and mesenteric nodule. ERCP with stent placement was performed for biliary drainage. The patient was treated with steroids with improvement in symptoms.

IMPACT/DISCUSSION: Internists frequently encounter hepatobiliary pathology when caring for patients. In this case, the patient's clinical picture was more consistent with biliary obstruction. After more common causes were ruled out, including autoimmune hepatitis, an obstructive pancreatic lesion and gallstones, more advanced diagnostics were performed. IgG related disease was suspected based on elevated IgG, recent history of pancreatitis and CT imaging findings. However, primary sclerosing cholangitis and cholangiocarcinoma can also present with biliary obstruction. Therefore, tissue samples were obtained from both the gallbladder and mesenteric nodules. This biopsy revealed a plasma cell infiltrate and storiform fibrosis, characteristic histology of IgG disease. IgG related diseases represents a spectrum of disorders that most commonly include autoimmune pancreatitis and IgG related sclerosing cholangitis, but it can affect most other organs. The clinical presentation is variable depending on the organ involved but when it involves the biliary system, it often mimics more common causes of cholecystitis, cholangitis and pancreatitis. While our patient presented without pancreatitis, which occurs in up to 30% of cases of IgG related sclerosing cholangitis, it is likely that his most recent episode represented autoimmune pancreatitis as well.

CONCLUSION: IgG related sclerosing cholangitis is the most common extra-pancreatic manifestation of autoimmune pancreatitis and is an important syndrome for internists to recognize, as it frequently mimics more common manifestations of biliary pathology.

MASSIVE ABDOMINAL WALL HEMATOMA

Eric H. Lee; Andrew Lai. UCSF, San Francisco, CA. (Control ID #3144128)

LEARNING OBJECTIVE #1: To identify abdominal wall hematoma as a hemorrhagic complication of paracenteses.

CASE: A 45-year-old man with decompensated alcoholic cirrhosis presented to the emergency department with abdominal pain following a routine outpatient paracentesis. Physical examination revealed a distended abdomen with diffuse left lower quadrant tenderness. Initial laboratory tests revealed a hemoglobin level of 9.3 grams per deciliter (reference range, 14-18). Computed tomography of the abdomen and pelvis revealed a new abdominal wall hematoma (22 x 9 x 6.5 cm). He was initially admitted to an inpatient medicine wards service for monitoring. However, within 24 hours he was transferred to the intensive care unit for hemodynamic monitoring and large volume blood product transfusions. Due to evolving disseminated intravascular coagulation and new renal replacement therapy requirement, he was transferred to another hospital for expedited liver transplantation evaluation. On arrival, the patient's Model for End-Stage Liver Disease (MELD-Na) score was 39. Repeat imaging (Panel A, black arrow) showed a rapidly expanding hematoma (35 x 28 x 18.5 cm) with abdominal mass effect. He underwent successful embolization of the left inferior epigastric artery, but later developed a spontaneous perihepatic hemorrhage (Panel B, white arrow) that led to hemodynamic collapse. He was subsequently transitioned to comfort care and died five days after transfer.

IMPACT/DISCUSSION: Paracentesis is a core internal medicine bedside procedure. While paracentesis complications are rare (1%), hemorrhagic complications can be life-threatening, especially in those with end-stage liver disease. IR-guided embolization of the inferior epigastric artery may halt hemorrhagic progression.

CONCLUSION: Abdominal wall hematomas are the most common hemorrhagic complication of paracenteses.

MECHANICAL TRICUSPID VALVE THROMBOSIS PRECIPITATED BY INCARCERATION

Daniel Brady; Aaron W. Sweeney. Tulane University School of Medicine, New Orleans, LA. (Control ID #3180130)

LEARNING OBJECTIVE #1: Diagnose mechanical valve thrombosis with appropriate imaging modalities

LEARNING OBJECTIVE #2: Recognize that incarceration can precipitate medical illness

CASE: An incarcerated 36 year old woman presented with acute onset, substernal chest pain. It was constant, sharp and radiated to the left axilla. Taking a deep breath and laying flat made it worse, while sitting forward provided relief. She denied cough, lightheadedness, leg swelling and dyspnea. Medical history included tricuspid valve endocarditis as a result of intravenous heroin use for which she received mechanical valve replacement four years prior. She denied drug use for three years. Her medications included warfarin; however, she was incarcerated four days prior and had not received any medications since. Her physical exam was unremarkable with no murmur or click. Laboratory data was relevant for a subtherapeutic INR and negative serial troponins. Her electrocardiograms had no changes from prior. She was started on a heparin drip. A transthoracic echocardiogram revealed moderate regurgitation and severe stenosis of the tricuspid valve. Leaflet motion was not well visualized; however, a transesophageal echocardiogram the following day revealed immobility

of all leaflets, concerning for prosthetic valve thrombosis. Fluoroscopy was performed and revealed minimal motion of the mechanical leaflets, confirming the diagnosis. She received thrombolytic therapy with tissue plasminogen activator and had subsequent resolution of symptoms. Repeat echocardiogram showed resolution of regurgitation and stenosis. She was discharged on therapeutic Warfarin.

IMPACT/DISCUSSION: This case illustrates the diagnosis and successful management of mechanical tricuspid valve thrombosis. Although there is extensive literature on left-sided prosthetic valvular thrombosis, there is little published and no current guidelines on this same phenomenon for right-sided prosthetic valve thrombosis. The case highlights how different imaging modalities are crucial in confirming the diagnosis. It also demonstrates successful management of this under-reported clinical situation. Limited data suggest that thrombolytic therapy is effective for these patients, as demonstrated by this case. With the rise of the opiate epidemic with concomitant increase in prevalence of infectious endocarditis necessitating heart valve replacement, the investigation into this condition is certainly warranted. The case also highlights flaws in our correctional system. The majority of cases of prosthetic valve thrombosis are due to subtherapeutic anticoagulation, and in this case was directly attributable to the withholding of medication during incarceration. It certainly calls for improvements in the medical management of incarcerated patients.

CONCLUSION: Mechanical tricuspid valve endocarditis is a rare clinical presentation that warrants further investigation. Incarcerated patients are at risk for inappropriate medical management that may lead to serious complications.

MEDIASTINAL GERM CELL TUMOR (MGCT) AS INITIAL PRESENTATION OF KLINEFELTER SYNDROME (KS)

Sarah S. Roderick; Aaron R. Kaufman; Cara Guenther. Boston Medical Center, Boston, MA. (Control ID #3165765)

LEARNING OBJECTIVE #1: Recognize cough, dyspnea, fevers, and weight loss as presenting symptoms of a mGCT in a young and healthy patient.

LEARNING OBJECTIVE #2: Recognize the relationship between KS and the elevated risk of mGCT.

CASE: A 23-year-old man with no prior medical history presented with three months of cough, fevers, chills, night sweats, weight loss and pleuritic chest pain. The patient had immigrated from Colombia ten years ago and was recently exposed to tuberculosis (TB). His exam were notable for mild tachycardia and absent breath sounds in the left lung fields. Chest CT identified a large anterior mediastinal mass with central necrosis, compressive left lung atelectasis, and lateral displacement of the heart and mediastinum. PET CT showed hypermetabolic activity of the mass, the L2 and L4 vertebrae, and multiple lymph node chains. Labs demonstrated a negative interferon-gamma release assay (IGRA) and HIV, normal beta-HCG, and an elevated AFP. The mass was biopsied and pathology was consistent with yolk sac tumor. On testicular exam, the patient was noted to have small testes. Given recent diagnosis of a mGCT, suspicion was increased for underlying KS. Subsequent scrotal ultrasound visualized small volume testes. Labs showed an elevated FSH and LH, low testosterone, and normal estradiol and prolactin. Further testing demonstrated a 47,XXY karyotype, confirming diagnosis of KS. The patient was initiated on ifosfamide/etoposide/cisplatin (VIP). He was subsequently discharged with plan for three additional chemotherapy cycles along with surgical evaluation for possible resection of the remaining mass.

IMPACT/DISCUSSION: With a new diagnosis of mGCT in a young and healthy patient with small testes, it is important to consider the association between KS and increased risk of mGCT.

CONCLUSION: Given symptoms of cough, dyspnea, fevers, night sweats, pleuritic chest pain, and weight loss in an otherwise young and healthy individual from Colombia, TB is high on the differential. However, given the patient's negative IGRA and large mediastinal mass seen on imaging, it's also important not to miss malignancy. In young adult

men, the most common type of mediastinal malignancies is GCT, including nonseminomatous GCT, with yolk sac tumors being the most common. An elevated AFP is present in a majority of patients, while a small minority present with an elevated B-hCG. GCT tends to be metastatic on presentation; therefore, treatment is with chemotherapy (VIP) followed by resection of any residual mass. Prior literature has illustrated that patients with KS are at an elevated risk of developing GCT. The classic phenotype includes tall stature, gynecomastia, small testes, and psychosocial impairments. Interestingly in our patient with karyotype-confirmed diagnosis, the only phenotypic finding was small testes. Identification of KS has importance for fertility counseling, especially in the setting of pre-chemotherapy decision-making (e.g. sperm banking).

MELANOMAS MASQUERADE AS LIPOSOMAS, AND THE MORBID CONSEQUENCES

Matthew Lipinski¹; Diane Herschok². ¹Penn State University at Hershey Medical Center, Hummelstown, PA; ²Penn State University at Hershey Medical Center, Hershey, PA. (Control ID #3185560)

LEARNING OBJECTIVE #1: Describe the variety of clinical presentations of melanoma.

LEARNING OBJECTIVE #2: Discuss the prognosis and treatment for metastatic melanoma.

CASE: A 22 year-old woman presented with several months of multiple progressively enlarging subcutaneous nodules. The week prior to admission, she had also developed diplopia and nausea. She does not go outside often, and uses sunscreen when she does. Two siblings have had biopsy-proven lipomas in the past. There is no history of skin cancer in her family. On physical exam, she had multiple small flesh-colored, freely mobile nodules with irregular borders that were present on her right axilla, left arm, back, and chest wall. There was a large five centimeter flesh-colored nodule on her right scalp. There were two one centimeter blue-pigmented nodules in her left axilla. Skin biopsy of a nodule revealed metastatic melanoma. MRI of her brain revealed a four centimeter lesion in the right occipital lobe with radiographic signs of metastatic melanoma.

IMPACT/DISCUSSION: Skin lesions are encountered frequently by internists, and are a common reason for patients to make an appointment. Superficial spreading melanoma presents as intensely dark macules with irregular borders on the skin surface. This is by far the most common type of melanoma, therefore many physicians associate melanoma only with this presentation. However, melanomas can have multiple colors, or be non-pigmented and resemble subcutaneous nodules. Nodular melanoma, especially when skin-colored, usually has the worst prognosis; this is partly due to delay in recognition. The ABCDEs of melanoma (asymmetry, border irregularity, color abnormalities, large diameter, enlarging rapidly) can be applied to any concerning skin lesion. Any rapidly growing skin lesion warrants a discussion with the patient about potential biopsy. Metastatic melanoma portends a very poor prognosis for patients. Treatments have evolved from the prior poorly efficacious chemotherapy, and now center around immunotherapy with inhibitors of CTLA-4 and the PD-1 receptor. Despite these advances, the overall average prognosis is still approximately two years.

CONCLUSION: Due to its many possible clinical presentations and high morbidity and mortality, internists need to have a high clinical suspicion for melanoma when presented with abnormal skin findings. Treatment options have improved but overall survival is still very poor.

MESENTRIC PANNICULITIS: A RARE CAUSE OF EPIGASTRIC PAIN

Nikita Fernandes¹; Lakshmi Priyanka Mahali¹; Hiliary Hertan². ¹Montefiore Medical Center, Bronx, NY; ²Montefiore Medical Center, BRONX, NY. (Control ID #3185993)

LEARNING OBJECTIVE #1: Expand the differential diagnosis for epigastric pain.

LEARNING OBJECTIVE #2: Diagnose mesenteric panniculitis.

CASE: A 52 year old woman with history notable for gastroesophageal reflux disease, hypertension and cholecystectomy was admitted for severe epigastric pain and bloating that had been worsening over one week. Patient was seen at the Gastroenterology clinic in the past for persistent epigastric pain since two years and patient was treated with proton pump inhibitors (PPI) and sucralfate. Patient had persistent epigastric pain which was refractory to PPI treatment. Patient had not taken NSAIDs in the past. Ultrasonography of the abdomen did not reveal any abnormality. EGD done one year ago revealed gastritis. Computed tomography (CT) of the abdomen and pelvis during this hospital visit revealed mesenteric panniculitis and patient was started on NSAIDs. After receiving treatment with NSAIDs for two weeks, patient improved symptomatically.

IMPACT/DISCUSSION: Mesenteric panniculitis is a rare inflammatory condition characterized by acute and chronic non-specific inflammation of the adipose tissue of the intestinal mesentery. The disease affects Caucasian men more commonly, with a male-to-female ratio of 3:1. Our patient is unique in that she is a woman and she is of Hispanic origin. As of 2016, less than 300 cases have been reported. It may be associated with a variety of conditions such as prior abdominal surgery, malignancy, autoimmune disease, infections and gall stones. Our patient was found to have a history of cholecystectomy for cholelithiasis. The pathogenic mechanism is unknown, however non-specific immune response to a variety of stimuli has been suggested. Clinical presentation is non-specific, but abdominal pain is reported to be the most common symptom. Symptom duration may be twenty-four hours to two years. It presents mainly in the sixth to seventh decade. Clinical examination and laboratory test are usually not helpful in the diagnosis but help to exclude more common conditions. CT scan is the investigation of choice. CT scan may reveal soft tissue masses, prominent lymph nodes, inflammation and/or fibrosis of the mesentery. Treatment options are based on case reports as the condition is rare. NSAIDs, steroids, azathioprine, cyclophosphamide, colchicine, tamoxifen and radiotherapy have been used for treatment of Mesenteric Panniculitis. Spontaneous resolution of the illness has also been reported. Surgery is indicated in those patients with compressive or obstructive symptoms. The disease can resolve and recur spontaneously over the years. The best treatment option is unknown.

CONCLUSION: Most cases of epigastric pain are treated with PPI and patients are advised to avoid NSAIDs. Conversely, NSAIDs are used for treatment of mesenteric panniculitis which also presents as epigastric pain.

METASTATIC LUNG CARCINOMA OF UNKNOWN PRIMARY ORIGIN: IS IMMUNOHISTOCHEMISTRY ENOUGH?

Mario A. Scarpinato¹; Daniel Roadman²; Pakhadi Buddhadev¹. ¹Medical College of Wisconsin, Milwaukee, WI; ²Medical College of Wisconsin, Milwaukee, WI. (Control ID #3186036)

LEARNING OBJECTIVE #1: Unusual presentation of lung cancer

LEARNING OBJECTIVE #2: Use of immunohistochemistry and genetic testing for lung cancer diagnosis

CASE: A 55-year-old male was admitted for acute respiratory distress. Past medical history included hypertension, hyperlipidemia, schizophrenia, and anxiety. Social history was negative for tobacco or alcohol use. Family history was significant for paternal lung cancer at age 50. A chest radiograph showed a white out of the right hemithorax; a chest tube collected 3,700 mL of serosanguinous fluid throughout the admission. The pathology was positive for malignancy: immunohistochemistry (IHC) was MOC-31(+), C22(-), C40(-), calretinin(-) and TTF-1(-). Metastatic workup included a CT chest which identified an anterior mediastinal mass at the right cardiophrenic angle partly invading the suprahepatic inferior vena cava as well as a 3.1 cm spiculated right upper lobe mass. MRI of the brain identified two small brain lesions at the gray-white

junction in each frontal lobe. A PET/CT showed a hypermetabolic anterior mediastinal mass, along with multiple hypermetabolic nodules in the lung and pleural surface. A CT-guided biopsy of the anterior mediastinal mass was positive for metastatic carcinoma, favoring urothelial carcinoma after an IHC staining for GATA-3(+), CK7(+), CK20(+), p40(+), and focal nuclear positivity for TTF-1. A urologic oncologist worked up the suspected urothelial carcinoma with a CT Urogram and cystoscopy without evidence of a primary uroepithelial neoplasm in the genitourinary tract. The patient also had no risk factors for primary urothelial cancer and no urinary symptoms suggesting a urologic primary. The medical oncology team started gemcitabine and cisplatin based on the initial IHC pathology consistent with urothelial carcinoma. However, after just one day of gemcitabine and cisplatin, the patient's genetic testing revealed an EGFR exon 19 deletion, heavily favoring metastatic lung adenocarcinoma. He was switched to osimertinib and has tolerated it well thus far.

IMPACT/DISCUSSION: In diagnosis of metastatic carcinomas of unknown primary origins, the role of IHC helps determine the origin. In this patient, IHC staining of CK7(+)/CK20(+), GATA-3(+), and p40(+) suggested a urinary bladder origin. In this case, IHC was not enough. Without genomic testing, this patient would still be receiving the treatment for metastatic urothelial carcinoma, which can be used for lung adenocarcinoma but is not the best choice in lung cancers with an EGFR mutation. The definitive diagnosis allowed treatment with osimertinib, targeted chemotherapy, which has shown an additional 6-month life expectancy benefit compared to platinum-based chemotherapy.

CONCLUSION: After initial workup, discussion of risk factors and clinical gestalt should not be ignored. This patient had a family history of lung cancer, a positive clinical picture, and no risk factors for urothelial carcinoma. It took the combination of IHC, consultant services, and genetic testing to make the correct diagnosis.

METFORMIN ASSOCIATED LACTIC ACIDOSIS IN A PATIENT WITH CKD

Hayley Crossman; Sarah J. Flynn; Dorothy Rimmelin; Shirin Hemmat; Meghna Motiani. University of California, San Francisco, San Francisco, CA. (Control ID #3186038)

LEARNING OBJECTIVE #1: Distinguish Type A from Type B lactic acidosis

LEARNING OBJECTIVE #2: Recognize management of Type B lactic acidosis due to metformin

CASE: An 85-year-old female with a history of HTN, DM, CKD, and CHF presented with abdominal pain, nausea, and vomiting. Her home medications included glipizide, metoprolol, spironolactone, furosemide, aspirin, and atorvastatin. Vital signs were T 33.3 C, HR 93, R 18, BP 63/40, SpO2 100% on 6L. Physical exam revealed a well appearing elderly woman in no apparent distress. Rest of exam was unremarkable. Labs were notable for WBC 22.8, Potassium 5.8, Bicarbonate 5, Anion Gap 45, BUN 130 and Creatinine 5.66 (from baseline 1.97). VBG showed pH 6.9 and pCO2 24, with lactate of 24. The patient was started on broad spectrum antibiotics and was volume resuscitated. She remained hypotensive and norepinephrine, vasopressin, and epinephrine were required for presumed septic shock. Despite this, the patient's lactate uptrended to 26 and she remained profoundly acidotic. A bicarbonate drip was started with no improvement in pH. CVVH was then initiated. Fifteen hours following the initiation of CRRT, the lactate normalized. Vasopressor requirements resolved and CRRT was discontinued. The patient's renal function continued to improve over the ensuing days.

IMPACT/DISCUSSION: Lactate is generated from glucose metabolism via the glycolytic pathway, and lactic acidosis occurs when lactate production exceeds clearance. Most cases of lactic acidosis are due to marked tissue hypoperfusion and subsequent impaired tissue oxygenation (Type A). This can be seen in cases of hypovolemia, heart failure, and sepsis. By contrast, Type B lactic acidosis is characterized by toxin-induced

impairment of cellular metabolism. In these cases, evidence of systemic hypoperfusion are absent. There are several causes of this, including diabetes, malignancy, alcoholism, HIV, beta-adrenergic agonists, and mitochondrial dysfunction. Our patient had metformin associated lactic acidosis (MALA), a rare clinical entity thought to occur due to decreased gluconeogenesis from alanine, pyruvate, and lactate. The incidence of MALA is estimated as 4.3 cases per 1000,000 patient years. Symptoms, as seen with our patient, are non-specific and include anorexia, nausea/vomiting, abdominal pain, lethargy, and hypotension. Overdoses of metformin or pre-existing renal insufficiency are at risk factors for developing MALA. Mortality is estimated at 45%. In cases of suspected MALA, metformin should be promptly discontinued. No antidotes to metformin toxicity exist. Supportive care with bicarbonate therapy should be initiated. Extracorporeal removal is considered in those who fail to improve or those in whom pH <7.0 or lactate >20. Hemodialysis is preferred to CRRT in MALA, as it promotes rapid clearance of lactic acid. CRRT should be reserved for hemodynamic instability.

CONCLUSION: Metformin associated lactic acidosis is a rare entity with high mortality; management may require extracorporeal removal.

METHEMOGLOBINEMIA & MULTI-ORGAN PIGMENTATION IN PHENAZOPYRIDINE OVERUSE

Alicia Cowley^{2, 1}; David Wei^{3, 1}. ¹New York University, New York, NY; ²NYU Langone Tisch Hospital, New York, NY; ³NYC Health + Hospitals/Bellevue, New York, NY. (Control ID #3160224)

LEARNING OBJECTIVE #1: Recognize methemoglobinemia & its sequelae

LEARNING OBJECTIVE #2: Recall medications that confer risk of iatrogenic methemoglobinemia & treatment

CASE: An 89-year-old woman was admitted with abdominal discomfort plus five days of dysuria and urinary frequency. Previously, she had seen a urologist for chronic dysuria and was prescribed estrogen cream for vaginal atrophy. On admission, her vital signs were notable for oxygen saturation of 88%, unresponsive to oxygen supplementation. Other clinical findings included jaundice, right upper quadrant and suprapubic tenderness, anemia (hemoglobin 8 g/dL), serum creatinine 2.2 mg/dL, unremarkable liver function testing and ultrasound imaging, plus a urinalysis consistent with a urinary tract infection (UTI). Her chest X-ray was unremarkable and an arterial blood gas (ABG) obtained off of oxygen demonstrated normal partial pressure of oxygen (PaO₂). Given the discrepancy between oxygen saturation on pulse oximetry and PaO₂, methemoglobinemia was suspected. Co-oximetry revealed oxyhemoglobin 70%, methemoglobin >21%. The patient denied recent benzocaine, nitrates, or dapsone use, but eventually disclosed taking phenazopyridine for several weeks prior to admission. Intravenous methylene blue was administered, ceftriaxone was given for her UTI, and supportive care was provided until her clinical status returned to baseline.

IMPACT/DISCUSSION: Methemoglobinemia, a condition whereby functional anemia and tissue hypoxia are precipitated by acutely elevated methemoglobin concentration, is often iatrogenic. Non-specific symptoms plus anemia and acute kidney injury (AKI) can be mistaken for many ailments, highlighting the importance of thorough medication review and having a high index of suspicion when there is a recent use of medications such as oxidizing agents (e.g. topical anesthetics, dapsone), nitrates, phenytoin, or antimalarials. The pathophysiology of acute respiratory distress in methemoglobinemia relates to the reduced erythrocyte oxygen-carrying capacity of functionally impaired hemoglobin. Skin discoloration, hemolytic anemia, and AKI have also been associated with phenazopyridine toxicity. The pathophysiology of AKI is still being investigated but may be multifactorial, including renal tubular epithelial cell injury, heme pigment-induced nephropathy from hemolytic anemia, and hypoxic injury from methemoglobinemia itself.

CONCLUSION: Methemoglobinemia presents with non-specific symptoms (e.g. headache, dizziness, dyspnea, fatigue, mental status changes). When a patient exhibits hypoxia unresponsive to supplemental oxygen, chocolate-brown hued arterial blood, and a discrepancy between pulse oximetry and ABG, methemoglobinemia should be at the top of one's differential. History-taking should include a thorough medication review (including over-the-counter agents) and chemical exposures. Once the diagnosis is confirmed with co-oximetry, methylene blue and supplemental oxygen should be given when methemoglobin level is greater than 20%.

METRONIDAZOLE-INTRODUCED ENCEPHALOPATHY: A RARE BUT POTENTIALLY IRREVERSIBLE NEUROTOXICITY OF A COMMONLY USED ANTIBIOTIC

Tomohiro Matsumoto²; Hayato Mitaka¹; Osamu Hamada³; Matthew Harrington⁴. ¹Mount Sinai Beth Israel, New York, NY; ²Nerima Hikarigaoka Hospital, Nerima-ku, Japan; ³Takatsuki General Hospital, Takatsuki, Japan; ⁴Icahn School of Medicine at Mount Sinai, New York, NY. (Control ID #3169406)

LEARNING OBJECTIVE #1: - Recognize metronidazole-induced encephalopathy characterized by cognitive and cerebellar dysfunction. - Identify the clinical presentation and MRI findings of metronidazole-induced encephalopathy.

CASE: A 69-year-old man presented to the emergency department with gait disturbance and drowsiness. He was recently hospitalized for cholecystitis complicated by *E. coli*, *K. oxytoca*, and *C. perfringens* liver abscess and bacteremia. He was treated with four weeks of ampicillin-sulbactam and cefmetazole in the hospital followed by levofloxacin 500 mg once daily and metronidazole 500 mg four times daily at discharge, a regimen he had been taking for five weeks prior to presentation. The patient's wife reported four days of unsteady, wide-based gait followed by one day of drowsiness and confusion. On exam, the patient was drowsy and slow in response to verbal commands. Glasgow Coma Scale was E4V4M6. Vital signs were within normal limits. His gait was ataxic and wide-based. Finger-Nose-Finger test showed bilateral dysmetria with intention tremor. Montreal Cognitive Assessment (MoCA) score was 16/30, suggestive of mild cognitive impairment. Complete blood counts, electrolytes, glucose, renal and liver function tests were normal. CT of the abdomen with contrast showed resolution of liver abscess. MRI of the brain showed symmetric, hyperintense FLAIR signals of the cerebellar dentate nuclei, consistent with metronidazole-induced encephalopathy. He was admitted to the hospital. Metronidazole was discontinued. His cognitive and cerebellar symptoms improved. Repeat MRI on hospital day 8 showed complete resolution of the abnormal findings. At time of discharge on hospital day 23 he had persistent impairment of short-term memory and a slightly wide-based gait. At his follow-up visit one week later, his MoCA score remained below normal at 25/30 but his gait was normal.

IMPACT/DISCUSSION: Encephalopathy is a side effect of metronidazole typically reported among patients receiving prolonged courses of the antibiotic. Clinical manifestations include cerebellar dysfunction (75 %), altered mental status (33 %), and seizure (13 %). MRI shows symmetric enhanced FLAIR signals of the dentate nuclei of the cerebellum, a pathognomonic finding of metronidazole-induced encephalopathy. MRI abnormalities may resolve despite persistence of symptoms, as demonstrated by our patient. The majority of patients experience complete resolution of symptoms after discontinuation of metronidazole, but some patients experience permanent neurologic symptoms. Case reports suggest cognitive symptoms and seizures are more likely to completely resolve than are cerebellar symptoms, however our patient experienced the opposite result.

CONCLUSION: - Encephalopathy is a rare side effect of metronidazole, usually associated with a prolonged course of the antibiotic. - Clinicians utilizing prolonged courses of metronidazole should maintain vigilance for the development of cerebellar or cognitive dysfunction in their patients.

MILIARY TB AND A PARADOXICAL REACTION TO TB TREATMENT IN AN IMMUNOCOMPETENT ADULT

Vikas Gampa; Linda Shipton; Eirini Iliaki. Cambridge Health Alliance, Somerville, MA. (Control ID #3176542)

LEARNING OBJECTIVE #1: TB treatment can cause paradoxical reactions in immunocompetent patients

LEARNING OBJECTIVE #2: Miliary TB can occur in immunocompetent patients

CASE: Mr. D is a 24 y/o M with no PMH, who presented with fevers, weight loss, cough, and headache. He was born in Somalia, and had recently traveled to Africa. Physical exam was unremarkable. Initial work-up showed CXR normal, and labs showed mild transaminitis. He was without signs of immunosuppression (HIV negative, CBC unremarkable). Ultrasound of the abdomen showed hypoechoic lesions in the liver; MRI showed innumerable lesions in the liver and spleen. CT chest notable for prominent right hilar lymph nodes. Head CT and LP were unremarkable. Pathology of liver biopsy was unremarkable. A mediastinal lymph node biopsy showed necrotic lymph node and acid-fast bacilli. He was diagnosed with miliary tuberculosis, with concern for resistant TB. He was started on TB treatment, including moxifloxacin given risk for resistant TB; cultures showed a pansensitive organism. One month later, he had new cough and dyspnea; CT scan of the chest showed new cervical and mediastinal lymphadenopathy, and endobronchial lesions. Pathology revealed bronchial mucosa with chronic inflammation, without mycobacterium. The presentation was consistent with a paradoxical reaction to TB treatment. He was treated with prednisone with successful resolution of his symptoms; however, after the completion of 3 month course of steroids, he developed recurrent cough and dyspnea and was diagnosed with recurrent paradoxical reaction with increase in size of lymph nodes and endobronchial lesions, which caused right middle lobe collapse. Steroids were restarted; he also underwent bronchoscopy with lesion debridement with cryoextraction, and recannulization of RML bronchus. Tissue culture was negative for growth of AFB, fungi or other organisms. Pathology showed rare AFB and necrotizing granulomatous inflammation. He was started on an extended course of prednisone and an extended course of TB therapy.

IMPACT/DISCUSSION: Miliary tuberculosis is a rare presentation and occurs most often in immunosuppressed patients. Paradoxical reactions are defined by the radiographic or clinical development of new lesions or pre-existing tuberculous lesions when treated with TB treatment. Paradoxical reactions are rare and some case series have identified immunosuppression as a potential risk factor for its development. This case represents an unusual occurrence in which underlying immunosuppression did not play a significant role in the development of disease.

CONCLUSION: Miliary TB and paradoxical reactions to TB treatment can rarely occur in HIV-negative patients. Paradoxical reactions can result in significant morbidity or mortality. The pathophysiology is unknown; however, patients who have paradoxical TB reactions may have some underlying immunosuppression. Our patient may yet have an underlying immunosuppressive disorder, given the miliary TB and paradoxical reactions.

MIND ALTERING SUBSTANCE: AN ELECTROLYTE STORY

Jonathan Chang. Tulane University School of Medicine, New Orleans, LA. (Control ID #3185245)

LEARNING OBJECTIVE #1: Recognize electrolyte abnormalities as a cause of altered mental status

LEARNING OBJECTIVE #2: Differentiate the causes of hypercalcemia in malignancy

CASE: A 79-year-old woman with history of metastatic lung adenocarcinoma presented with one day of altered mental status. Vital signs were normal. The patient was somnolent with speech limited to incomprehensible mumbling but aroused to loud voice and followed commands

intermittently. At baseline, the patient was fully oriented and functionally independent. Laboratory studies showed serum calcium of 13.3mg/dL, phosphorus of 6.3mg/dL, acute kidney injury with creatinine of 2.4mg/dL, and lactic acid of 4.2mmol/L. Parathyroid hormone (PTH) was undetectable, 1,25-dihydroxyvitamin D was low, and parathyroid hormone-related peptide (PTHRP) was negative. CT head without contrast was negative for hemorrhage or mass but revealed multiple new osteolytic skull lesions. EEG demonstrated diffuse slowing without epileptiform activity, compatible with toxic-metabolic encephalopathy. Lumbar puncture was unsuccessful, but the patient became fully oriented by the next day and refused a repeat attempt. The hypercalcemia and other abnormalities resolved with aggressive hydration, calcitonin, and pamidronate. Empiric antibiotics for meningitis were discontinued after 24 hours as she exhibited no signs of acute infection and had returned to baseline mental function. She was discharged several days later.

IMPACT/DISCUSSION: Hypercalcemia of malignancy is an important consideration for the general internist as it is by far the leading cause of symptomatic hypercalcemia. This process affects 20-30% of all cancer patients and portends a worsening prognosis. It is predominately caused by tumor secretion of PTHrP (80%) or direct bone release from osteolytic metastasis (20%). In Hodgkin lymphoma, hypercalcemia almost exclusively results from excess 1,25-dihydroxyvitamin D. Paraneoplastic PTHrP production, known as humoral hypercalcemia of malignancy, is mostly associated with squamous cell carcinomas and carcinomas of the breast, kidney, bladder, and ovary. PTHrP has significant homology with PTH and drives calcium resorption from the bone and renal tubules as well as urinary phosphorus excretion. Osteolytic metastasis is particularly common in breast carcinomas and multiple myeloma. Bone breakdown is mediated by cytokines that stimulate osteoclast activity, causing concurrent phosphorus elevation. With low PTH, negative PTHrP, and low-to-normal vitamin D levels, clinicians should consider imaging studies and serum/urine protein electrophoresis to evaluate for bony metastases and monoclonal gammopathies.

CONCLUSION: Hypercalcemia of malignancy is the most common cause of symptomatic hypercalcemia. Imaging studies to assess for bony metastasis should be considered with low PTH, negative PTHrP, and low-to-normal vitamin D levels.

MIND THE GAP: AN UNUSUAL CASE OF DYSPNEA IN A RENAL TRANSPLANT PATIENT

Ann Wang; Samuel Rednor; Sumit Kapoor. Montefiore Medical Center, Bronx, NY. (Control ID #3186228)

LEARNING OBJECTIVE #1: Recognize a potentially fatal but interventional cause of hypoxia in patients taking dapsone.

LEARNING OBJECTIVE #2: Treat symptomatic methemoglobinemia.

CASE: A 51-year-old woman presented with shortness of breath and fatigue. She had a history of lupus nephritis, and two weeks prior to presentation had received a renal transplant and was started on immunosuppressive and prophylactic medications. Physical exam revealed a fatigued and cyanotic-appearing woman with clear breath sounds. Her oxygen saturation on room air was 87%. Labwork was significant for creatinine of 4.8 mg/dl. Non-contrast computed tomography of the chest was negative for infiltrate or edema. A ventilation-perfusion scan was negative for pulmonary embolism. She was placed on high-flow nasal cannula and then BiPAP. However, pulse oximeter continued to read 87-89%. An arterial blood gas (ABG) was then drawn, revealing pH 7.49, pCO₂ 31mmHg, pO₂ 184 mmHg, and methemoglobin of 17%. The patient received methylene blue intravenously, with rapid improvement in dyspnea. Of note, she had previously tested normal for G6PD. Within 24 hours, repeat ABG showed methemoglobin of 9.2% and pulse oximeter read 97% on 2L/min nasal cannula. Dapsone was discontinued and atovaquone started for PJP prophylaxis.

IMPACT/DISCUSSION: Methemoglobin is formed when the ferrous iron in hemoglobin becomes oxidized to ferric iron, which is unable to bind or deliver oxygen. Methemoglobinemia can be congenital or acquired. Clinically, patients present with dyspnea, cyanosis, fatigue, lethargy, and lightheadedness. The "saturation gap" is classic, where pulse oximeter reads 87-88%, and ABG reveals a normal or increased pO₂. Symptoms typically are present with methemoglobin levels of >10%. At methemoglobin levels >30%, patients may experience respiratory depression, coma, seizures, and death. Dapsone is the most commonly implicated agent in drug-induced methemoglobinemia, although the true incidence of dapsone-induced methemoglobinemia is not well documented. In one study of renal transplant patients at a tertiary care center, over 20% developed symptomatic methemoglobinemia with a mean of 66 days on dapsone. The incidence can be expected to increase as the number of organ transplant recipients increases. The renal transplant population may be especially vulnerable as dapsone and its metabolites are renally excreted. Patients with methemoglobin levels >20%, or who are symptomatic at lower levels, should be treated with IV methylene blue. The causative agent should be discontinued. For patients with reduced renal function on dapsone, clinicians may consider periodic monitoring of methemoglobinemia levels, or preemptively using alternative agents for PJP prophylaxis.

CONCLUSION: Dapsone is the most common cause of drug-induced methemoglobinemia. Methemoglobinemia should be suspected in patients with unexplained hypoxia and a saturation gap. Patients with symptomatic methemoglobinemia or methemoglobin levels exceeding 30% should be treated with the administration of methylene blue.

MIND THE GAP: DIABETIC KETOACIDOSIS MASKED BY HEMODIALYSIS

David Staudt¹; Deepa R. Nandiwada². ¹Hospital of the University of Pennsylvania, Philadelphia, PA; ²University of Pennsylvania, Ardmore, PA. (Control ID #3181591)

LEARNING OBJECTIVE #1: To recognize the confounding impact of hemodialysis (HD) on the metabolic parameters used for diagnosis of diabetic ketoacidosis (DKA)

LEARNING OBJECTIVE #2: Critically analyze a differential when there is a discordance between a suspected illness script and diagnostic labs

CASE: A 66 year old woman with a history of type 1 diabetes mellitus (T1DM) complicated by end-stage renal disease presented via ambulance from her dialysis center after 3.5 hours of HD with somnolence. Prior to treatment she had endorsed two days of fatigue and abdominal discomfort. On presentation she was able to confirm that she had missed her insulin for 2 days due to feeling unwell. Vital signs at presentation were unremarkable and her exam was notable for confusion, an ability to answer only simple questions, paradoxical lip smacking, and mild abdominal tenderness. Initial laboratory studies were notable for a glucose of 180, venous pH of 7.43, bicarbonate of 25 mmol/L, anion gap of 24 (from a baseline of 14), a normal lactate, and a urinalysis with 2+ ketones. Serum beta-hydroxybutyrate was elevated to 5.66 mmol/L (normal < 0.27). The patient was admitted to the medicine service for altered mental status of unclear etiology. Given her history of missed insulin, abdominal pain, and altered mental status with presentation immediately following dialysis, masked DKA was suspected. With administration of insulin and fluids her abdominal pain, mental status, paradoxical movements, and anion gap improved to her baseline.

IMPACT/DISCUSSION: In this case, our patient presented with clinical symptoms matching the illness script for DKA- missed insulin, abdominal pain, and neuroglycopenic symptoms. However the diagnosis was initially not considered because her laboratory studies did not meet technical criteria for DKA despite her significantly elevated beta-hydroxybutyrate and anion gap. Given her presentation this was likely an effect of dialysis treatment which can normalize glucose levels and mask the metabolic acidosis of DKA by creation of a secondary metabolic alkalosis from bicarbonate-

containing dialysate. This phenomenon has been noted in the past.¹ In fact, dialysis has been used to treat refractory cases of DKA, as it can effectively correct acidosis and improve glycemia.^{2,3} This case is an example of a discrepancy between an illness script (DKA) and laboratory studies likely created by dialysis. In patients with end stage renal disease, clinicians should scrutinize seemingly normal laboratory studies and consider dialysis' modifying effect on diagnostics prior to excluding a diagnosis.

CONCLUSION: -When a discrepancy exists between a clinical presentation and laboratory testing, clinicians need to consider the confounding effect of other factors including dialysis -Clinicians should critically assess their differential of seemingly normal labs in patients who recently received dialysis.

MISUNDERSTOOD AND MISDIAGNOSED: A CASE OF CATATONIA IN A WOMAN WITH UNKNOWN MEDICAL HISTORY

Kathryn Leyens²; Jill Allenbaugh¹. ¹Temple University, Philadelphia, PA; ²University of Pittsburgh, PITTSBURGH, PA. (Control ID #3182482)

LEARNING OBJECTIVE #1: Define the prevalence of catatonia

LEARNING OBJECTIVE #2: Identify the presenting symptoms and treatment of catatonia

CASE: A 35-year-old female with a history of bipolar disorder, depression, and mild mental retardation presented as a transfer from an outside hospital with altered mental status. The patient was minimally interactive, perseverative, and anxious. Limited past medical history was obtained by family members over the phone. Additional medical records were not available as the patient had been living out of state. Her family reported she had returned home after the recent death of her father, and she had been restricting her diet and seemed increasingly depressed. On admission she was hemodynamically stable, with labs remarkable for hypokalemia and UA with ketones. Urine drug screen, chest x-ray, and non- contrasted CT of her head were unremarkable. After ruling out common toxic, metabolic, and infectious causes for her altered mental status, the focus shifted to her refusal to eat and repetitive hand movements. Catatonia was discussed as a potential cause based on these presenting symptoms and she was given 1mg of lorazepam. Within ten minutes, she became more alert, interactive, and resumed oral intake. She was subsequently started on lorazepam 1mg BID and was transferred to the psychiatric hospital for further management.

IMPACT/DISCUSSION: This case presented the challenge of managing a patient with unclear past medical history, and inability to participate in her care. The inclusion of catatonia in our differential helped to quickly make an accurate diagnosis and administer the appropriate treatment. Although not commonly included as a differential diagnosis, catatonia is an important consideration. The prevalence of catatonia is reported as high as 38 percent in psychiatric patients. Many of the symptoms of catatonia are non-specific and may be mistaken for other conditions; however, there are certain findings that should prompt the clinician to consider catatonia as a diagnosis. These signs and symptoms include: verbigeration, echolalia/echopraxia, mutism, posturing, perseveration, excitement, and impulsivity. Recognition of these psychomotor symptoms and administration of the appropriate treatment improves the outcome for patients with catatonia. There are various rating scales that can be used to help aid in the identification of catatonia which include and are not limited to the Bush-Francis Catatonia Rating Scale and the Bräunig-Catatonia Rating Scale. If there is suspicion for catatonia, treatment should be considered. Prognosis is good, and lorazepam can induce remission up to 79% of the time. In the setting of catatonia that is refractory to lorazepam, there are other treatments including amantadine, zolpidem, and electroconvulsive therapy.

CONCLUSION: Catatonia is prevalent and can be present in more than 1/3 of psychiatric patients. Therefore, it should be included in the differential, particularly when a patient has characteristic psychomotor symptoms.

MIXED BACTERIAL AND FUNGAL INFECTION IN A CASE OF EFFUSIVE CONSTRICTIVE PERICARDITIS IN ESRD

Satyaki Chakrabarty²; Aya Shnawa¹; Michael Maysky². ¹Jordan University of Science and Technology, Irbid, Jordan; ²St. Elizabeth's Medical Center, Tufts University School of Medicine, Boston, MA. (Control ID #3184704)

LEARNING OBJECTIVE #1: Careful assessment of etiology in pericarditis in patients with end-stage renal disease.

LEARNING OBJECTIVE #2: Management of effusive constrictive pericarditis due to Candidal infection of pericardium.

CASE: A 79 year old male with a past medical history significant for end stage renal disease and hypertension experienced an episode of near syncope during a hemodialysis session. Vital signs included a body temperature of 98.2 F, blood pressure of 74/60 mmHg, heart rate of 119 beats/min, respiratory rate of 24/min and oxygen saturation of 90% on room air. Physical examination was notable for muffled heart sounds along with jugular venous distension which increased on inspiration. Initial laboratory findings were significant for: white blood cell count of 16,100/mm³ with 87.0% neutrophils; BUN, 31 mg/dL ; serum creatinine, 5.5 mg/dL; lactic acid, 2 mmol/L; NT pro B-NP, 4380 pg/mL. There was no evidence of growth on blood cultures. An Echocardiogram showed evidence of pericardial effusion along with diastolic collapse of the right atrium and ventricle, suggesting tamponade physiology. A right heart catheterization confirmed equalization of intracardiac pressures after which 675 mL of serosanguinous pericardial fluid was removed through pericardiocentesis. Right atrial pressure remained elevated at 28 mm Hg, confirming an effusive-constrictive physiology. Pericardial fluid demonstrated heavy growth of *Candida albicans* along with many white blood cells. A further 400 mL was removed though a pericardial drain. The patient's clinical condition improved significantly and he was started on an oral regimen of Flucanazole and Colchicine, which he continued for 6 weeks. Prior to his follow up, we noted that the pericardial fluid was also growing *Mycobacterium avium*. At follow up, a repeat Echocardiogram showed complete resolution of the pericardial effusion and we decided to refrain from further medical therapy.

IMPACT/DISCUSSION: Purulent pericarditis caused by *Candida* species is a rare condition with high mortality rates despite treatment. Our patient was immunocompromised due to his ESRD and Candidal infection of an already uremic pericardium added more insult to injury. What was unusual in this case is the concomitant infection with *M. avium*. Tuberculosis happens to be a frequent cause of ECP in immunosuppressed patient populations. Our patient's clinical condition resolved with just large volume pericardiocentesis, anti-fungal therapy and anti-inflammatory therapy, negating the need for pericardectomy.

CONCLUSION: To our knowledge, this is the first reported case of ECP caused by mixed bacterial and fungal infection in a patient with ESRD. This argues towards careful assessment of etiology while treating pericarditis in chronic kidney disease. Also, we demonstrate how candidal infection of the pericardium can be successfully treated with oral fluconazole and percutaneous drainage.

MORE THAN DIABETIC NEUROPATHY: A PINS AND NEEDLES CASE OF ANTI-LGI1 AND ANTI-CASPR2 ASSOCIATED LIMBIC ENCEPHALITIS

Sagar Wagle; Simarjeet S. Lamba; Ali Saadi; Eliith Martinez. UCSF Fresno, Fresno, CA. (Control ID #3183723)

LEARNING OBJECTIVE #1: Recognize clinical manifestations of anti-LGI1 and anti-CASPR 2 limbic encephalitis.

LEARNING OBJECTIVE #2: Identify treatment modalities for limbic encephalitis.

CASE: A 78-year-old male with diabetic neuropathy presented with worsening neuropathic pain with stocking-glove pattern. Further history

revealed a 30 lb weight loss over 3 months. CT Chest was notable for a 4 cm thymoma. The thymoma was resected resulting in partial resolution of neuropathic symptoms. Six weeks later, the patient was re-admitted for generalized weakness, confusion, visual hallucinations, and agitation. Vitals were unremarkable and exam was notable for bilateral temporal wasting. He had slurred speech, was oriented only to self, and had poor short-term memory recall. Strength was intact. Workup including MRI brain, EEG, EMG, and lumbar puncture were unremarkable. Serum antibodies were positive for anti-CASPR 2 (contactin-associated protein-like 2) at 1:160 titer, anti-LGI1 (leucine-rich glioma-inactivated1) at 1:10 titer, and VGKC (voltage-gated potassium channel) at 257 pmol/L (normal < 80). The patient received 5 days of methylprednisolone 1g daily followed by 5 sessions of plasmapheresis. He had resolution of confusion, hallucinations, and neuropathy.

IMPACT/DISCUSSION: Limbic encephalitis is an autoimmune inflammation of the limbic system. It usually occurs as a paraneoplastic syndrome and can precede a diagnosis of malignancy. Clinical manifestations of anti-LGI1 positive limbic encephalitis include seizures, psychiatric symptoms, neuropathy and memory problems. MRI findings include signal changes in the temporal lobe and hippocampus. Immunotherapy (IVIG, steroids, and plasmapheresis) remains the mainstay of treatment. Most anti-CASPR 2 positive patients with limbic encephalitis are elderly male and thymoma is the most common tumor. Patients with tumor have symptomatic recovery after surgery or chemotherapy, and patients without tumor often have recovery after immunotherapy. With an annual incidence of less than 1 in one million, this case contributes to the literature of autoimmune encephalitis given its broad clinical presentation before a diagnosis is made. While most anti-CASPR 2 patients have full neurological recovery after tumor resection, our patient had transient improvement and subsequent encephalopathy. His symptoms improved only after immunotherapy was started. Currently, there are no set treatment guidelines. Further investigation is required to assess the benefit of sequential use vs concomitant administration of steroids with PLEX. While some providers add other immunotherapies including rituximab and cyclophosphamide, our patient will continue with plasmapheresis in the outpatient setting.

CONCLUSION: Limbic encephalitis presents with memory loss, confusion, seizures, and psychiatric symptoms like personality change, irritability, anxiety, and depression. Its treatment includes immunotherapy and treatment of underlying malignancy (if present).

MULTIPLE ABSCESSSES AND RED HERRINGS

Stephen Sexauer; David O'Dell; Michael P. Smith. University of Nebraska Medical Center, Omaha, NE. (Control ID #3186340)

LEARNING OBJECTIVE #1: Develop an evaluation and treatment approach to multiple abscesses

LEARNING OBJECTIVE #2: Recognize the *Streptococcus anginosus* group as the potential causative agent for multiple abscesses and common treatment pitfalls

CASE: A 52 year-old man presented with fevers, intractable headaches, photophobia, and SOB that had progressed over the period of one week. He had a history of psoriasis treated with etanercept and who worked as a pig butcher and had a pet squirrel. He was afebrile and hemodynamically stable. There was nuchal rigidity, however, the remainder of the physical exam was unremarkable, including a clear oropharynx. Brain MRI revealed small cerebral abscess and Chest X-ray revealed a lower lobe cavitary lesion. He underwent lumbar puncture that revealed elevated protein, consistent with a viral meningitis. He was treated supportively. He subsequently underwent CT of his chest to further evaluate the lesion seen on Xray which confirmed the presence of an abscess. He was started on empiric coverage for Nocardiosis with ceftriaxone and his headaches were treated symptomatically. He underwent lung abscess biopsy which was unrevealing and did not grow any organisms. He failed to improve symptomatically after several

weeks of antibiotic therapy so he subsequently underwent brain abscess biopsy and drainage which grew *Streptococcus intermedius*. Antibiotics were targeted to the cultured organism based on culture and sensitivity data and he was treated with a prolonged course of TNP-SMX. He underwent oral panoramic x-ray which revealed multiple periapical abscesses and was referred for outpatient tooth extraction.

IMPACT/DISCUSSION: An abscess is a common problem for the general internist in both the hospital and outpatient setting. Developing a systematic approach to how an abscess should be managed can help expedite appropriate diagnosis and treatment. Commonly abscesses are presumed to be *staph aureus* or other *staph* species. *Streptococcus intermedius* is an aerotolerant anaerobic bacterium that is commensal oral flora but has been implicated in disseminating and forming brain and liver abscesses, especially in immunocompromised hosts. It is a member of the *Strep anginosus* group that also include *Strep anginosus* and *Strep constellatus*. *S. anginosus* and *S. intermedius* are more likely to have altered penicillin binding proteins leading to resistance to beta-lactams. Vancomycin is a suitable alternative. It is important to be aware of these treatment implications as this group of organisms are known to cause abscesses in areas that are difficult to biopsy including the brain, thoracic cavity, and abdominal cavity. Some members of the *S anginosus* group can also produce superantigens leading to necrotizing complications, making prompt recognition even more important.

CONCLUSION: General Internists must consider *S. intermedius* in their diagnostic approach to patients with abscesses and with history of immunomodulators, which are increasingly more common in today's age of targeted biologic therapies.

MURINE TYPHUS: A FLEA-TING DIAGNOSIS

Adam J. Klein; Steven Klemow. Methodist Dallas Medical Center, Dallas, TX. (Control ID #3184346)

LEARNING OBJECTIVE #1: Recognize clinical features and risk factors for murine typhus

LEARNING OBJECTIVE #2: Recognize changing patterns of endemic infections

CASE: 29 year old female with no significant past medical history presented with fever, nausea, vomiting. Patient stated that symptoms started 1 month ago with a prodrome of headache, photophobia and flu like symptoms, which had resolved, but fevers persisted. She had a max temperature of 104 degrees F with worsening fatigue and lethargy which prompted her presentation to this hospital. On admission, she denied headache, sore throat, chest pain, dyspnea, abdominal pain, diarrhea, dysuria, arthralgias, myalgias, rash, new medications or drug use. She had no known sick contacts and no recent travel/camping and denied any tick or animal bites. She lives in a rural area with her spouse and pet pig. She had a temperature of 102F, heart rate of 98, blood pressure 107/82 breathing comfortably on room air. There was no lymphadenopathy, lung sounds were clear, no cardiac murmur was appreciated, abdomen was soft and non-tender, and no visible rash or wounds. Labwork revealed WBC 12.1, CRP 157, Procalcitonin 4.21, LDH 1,552, ALT 105, AST 103, Alkaline Phosphatase 137. Rapid influenza, acute hepatitis panel, blood cultures, HIV, RPR and T-Spot were negative. Imaging was non-contributory. Anaplasma, ehrlichia, brucella, CMV, EBV, and fungal studies were negative. *Rickettsia typhi* IgM and IgG antibody by IFA returned at 1:2048 and 1:128 respectively, consistent with a diagnosis of Murine Typhus. Doxycycline was started and her fever defervesced within 48 hours. It was discovered that there was a local *R. typhi* outbreak in the patient's county. Indoxacarb was provided for the patient's pet pig as possible host. 2 weeks after discharge, symptoms had not returned and repeat IgM antibody was 1:512.

IMPACT/DISCUSSION: Murine typhus is a rare bacterial infection caused by *Rickettsia typhi* with a worldwide geographic distribution, and in the United States, predominately in Los Angeles County and southern

Texas. Humans are infected by inoculation of infective flea feces in bite wounds. While worldwide, rats are the main host, in the United States, domestic cats and opossums act as the main host with cat fleas acting as the vector. The cat flea is an indiscriminate feeder and commonly parasitizes many animals of similar size. In a review of outbreaks in south Texas, the majority presented with fever, headache, myalgias, fatigue, rash, thrombocytopenia and elevated hepatic transaminases. Overall there has been an upward trend in the number of reported cases in the north Texas region over the last 5 years. While there are many reasons that can be contributing to the changing epidemiology, this has not been formally studied yet.

CONCLUSION: Murine typhus can be challenging to diagnose due to the non-specific presentation. It is important to recognize the clinical signs as the changing epidemiology pattern will impact physicians outside endemic regions more frequently.

MY WATCH SAYS IT'S TIME TO GO TO THE DOCTOR

John Xie; Sanjin Tunovic. Tulane University School of Medicine, New Orleans, LA. (Control ID #3184073)

LEARNING OBJECTIVE #1: Describe the clinical presentation and diagnosis of hyperthyroidism

LEARNING OBJECTIVE #2: Review recent technology in healthcare assessment and delivery

CASE: A 48-year-old man with recently diagnosed Grave's disease two months prior presented when his Apple watch reported his heart rate was in the 150s. He endorsed mild anxiety, but had no palpitations, tremor, vision changes, weight loss, nausea, vomiting, or abdominal pain. EKG was consistent with sinus tachycardia with a heart rate in the 160s. Labs returned with TSH suppressed with slightly elevated total T4 as well as free T4. The Burch-Wartofsky Point Scale (BWPS) for Thyrotoxicosis was 30 suggesting impending thyroid storm. He was prescribed methimazole and propranolol with improvement in his symptoms.

IMPACT/DISCUSSION: Thyrotoxicosis, a condition caused by excess circulating thyroid hormone, has an estimated prevalence of 0.1-0.5%. Thyroid hormone can affect any organ in the body, which can make diagnosis challenging. Some presentations can be innocuous, such as anxiety and tachycardia, but can also include heat intolerance, palpitations, weight loss, muscle weakness, and diarrhea. If untreated, thyrotoxicosis can increase the risk for atrial fibrillation, congestive heart failure, osteoporosis, and thromboembolism. The most serious complication is thyroid storm, characterized by altered sensorium, and has a high mortality unless treated promptly. Initial tests to diagnose thyrotoxicosis include a suppressed TSH and elevated total and free T4. The Burch-Wartofsky Point Scale (BWPS) for thyrotoxicosis can also be used to estimate the likelihood of thyroid storm based on clinical presentation. Laboratory data is not included in this scoring system. The advent of new mainstream technology in healthcare has the potential to impact which patients seek medical care. In particular, the recently released Apple Watch Series 4 is the first smartwatch to get FDA clearance for EKG monitoring. This device simulates a one-lead EKG by placing electrodes on the back of the watch and in the digital crown. Thus far, the EKG app can only give two heart rhythms - normal sinus and atrial fibrillation. The Apple Heart Study was started in November 2017 to determine if the Apple Watch can accurately diagnose atrial fibrillation. This study included 588 individuals, half with atrial fibrillation and the other half with normal sinus rhythm. The watch algorithm accurately identified 98.3 percent of people with atrial fibrillation, and correctly identified 99.6 percent of people who did not have atrial fibrillation.

CONCLUSION: Low TSH and elevated thyroid hormones establish a diagnosis of hyperthyroidism. The BWPS can estimate likelihood of thyroid storm based on symptom severity, independent of laboratory results. As wearable device technology continues to advance it will likely have an increasing role in disease detection and monitoring in the outpatient setting.

MYCOBACTERIUM IMMUNOGENUM INFECTION PRESENTING AS DISSEMINATED CUTANEOUS INFECTION

Michael Yang²; Ribka Ayana¹. ¹Washington DC VA Medical Center, Washington DC, DC; ²Medstar Georgetown University Hospital, Washington, DC. (Control ID #3184963)

LEARNING OBJECTIVE #1: Recognize the clinical features of non-tuberculous mycobacteria (NTM) infection

LEARNING OBJECTIVE #2: Recognize the diagnostic and treatment challenges associated with Mycobacterium Immunogenum (M. immunogenum) infection

CASE: A 46-year-old man presented with a 3 cm tender, indurated lesion on the left hand five days after injecting IV cocaine into the right arm. He also had discrete, non-tender, non-erythematous nodules on the right forearm and left leg. He was exposed to gardens and fish tanks weeks prior to presentation. He had no fever or leukocytosis. All lesions were surgically drained and cultured, without bacterial growth. He was discharged on Clindamycin but returned two days later with new non-erythematous, rubbery nodules on the right forearm and the left axilla. Infectious disease (ID) was consulted and advised biopsy with AFB and fungal cultures. Mycobacterium chelonae-abscessus group was isolated from the AFB culture. Further gene sequencing at the National Institutes of Health revealed M. immunogenum with resistance to fluoroquinolones, cefoxitin, doxycycline, tobramycin, and TMP-SMX, and intermediate carbapenem sensitivity. The patient received 10 weeks of IV amikacin, meropenem, and azithromycin, followed by 6 week oral course of azithromycin and moxifloxacin.

IMPACT/DISCUSSION: NTM are found in soil, fresh water, and tap water. They include the M. chelonae-abscessus group, M. fortuitum, and M. marinum. M. immunogenum is a NTM first described in 2001 and added to the M. chelonae-abscessus group in 2007. NTM SSTIs have been linked with skin trauma, cosmetic procedures, surgeries, tattoos, piercings, and acupuncture, often in the setting of immunosuppression. The distal extremities are the most common sites of infection. Susceptibility patterns vary by species. M. fortuitum is the most susceptible; M. chelonae-abscessus group is susceptible to aminoglycosides with varying susceptibility to carbapenems, fluoroquinolones, tetracyclines, and linezolid. Widespread penicillin and cephalosporin resistance mitigate their use. Macrolide susceptibility is common, but inducible macrolide resistance exists. Our case adds to the limited number of case reports in literature describing infection with M. immunogenum. M. immunogenum infection can cause substantial morbidity due to clinical under recognition resulting in delayed diagnosis as well as diagnostic challenges as definitive identification requires gene sequencing at a specialized center. Management is further complicated by extensive drug resistance.

CONCLUSION: NTM infection should be considered in all patients in whom bacterial cultures are negative, especially those with distal extremity involvement, immunodeficiency, or the appropriate environmental exposures. M. immunogenum is a difficult-to-treat pathogen. The optimal treatment for disseminated cutaneous M. immunogenum infection remains unknown and is complicated by extensive drug resistance. Management involves AFB culture, ID consultation, where available, and prolonged courses of multiple antibiotics.

MYCOBACTERIUM TUBERCULOSIS IN A PATIENT FROM AN ENDEMIC REGION. WHAT ELSE COULD IT BE?

Behnam Laderian; Takaaki Kobayashi; Jason H. Barker. University of Iowa Hospitals and Clinics, Iowa City, IA. (Control ID #3181737)

LEARNING OBJECTIVE #1: Differential diagnosis in patients suspected to be infected with *mycobacterium tuberculosis*

LEARNING OBJECTIVE #2: Recognize the clinical manifestation, diagnosis and treatment for blastomycosis

CASE: A 33 year-old man from Honduras with no significant past medical history arrived for evaluation of refractory pneumonia. Patient's symptoms of dry cough, malaise, night sweats, and fevers mostly occurring at night started a month prior to presentation. Multiple visits to local emergency room resulted in receiving treatment for community-acquired pneumonia. Patient's symptoms continued despite completing appropriate antibiotics. Upon presentation, computer tomography of the chest was obtained with intravenous contrast revealing extensive pneumonia in the right lung with a collapsed right middle lobe bronchus, extensive mediastinal and hilar lymphadenopathy, and numerous pulmonary nodules. The constellation of patient's symptoms, background, and imaging findings prompted testing for pulmonary tuberculosis (TB). Acid fast bacillus stain of sputum, and PCR were negative for TB. *Blastomyces* urine antigen was elevated at 4.27 ng/mL. *Histoplasma* urine antigen was also mildly positive at 1.91 ng/mL due to cross-reaction. Patient was diagnosed with blastomycosis pneumonia and appropriate treatment was initiated.

IMPACT/DISCUSSION: TB should be considered if a patient from an endemic region presents with fevers, night sweats, weight loss, and respiratory symptoms or refractory pneumonia despite adequate treatment with antibiotics. Once TB has been ruled out, consideration must be given to other causes such as viral infection, fungal infection or even malignancy. Blastomycosis is a systemic pyogranulomatous infection that arises after inhalation of conidia of *Blastomyces dermatitidis*. The fungus lives in the midwestern, south-central, and southeastern states. The clinical manifestations of blastomycosis include asymptomatic infection, acute or chronic pneumonia, and extrapulmonary disease. Symptoms include cough, sputum production, shortness of breath, weight loss, fever, and night sweats. The lungs are the most common site of infection, followed by the skin, bones, and genitourinary system. Chest imaging may show nodules and consolidation with or without cavitation. While culture and cytopathology remains the gold standard for definite diagnosis, the detection of fungal antigen in urine has proven useful. The sensitivity is 89-93%, whereas specificity is 79% due to cross-reaction to histoplasmosis. The antigen level is also useful for evaluating response to treatment. For patients with mild to moderate disease, itraconazole is recommended, whereas severe disease requires amphotericin B. **CONCLUSION:** Blastomycosis can mimic other diseases including community-acquired pneumonia, malignancy or TB and is often misdiagnosed due to the variability of presentation and its relative rarity. A high index of suspicion is needed when the diagnosis is uncertain and patients live in or have traveled to areas endemic for blastomycosis.

MYCOPLASMA PNEUMONIAE INFECTION PRESENTING AS STEVEN-JOHNSON SYNDROME-TOXIC EPIDERMAL NECROLYSIS IN AN ADULT

Ashley Thompson; Minni Shreya Arumugam; Jivan Lamichhane. SUNY Upstate Medical University, Cayuga, NY. (Control ID #3185854)

LEARNING OBJECTIVE #1: Recognize that SJS-TEN is a rare dermatologic manifestation of *Mycoplasma pneumoniae* infection in the adult population

CASE: A 43-year old man with history of smoking and alcohol abuse, and recent upper respiratory illness presented with altered mental status, rash, and severe oropharyngeal bleeding. The patient denied any medication use. Physical exam was notable for maculopapular rash of abdomen with significant desquamation and hemorrhagic bullae of eyelids, nares, oropharynx, extremities, and glans of penis. Vitals were notable for tachycardia, hypertension, and hypothermia. Labs showed leukopenia, thrombocytopenia, mild transaminitis, high-normal lactate, and electrolyte abnormalities. Chest X-ray noted increased interstitial markings. CT chest was remarkable for tree-in-bud appearance and ground glass opacities. *M. pneumoniae* PCR was positive, which was confirmed with positive IgM serology. Other infectious work up was negative. The patient was started on Azithromycin and Prednisone and transferred to the ICU

for management of septic shock. Biopsy revealed erythema multiforme, and Stevens-Johnson Syndrome-Toxic Epidermal Necrolysis (SJS-TEN) overlap syndrome was diagnosed based on body surface area involvement. He eventually underwent a tracheostomy and gastric tube placement. Over five weeks, his respiratory status and cutaneous lesions slowly improved, and he was discharged to a rehabilitation facility.

IMPACT/DISCUSSION: *Mycoplasma pneumoniae* is a well-known cause of mild and self-limited community acquired pneumonia. Extra-pulmonary manifestations, however, are reported to occur in 25-33% of cases, occasionally severe enough to require ICU level of care. While severe rash and mucositis phenomenon are reported to occur in pediatric infections, SJS-TEN is a rarely documented extra-pulmonary manifestation of *M. pneumoniae* infections in adults. Alternatively, SJS-TEN observed in the adult population is most commonly postulated to be due to drug reactions. The educational objective of this case report is to highlight that dermatologic manifestations as severe as SJS-TEN may occur with *M. pneumoniae* infection in adults, which, when recognized early and treated appropriately, can lead to significantly better patient outcomes.

CONCLUSION: This case establishes *M. pneumoniae* as an uncommon etiology of SJS-TEN spectrum in the adult population. Despite several pediatric reports of severe cutaneous manifestations, such as SJS-TEN, associated with *M. pneumoniae* infection, its presentation in adults is not well illustrated in the literature. As such, consideration of this bacterium in the diagnosis and management of the critically ill patient presenting with SJS-TEN can lead to earlier implementation of crucial and necessary treatment, leading to improved patient outcomes.

MYCOTIC ANEURYSM MASQUERADE AS INFERIOR STEMI

Sherman Yu²; Sudhi Tyagi¹; Jorge Saucedo². ¹Medical College of Wisconsin, Wauwatosa, WI; ²Medical College of Wisconsin, Milwaukee, WI. (Control ID #317554)

LEARNING OBJECTIVE #1: Recognize mycotic coronary aneurysms as a complication of infective endocarditis in high risk hemodialysis patients.

CASE: A 60-year old male with ESRD, IV drug abuse and recent massive gastrointestinal bleed was found unresponsive after completing an outpatient hemodialysis session. EMS was dispatched, discovered an inferior STEMI on EKG and transported him to the hospital. On arrival, the patient's MAP was 50mmHg. Inferior STEMI was confirmed. Troponin was elevated at 0.138. IV fluids, vasopressors and naloxone were administered, normalizing the patient's somnolence, hemodynamics and derangements on EKG. Soon after, the patient's mental status again waned, requiring intubation. Repeat EKG again showed inferior STEMI. He was then taken to the cardiac catheterization lab on vasopressors. His left coronary circulation revealed atherosclerosis without acute plaque rupture. Angiography of the RCA revealed a 2cmx3cm ovoid aneurysmatic dilatation near the ostium of the artery which was occluded distally and prevented contrast filling of the RCA. STAT TTE revealed a perforated mitral valve and a possible fistula between the left ventricular outflow tract and left atrium. The patient's MAP dropped to 30mmHg and CPR was initiated. A prompt multidisciplinary conference was held at bedside and the patient was ultimately deemed a poor candidate for further interventions. He died soon after CPR was discontinued due to medical futility. A subsequent review of records from an outside hospital revealed a history of infective endocarditis (IE), severe mitral valve regurgitation and blood cultures positive for *Streptococcus pneumoniae* six months prior to presentation.

IMPACT/DISCUSSION: This case highlights the extraordinarily high risk of IE in hemodialysis patients with a history of IV drug use and bacteremia. Bloodstream infections are the second most common cause of mortality among ESRD patients. Such patients are 25 times more likely to develop a bacteremia compared to the general population. Furthermore,

the severity of illness in ESRD patients is significantly higher, often resulting in prolonged hospital stays. IE is a serious complication of bacteremia, for which dialysis and IV drug use are independent risk factors. Mycotic coronary aneurysms (MCA) are an extremely rare complication of IE, occurring in less than 0.5% of such cases. Various mechanisms may lead to its development: infarction of the vasa vasorum, immune complex deposition, and bacterial invasion of the vessel wall. The prognosis is grave, characterized by high morbidity and mortality. In this patient who presented with an inferior STEMI, we suspect a MCA located in the RCA compressed the arterial lumen leading to acute myocardial ischemia in the setting of decreased preload after a dialysis session, further exacerbated by severe mitral valve regurgitation.

CONCLUSION: IE may be complicated by MCAs and should be recognized in high-risk populations including hemodialysis patients with IV drug use history and prior bacteremia.

MYOCARDITIS IN UNCONTROLLED ADULT-ONSET ASTHMA

Lesley Wu; Misa Hyakutake. Mount Sinai Beth Israel, Manhattan, NY. (Control ID #3161305)

LEARNING OBJECTIVE #1: Recognize and promptly treat eosinophilic myocarditis

LEARNING OBJECTIVE #2: Diagnose eosinophilic granulomatosis with polyangiitis in patients with adult-onset asthma

CASE: A 59-year-old Caucasian man with adult-onset asthma and chronic sinusitis presented to ED with dyspnea that awoke him from sleep. He reported fatigue and dyspnea for a year that significantly worsened in the past month with wheezing upon exertion and dry cough refractory to inhaled steroids. Two weeks prior, patient had an exacerbation that responded well to a short course of oral steroids. He denied chest pain, fever, rash, or edema. Three years prior, he was diagnosed with asthma. Eosinophilia of 1500 was noted for a year without identified cause. Patient had allergies to penicillin and aspirin. He was a never smoker. Vitals and physical exam were unremarkable. Laboratory test showed leukocytosis of 14,400 with eosinophil of 4,500 and troponin of 15. EKG showed loss of R wave in V1-V4. Suspected for myocardial infarction, patient underwent left-heart catheterization, which showed diffuse non-obstructive disease. Transthoracic echocardiogram showed reduced left ventricular ejection fraction (LVEF) of 38% from 58% three years prior. Cardiac MRI revealed diffuse myocardial enhancement with edema. Right ventricle biopsy showed inflammatory infiltrates with prominent eosinophils and myocyte damage consistent with eosinophilic myocarditis. Patient met the diagnostic criteria for eosinophilic granulomatosis with polyangiitis, and intravenous steroids were initiated with immediate symptom alleviation and resolution of eosinophilia and troponin elevation. He was discharged on oral steroids with improvement of LVEF to baseline at one-month follow up. Later, ANCA serology returned within normal values.

IMPACT/DISCUSSION: Adult-onset asthma, dyspnea refractory to asthma treatment, and peripheral eosinophilia should prompt investigation of eosinophilic granulomatosis with polyangiitis.

CONCLUSION: Eosinophilic myocarditis (EM) is a rare yet life-threatening inflammatory complication that accounts for half of the mortality attributable to eosinophilic granulomatosis with polyangiitis (EGPA). The diagnosis of EM requires biopsy to confirm; however, expeditious initiation of systemic glucocorticoids before results of all investigation are available can minimize permanent myocardial damage. Diagnosing EGPA is often difficult because of the sequential nature of clinical manifestations and low sensitivity of laboratory tests. Although ANCA serology is a pathognomonic workup for EGPA, ANCA is only positive in up to 38% of the patients. In fact, cardiac involvement is observed more in ANCA negative patients. The presence of adult-onset asthma refractory to appropriate asthma treatment warrants workup for masqueraders of asthma including EGPA. Our case supports literature that

reported 21 out of 22 EGPA patients had asthma diagnosed during adulthood. Adult-onset asthma could be an additional clue with other clinical findings that raise suspicion for EGPA and EM.

NATIVE VALVE ESCHERICHIA COLI ENDOCARDITIS IN A PATIENT WITH NEWLY DIAGNOSED SYSTEMIC LUPUS ERYTHEMATOSUS

Rachel A. Sibley; Michael Rosman; Verity E. Schaye. NYU Langone Medical Center, New York, NY. (Control ID #3183518)

LEARNING OBJECTIVE #1: Identify non-HACEK gram-negative endocarditis early in its clinical course.

LEARNING OBJECTIVE #2: Recognize the morbidity and mortality of Escherichia coli endocarditis.

CASE: A 54 year-old Hispanic man with no known past medical history presented with one month of constitutional symptoms: unintentional weight loss, anorexia, fatigue, and arthralgias. On admission, he was febrile, tachycardic, and breathing comfortably on room air. The exam was otherwise significant for a thin stature with temporal wasting, thrush, a lateral tongue ulcer, a raised non-blanching erythematous macular rash on sun-exposed areas of the extremities, and erythematous papules on the hands. There were no murmurs detected on cardiac auscultation. Initial labs were significant for anemia and leukopenia. A broad differential diagnosis initially included malignancy, rheumatologic disease, and systemic infection. Work-up revealed positive anti-Smith and anti ds-DNA antibodies, C3/C4 hypocomplementemia, and a pericardial effusion on transthoracic echocardiogram (TTE). He was diagnosed with systemic lupus erythematosus (SLE), and started on hydroxychloroquine and steroids with improvement. On hospital day three, blood cultures grew Escherichia coli (*E. coli*) in four bottles, with an unclear source with aseptic urine and no localizing symptoms. CT scans of the head, chest, abdomen, and pelvis were notable for multiple peripherally located pulmonary airspace opacities concerning for septic emboli. A TTE was negative for vegetation, but given the high clinical suspicion for endocarditis, notwithstanding the rarity of *E. coli* as a pathologic organism, transesophageal echocardiogram (TEE) was pursued. TEE revealed a mobile echodensity on the aortic valve consistent with vegetation. The patient completed four weeks of ceftriaxone to treat *E. coli* endocarditis.

IMPACT/DISCUSSION: *E. coli* bacteremia is common; however, due to decreased adherence of the organism to the endocardium, infective endocarditis from *E. coli* is rare, accounting for 0.51% of cases. Risk factors include immunocompromised states. Our patient was leukopenic from SLE. Sources of infection are often gastrointestinal and urinary. However, as in our patient, initial source is unclear in approximately half of cases. Murmur is often absent, and the disease is more common in native valves than prosthetic or degenerative valves. For these reasons, diagnosis is difficult. One study reported at least one month from onset to clinical diagnosis in 90% of patients with non-HACEK gram-negative endocarditis. However, given its high surgical intervention rate (42%), high complication rate (including heart failure and abscess), and high mortality rate of 21% (drastically higher than the 4% from HACEK gram-negative endocarditis), clinicians should maintain a high degree of suspicion to make this diagnosis early.

CONCLUSION: *E. coli* endocarditis is rare, occurs in immunocompromised patients, and is difficult to diagnose. However, given its high morbidity and mortality, timely recognition is critical.

NECROTIZING FASCIITIS: AN UNUSUALLY COMMON PRESENTATION

Claire Drolen; Emily Sandberg. University of Pennsylvania, Philadelphia, PA. (Control ID #3181518)

LEARNING OBJECTIVE #1: Recognize early clinical presentations of necrotizing fasciitis (NF)

LEARNING OBJECTIVE #2: Incorporate tools to assist in diagnosis of early NF

CASE: A 62-year-old man presented after a syncopal episode. He endorsed two months of weight loss, fevers and night sweats. Past medical history included atrial flutter, prostate cancer with recent brachytherapy, and a recent pulmonary embolism (PE) on Rivaroxaban. Physical exam was notable for fever, tachycardia, and bilateral pitting edema to mid-shin. Labs showed elevated NTproBNP; ECG, echocardiogram and telemetry were unrevealing. CT chest revealed a small, acute PE for which he was started on heparin. On hospital day two he developed scrotal swelling and erythema; exam revealed pitting edema without crepitus or tenderness to palpation. Scrotal ultrasound showed cellulitis for which he was started on Vancomycin and Cefepime given continued fevers. On hospital day four he developed worsening fevers, tachycardia, and increased scrotal swelling, pain and discoloration. CT pelvis showed gas throughout the scrotum and perineum. Antibiotics were changed to Vancomycin, Piperacillin-Tazobactam and Flagyl. He underwent emergent surgical debridement and was found to have a rectoprostatic fistula complicated by Necrotizing Fasciitis (NF). He was discharged one month later and is expected to make a full recovery.

IMPACT/DISCUSSION: NF is a rare, life-threatening infection of the skin, fascia and subcutaneous tissue, with in-hospital mortality as high as 34%. It is typically polymicrobial; *E. Coli* and *Staph* species are isolated in most cases. Early recognition and debridement are major determinants of outcome, however diagnosis is often delayed due to nonspecific initial presentation. Classically NF is red, swollen, frankly necrotic, and exquisitely painful. While fulminant cases can present like this, subacute cases are often less obvious with non-specific fever, fatigue and skin changes that can be mistaken for cellulitis or dependent edema. Pathognomonic findings (bullae, crepitus) occur late and in less than 25% of patients. Localized anesthesia can replace pain if nerve damage has occurred, masking the classic pain out of proportion to exam. Existing risk tools have high diagnostic accuracy and can assist in differentiating NF from other soft tissue infections. Had we used one for our patient, we would have found a 50-75% risk of NF which may have prompted earlier CT imaging and diagnosis. Diabetes, immunocompromise, trauma and local instrumentation, such as our patient's recent brachytherapy, should serve as red flags. Cross-sectional imaging is the diagnostic study of choice; antibiotics and surgical debridement are definitive treatment.

CONCLUSION: Early, non-fulminant NF can present nonspecifically, without skin necrosis or pain out of proportion to exam. A high index of suspicion and use of diagnostic tools facilitate timely diagnosis of sub-acute NF.

NEVER TOO OLD FOR MYASTHENIA

Kyle T. Jones; Roshini Pinto-Powell. Dartmouth Medical School, Hanover, NH. (Control ID #3181205)

LEARNING OBJECTIVE #1: Recognize the changing incidence of myasthenia gravis

LEARNING OBJECTIVE #2: Identify cognitive biases that result in delayed diagnosis or misdiagnosis

CASE: A 74-year-old with a history of asthma, 5 weeks post hip arthroplasty, presented to the ED with 2 days of eye-lid droop, dysarthria and shortness of breath. She noted getting winded when speaking. The rest of her review of symptoms was negative. Post-op course had been uneventful, however she began taking aspirin 3 days prior to presentation. FHx was unremarkable. Meds: aspirin, Symbicort and Albuterol. Allergic to sulfa drugs. On Exam: Afebrile, HR 83, BP 148/61, RR 22, SpO₂ 99%. Mild tongue swelling, left eyelid droop, mild periorbital edema. Lungs clear, no wheezes. Cranial nerves intact, mild dysarthria, normal strength in all extremities. She was thought to have angioedema and asthma exacerbation due to aspirin allergy. Flexible laryngoscopy showed no laryngeal edema. She improved with epinephrine, Benadryl, and IV solumedrol, and was discharged on a 6-day steroid taper, cetirizine,

Benadryl, and a follow-up with Allergy. Five days later, the patient came to GIM clinic with worsening symptoms, including bilateral eyelid droop worse as the day progressed, hoarseness, difficulty swallowing, and SOB. Exam showed bilateral ptosis, and difficulty sustaining upward gaze. Neurology was consulted for suspected myasthenic crisis and the patient was admitted and started on IVIG and pyridostigmine. Nerve conduction studies showed 20% decrement in the right accessory nerve on repetitive stimulation. AChR binding antibody was 5.82 nmol/L (normal <= 0.02nmol/L). CT chest did not show a thymoma. Her symptoms improved and she was discharged on hospital day 5.

IMPACT/DISCUSSION: The classic bimodal epidemiology for Myasthenia Gravis is young women and older men. However, as this case illustrates, the incidence of MG is changing, with an increase in late onset MG (LOMG). Reasons for this changing epidemiology are unclear and may reflect an aging population, improved diagnostics, and environmental factors. LOMG can be difficult to diagnose and requires a high index of suspicion. Studies suggest that ocular MG is more common in LOMG, as seen in this patient. The initial diagnosis in this case demonstrates common cognitive biases that result in misdiagnosis and delayed care. The temporal relationship of symptoms to starting aspirin created a nidus for anchoring bias to an aspirin-related pseudoallergic reaction. Furthermore, the perpetuation of this idea between the treating physicians created diagnostic momentum. On review of the patient's initial symptoms, she had classic signs of ocular and bulbar myasthenia: bilateral ptosis, dysarthria and SOB with speech.

CONCLUSION: The incidence of late onset MG is increasing and should be considered in older patients. Clinicians are subject to cognitive biases that in hindsight are clear. Reviewing cases and exposing these biases can help practitioners become mindful of cognitive errors in an attempt to reduce misdiagnoses.

NEW-ONSET SEIZURES: LOOK FOR A PRECIPITANT, PERHAPS A DRUG?

Mohamed Gabr; Radhika Gali; Dharmarajan S. Thiruvinvamalai. Montefiore Medical Center (Wakefield Campus), Bronx, NY. (Control ID #3183364)

LEARNING OBJECTIVE #1: Identify the etiology of new-onset seizures

LEARNING OBJECTIVE #2: Recognize the culprit medications, including SSRIs, that may precipitate seizures

CASE: A 75 year-old man presented after a first-time, witnessed, generalized seizure. Medical history included hypertension and depression; negative for prior strokes and personal or family history of seizures. Only known medications were aspirin, simvastatin and fluoxetine 40 mg daily. He did not recall symptoms or events that led to the seizure; denied alcohol or drug use. Neurological exam revealed intact motor strength, sensation and cranial nerve functions. His gait was unsteady and the finger-to-nose test was abnormal. Urine and blood toxicology were negative, including ethanol levels. Blood glucose and electrolyte levels were normal, and infectious work-up was negative. CT and MRI of the head revealed chronic microvascular ischemic changes and an old right cerebellar infarct. Transthoracic echocardiogram was normal; carotid ultrasound was negative for stenosis. An electroencephalogram (EEG) did not reveal epileptiform discharges. Fluoxetine was switched to sertraline prior to discharge due to its potential to lower seizure threshold.

IMPACT/DISCUSSION: In the initial evaluation of new-onset seizures, physicians must address personal and family history, history of head trauma, central nervous system (CNS) lesions or infections, childhood seizures, birth injury, and conduct a review of medications. Causes include hypoxia, hypoglycemia, electrolyte abnormalities, infections, drug / alcohol abuse and more. Brain MRI should be performed to rule out structural lesions. EEG helps assess for epileptic seizures, though the likelihood of routine EEG recording epileptiform discharges is 25-50%. Lumbar puncture is

done when CNS infection is a possibility. Several medications may lower seizure threshold, including bupropion, tramadol, quinolones, imipenem, penicillins, meperidine, and SSRIs. SSRIs have the ability to induce seizures, especially with chronic use and in higher doses; the exact mechanism is unknown. Fluoxetine, with a long half-life, should be used with caution in the elderly and in those with kidney disease.

CONCLUSION: In our patient's case, his only known medications were aspirin, simvastatin, and fluoxetine 40 mgs/day. Prolonged use of fluoxetine in a high dose was acknowledged as a potential inciting agent for his seizure. Drugs must be a consideration as inducing factors with new onset seizures, warranting meticulous screening of medications.

NIFEDIPINE-INDUCED SHOCK IN 18 WEEK GRAVIDA WITH CONGENITAL AORTIC STENOSIS

Cullen Soares; Michael Gilson. Brown University, Providence, RI. (Control ID #3183795)

LEARNING OBJECTIVE #1: Understand the clinical importance of diagnosing aortic stenosis in pregnancy

CASE: The patient is a 31 year-old G6P2032 at 18 weeks with a history significant for moderate stenosis secondary to a bicuspid aortic valve. Her current twin pregnancy was uncomplicated until 2 weeks prior to admission when she was diagnosed with twin-twin transfusion syndrome (TTTS). On her day of presentation she had an uncomplicated ablation of placental vessels for TTTS. She received two doses of short-acting 20mg nifedipine over 30 minutes (standard prophylactic tocolytic dose) and developed hypotension (BP 80/40), chest pain, and diffuse ST segment depressions on ECG. She was started on intravenous phenylephrine and transferred to the cardiac care unit. Exam was notable for a harsh mid-peaking systolic murmur radiating to the carotids, elevated venous pressures, and normal perfusion. Phenylephrine was switched to norepinephrine and she received two liters of lactated ringers with calcium gluconate. Bedside echocardiogram showed hyperdynamic ventricular systolic function (Ejection Fraction 78%) and moderate aortic stenosis. Lactate was normal, and peak troponin was 4.2. Indomethacin was started for tocolysis. Over 8 hours, blood pressures improved to baseline and she was weaned off pressors. ECG normalized and chest pain resolved. She was discharged to home with follow up with high risk pregnancy clinic and cardiology.

IMPACT/DISCUSSION: Dihydropyridine calcium channel blockers cause peripheral vasodilation, reduced cardiac contractility, and reduced aldosterone production, which together reduce blood pressure. Nifedipine is the preferred tocolytic due to its efficacy in suppressing uterine contractions. It is also the most potent dihydropyridine antihypertensive. Its use in tocolysis is common and generally well-tolerated, but studies show it still lowers blood pressure when used for tocolysis. Heart failure and mortality are rare in pregnant women with moderate aortic stenosis (AS). The hemodynamic changes of pregnancy, including increased cardiac output (CO) and decreased systemic vascular resistance (SVR) make this population particularly sensitive to nifedipine. Our patient had compensated for these changes but could not further compensate when stressed by nifedipine due to her stenotic valve. Because obstructive coronary disease is unlikely in this young woman, her ECG changes and troponin elevation can be attributed to global ischemia due to increased myocardial oxygen demand/supply.

CONCLUSION: Nifedipine should be avoided in patients with AS, especially in pregnant women due to their baseline higher CO and lower SVR. There should be a low threshold to echocardiographically assess pregnant women with exam findings suggesting AS. They should receive alternatives for tocolysis if/when required.

NITROUS OXIDE TOXICITY: NO LAUGHING MATTER

Nikita Donti; Hiba Sayed; John H. O'Neill. Christiana Care Health Systems, Wilmington, DE. (Control ID #3178606)

LEARNING OBJECTIVE #1: Recognize the clinical features of B12 depletion

LEARNING OBJECTIVE #2: Recognize the relationship between nitrous oxide poisoning and severe B12 depletion

CASE: A 23-year-old female Chinese university student with a one-year history of inhaled nitrous oxide (N2O) abuse in the form of "whippets" was brought to ER for progressive bilateral lower extremity weakness, dysesthesia, inability to ambulate, altered mentation, and urinary retention. Alcohol intake was infrequent. On exam, she was found to have decreased sensation distal to the ankles, inability to lift her lower extremities off of the bed, inversion of both feet, and +0/5 dorsiflexion and plantar flexion. No Babinski sign, clonus, or fasciculations were noted. Deep tendon reflexes were absent. Initial labs revealed a macrocytic anemia and B12 level was mildly decreased at 228 pg/mL. She was started on IM cyanocobalamin. A neuropathy workup was negative for HIV, syphilis, lyme disease, and heavy metal poisoning. Glucose, TSH, SPEP, hepatitis antibodies and ANA were normal. Methylmalonic acid (MMA) was normal at 0.21 nmol/L, however homocysteine was markedly elevated at 97.3 mcmol/L. MRI of the spinal cord showed pathologic enhancement of the C1-C6 dorsal columns, concerning for subacute combined degeneration. The patient had gradual clinical improvement of her lower extremity strength and sensation. She was ultimately discharged to a rehabilitation facility.

IMPACT/DISCUSSION: Nitrous oxide poisoning converts B12 from its active monovalent form to an inactive bivalent form, resulting in permanent inactivation of methionine synthase and thus inhibiting the normal production of myelin. Dorsal and lateral column spinal cord demyelination, classically known as subacute combined degeneration (SCD), can result in a severe peripheral neuropathy. Since SCD can also be seen in HIV, copper deficiency, and severe hepatic disease, these causes should be ruled out. Clinical symptoms may include paresthesia, abnormal proprioception, progressive weakness, spasticity, clonus, paraplegia, and urinary and fecal incontinence. Of note, the B12 blood level is not indicative of the extent of B12 depletion at the tissue level. Interestingly, the MMA level, which is typically elevated in B12 deficiency, was normal in our patient. For these reasons, this was a clinically difficult diagnosis. Because the relationship between N2O toxicity and Vitamin B12 depletion can result in grave neurological complications, it is important to recognize these clinical features and begin treatment promptly.

CONCLUSION: Nitrous oxide toxicity leads to inactivation of Vitamin B12, causing subacute combined degeneration of the spinal cord and peripheral neuropathy. The blood level of B12 is not always indicative of the extent of B12 depletion at the tissue level. It is important to recognize the clinical findings associated with Vitamin B12 depletion so that treatment may be started promptly.

NIVOLUMAB INDUCED ADRENAL INSUFFICIENCY (AI): RARE SIDE-EFFECT OF A NEW ANTI-CANCER THERAPY - IMMUNE-CHECKPOINT INHIBITORS

Maitreyee Rai¹; Mylene Go². ¹Crozer Chester Medical Center, Brookhaven, PA; ²Crozer Chester Medical Center, Upland, PA. (Control ID #3181657)

LEARNING OBJECTIVE #1: Recognise & diagnose a serious side-effect of the new immune-checkpoint inhibitor (ICPI) drugs

LEARNING OBJECTIVE #2: Manage a serious side-effect of the ICPIs

CASE: 77 y old male, past medical history of renal cell carcinoma(RCC) status post right nephrectomy, metastatic to lungs, chronic kidney disease, syndrome of inappropriate anti-diuretic hormone, hypertension, presented to the office with fatigue, loss of appetite and dizziness. His blood pressure (BP) was noted 76/44mmHg & referred to the emergency department(ED). In ED, his BP was 96/50mmHg, heart rate 72/minute & temperature 97.3°F. He received several boluses of intravenous(IV)

fluid, however, BP consistently stayed in 90s/40s. His examinations was significant for orthostatic hypotension. Patient reported being on Nivolumab for metastatic RCC for last 6 months, and the current symptoms started after the last dose given 2weeks ago. The labs showed low sodium at128 (baseline 133-139mmol/L), creatinine elevated 2.7 (baseline 1.1-1.4mg/dL). In view of the hypotension not responding to fluids, a morning cortisol level was checked to look for possible adrenal insufficiency (AI) due to Nivolumab. It was low 1.3mcg/dL. Endocrinology was consulted. Cosyntropin stimulation test revealed low basal cortisol 1mcg/dL & only a mild increase to 10.20mcg/dL after cosyntropin administration, findings suggestive of AI. To differentiate between primary or secondary cause, adrenocorticotrophic hormone level (ACTH) was checked that was low <5pg/mL, favoring a diagnosis of secondary AI, deemed likely due to hypophysitis from Nivolumab. T4 & TSH were found to be normal. In the meantime, the patient was started on intravenous (IV) hydrocortisone, that improved his hypotension & acute kidney injury significantly, eventually weaned to oral hydrocortisone. The nivolumab was discontinued and oncology decided to give a nivolumab re-challenge once patient stabilizes.

IMPACT/DISCUSSION: Patient presented with manifestations of AI (fatigue, hypotension, hyponatremia) which is a rare Immune-related Adverse Event (iRAE) occurring in <1% of patients on ICPIs. These are non-specific manifestations and can be easily overlooked if iRAE is not suspected. AI is a life-threatening side-effect of ICPIs that needs to be recognized immediately and managed with IV glucocorticoids. With the increased use of these drugs in the management of advanced cancers, there is an increased number of patients presenting to offices & EDs with complications due to iRAEs. Therefore, as internists it's imperative to be able to diagnose and intervene at an early stage to prevent serious outcomes that may result in discontinuation of effective anti-cancer therapy.

CONCLUSION: ICPIs like Nivolumab, Pembrolizumab, Ipilimumab are increasingly being used for advanced cancers (melanoma, RCC, non-small cell lung cancer). Checkpoint inhibition comes with a wide array of side effects known as irAEs, affecting pulmonary, gastrointestinal, endocrine systems. Early recognition and management can prevent serious outcomes.

NIVOLUMAB INDUCED HYPOPHYSITIS: A RARE CASE REPORT

Smile Kajal²; Ankit Agrawal¹; Raj Moses³. ¹Rutgers Robert Wood Johnson Medical School/Saint Peter's University Hospital, New Brunswick, NJ; ²All India Institute of Medical Sciences, New Delhi, India; ³Allegheny General Hospital, Pittsburgh, PA. (Control ID #3159344)

LEARNING OBJECTIVE #1: Recognize subtle clinical clues of immunotherapy induced hypophysitis.

CASE: A 84-year old Caucasian female was diagnosed with well differentiated adenocarcinoma of the left upper lobe of lung in 2009. She underwent left upper lobe wedge resection and mesh brachytherapy in November 2009. She was started on systemic chemotherapy with pemetrexed and carboplatin. The treatment response was monitored with CT imaging of chest, abdomen and pelvis. Her CT imaging in January 2012 showed disease recurrence at the wedge resection site. She completed her systemic chemotherapy with pemetrexed and carboplatin in March 2012 and was started on oral erlotinib which was later discontinued in January 2016 due to severe gastrointestinal upset. Nivolumab immunotherapy was initiated in March 2016. The patient had completed 11 cycles of nivolumab by October 2016. At this time, she complained of intense fatigue and excessive sleepiness. Laboratory investigations revealed hypothyroidism and levothyroxine was started. She completed 14 cycles of nivolumab immunotherapy by November 2016 without any symptomatic improvement and now had additional complains of frequent headaches, lightheadedness and nausea. Adrenocorticotrophic hormone (ACTH) stimulation test was ordered and the result confirmed

central adrenal insufficiency. Glucocorticoid therapy was started and significant clinical improvement was noted on follow-up clinic visit.

IMPACT/DISCUSSION: Hypophysitis is an acute or chronic inflammation of pituitary gland. It is a rare condition and the incidence has not been quantified. Immunotherapy associated hypophysitis often presents with headache and anterior hypopituitarism. Anterior hypopituitarism shows a characteristic but atypical pattern of deficiency of ACTH followed by thyroid stimulating hormone (TSH), gonadotrophins and prolactin deficiency or hyperprolactinemia. In a study conducted at MD Anderson Cancer Center in Houston, immunotherapy induced hypophysitis was defined as 1 pituitary hormonal deficiencies (either ACTH or TSH) plus MRI abnormality OR 2 pituitary hormonal deficiencies plus headache or MRI abnormality. Our patient had developed hypothyroidism and central adrenal deficiency. MRI of brain was also obtained which did not show any significant finding but she did report headaches, excessive sleepiness and nausea. Therefore, she was diagnosed with nivolumab induced hypophysitis based on clinical grounds and abnormal hormonal profile. She was started on glucocorticoids to which she responded well symptomatically further supporting our diagnosis.

CONCLUSION: Immunotherapy induced hypophysitis is a rare entity. This is the first case of nivolumab induced hypophysitis in a patient with recurrent non squamous non small cell lung carcinoma. Due to rarity of this condition, a high degree of suspicion and a multimodal approach is required for its timely diagnosis.

NO ALL HEADACHES ARE MIGRAINES

Priyanka Majety; Seda Babroudi. Tufts Medical Center, Boston, MA. (Control ID #3183546)

LEARNING OBJECTIVE #1: The significance of evaluating red flags in cases of acute headache.

LEARNING OBJECTIVE #2: Importance of a high clinical index of suspicion for diagnosing cavernous sinus thrombosis.

CASE: A 20-year-old African American female with past history of migraine presented to us with a 9-day history of left-sided throbbing headache associated with nausea, similar in presentation to prior migraine exacerbations but had negligible relief with NSAIDs. She was afebrile with normal complete blood count and was treated with intravenous pain medications including NSAIDs and anti-emetics with only minimal relief. She was diagnosed with "Status migrainosus" that was relieved after multiple IV pain medications, Sumatriptan and Magnesium sulfate and eventually was discharged. Two days later, she re-presented with high-grade fever, blurry vision in her left eye and WBC was elevated to 32,000. She was started on antibiotics for bacterial meningitis & a CT head showed extensive left sided maxillary, sphenoidal and ethmoidal sinus disease. Lumbar puncture studies were consistent with bacterial meningitis. Cultures from blood and ethmoid sinus grew *Streptococcus constellatus* sensitive to Ceftriaxone. Upon careful examination, left-sided 6th cranial nerve palsy (limited abduction by Lateral rectus) was noted and she underwent MR Venography that confirmed the diagnosis of cavernous sinus thrombosis with left-sided ophthalmic vein thrombosis, likely in the setting of infection.

IMPACT/DISCUSSION: This is a case of septic cavernous sinus thrombosis (CST) that underscores the importance of a systematic approach and the evaluation of the red flags of headache with detailed neurologic exam in cases of acute headache. The prevalence of migraine in the community is high (15%) & occasionally life-threatening diseases like CST can masquerade as an acute migraine attack. Attention to the danger signs including systemic symptoms (fever, weight loss), abnormal neurologic signs, new onset of headache (especially for age >50), previous history of headache that has changed in severity and history of trauma is critical, necessitating neuroimaging. Given its location, 6th cranial nerve is the first nerve compressed with increased intracranial pressure. Clinical presentation of CST is highly variable with acute, subacute or chronic onset and

can resemble migraine. Infections are responsible only for 6-12% of cases but are associated with high mortality (30%) and morbidity (30%), warranting an early diagnosis. Neuroimaging is valuable in diagnosing CST. The mainstay of treatment is antibiotics, surgical drainage along with anticoagulation, although there is limited data on anticoagulation given the rarity of the condition.

CONCLUSION: Red flags need to be assessed in every case of headache. CST needs to be considered in patients with sinusitis and cranial nerve palsies. Early diagnosis and treatment are essential. Randomized controlled trials are needed to determine the optimal therapy for this condition.

NO KIDDING AROUND: A CASE OF CUTANEOUS PARAPOX VIRUS INFECTION

Michael George; Andrea Carter. University of Pittsburgh Medical Center, Pittsburgh, PA. (Control ID #3164946)

LEARNING OBJECTIVE #1: Avoid premature closure in patients with intravenous drug use (IVDU).

LEARNING OBJECTIVE #2: Recognize the typical presentation of cutaneous zoonotic infections.

CASE: A 23 year-old woman with a history of opioid use disorder presented with one day of right hand swelling and redness. She was otherwise asymptomatic and afebrile. The patient had been abstinent from IVDU for one year, and her urine drug screen was consistent with use of prescribed buprenorphine without any illicit substances. A point-of-care ultrasound was performed in the Emergency Department and due to concern for thrombophlebitis, broad spectrum antibiotics were initiated for presumed septic thrombophlebitis caused by relapsed IVDU. On arrival to the medicine floor, examination of right hand demonstrated two isolated vesicular lesions on the index finger with associated erythema and swelling of the hand. Formal venous dopplers of the right upper extremity were negative for thrombus. Further review of history found that patient had been to a county fair several times over the previous week and had been petting animals including sheep and goats. Dermatology performed a punch biopsy of the ulcer which showed intraepidermal vesicles and a mixed cellular infiltrate without evidence of bacteria or neutrophilic predominant infiltrate seen with typical bacterial cellulitis. Based on the patient's history of animal exposure, biopsy findings, and the typical appearance of the lesion, a presumptive diagnosis of parapox virus was given. Antibiotics were discontinued, and after one day of observation, the patient was discharged home.

IMPACT/DISCUSSION: Parapox (or Orf) virus is a pathogen belonging to the Poxviridae family. It is generally limited to cutaneous infection, although patients may experience fever or lymphangitis and immunocompromised hosts are at risk for disseminated or "giant" pox. The true prevalence of Orf is unknown and is likely limited by limited recognition and incomplete reporting. Transmission occurs from direct contact with a lesion on a vector—typically sheep or goats, and can be facilitated by any damage to the skin barrier. The hallmark of cutaneous infection is a vesicular lesion, often solitary or with 1-2 satellite lesions that progress over weeks to develop a necrotic center and finally dry out to create a papilloma. These lesions typically resolve without treatment within 6 weeks. Confirmatory testing may be performed by examination under electron microscopy or polymerase chain reaction but with limited availability and expense may not be feasible and is unlikely to alter clinical course.

CONCLUSION: This case highlights the distinguishing historical and physical exam features of the cutaneous zoonotic infection parapox virus. This case serves as a reminder of the importance of taking a thorough history and avoiding premature closure, especially in the context of the national opioid epidemic and associated biases clinicians may have when treating patients with opioid use disorder.

NONSTOP RUNNY NOSE: A CASE OF SPONTANEOUS CSF RHINORRHEA COMPLICATED BY MENINGITIS

Thien Le^{1, 2}; Carlos Aguirre^{1, 2}; Brian Pulford^{1, 2}; Ruta Viktoria Totoraitis^{1, 2}; Charles W. Graeber^{1, 2}. ¹NCH Healthcare Systems, Naples, FL; ²Mayo Clinic School of Medicine and Science, Rochester, MN. (Control ID #3185109)

LEARNING OBJECTIVE #1: Managing acute meningitis in the setting of spontaneous cerebrospinal fluid leak

CASE: A 53-year-old Hispanic mother of 5 children with no past medical history presented to our emergency department with headaches. Over the last 10 months she suffered labile headaches, cough and unilateral left sided rhinorrhea. Previously, these headaches were well controlled with acetaminophen and ibuprofen. However, 2 days prior to admission, she experienced subjective fevers, chills, nausea and vomiting. There was no history of foreign travel or head trauma. She went to see an Otolaryngology (ENT) doctor and was diagnosed with allergic rhinitis, treated with steroid nasal spray and recommended for allergy testing. Her headaches were exacerbated with standing and resolved completely when lying flat. She reported no phonophobia, photophobia or vision changes. She was febrile at 102.6F, otherwise vital signs were normal at admission. Laboratory results including a complete blood count, basic metabolic panel and urinalysis were within normal limits. Computerized Tomography (CT) of the head ordered in the emergency department showed intracranial hypertension and a lumbar puncture (LP) was deferred. Empiric antibiotics and antiviral coverage was initiated. Her MRI was negative for intracranial mass lesion and a LP was performed which was consistent with acute meningitis post initiation of antibiotic. A ENT consult was placed for nasal endoscopy which show no visible evidence of CSF leakage. Ultimately, due to the unrelenting nature of her headaches we elected to pursue further investigation of her unilateral nasal fluid leak. Our Neurologist recommended nasal rhinorrhea fluid collection and analysis for Beta2-transferrin which positively identified CSF. Additional imaging with high resolution CT including bone views identified a cribriform plate depression versus questionable fracture with soft tissue extension into the posterior fossa. A consultation with neurosurgery was made and she was transferred for higher level of care with continuation of Ceftriaxone for 2 weeks and neurosurgery to follow.

IMPACT/DISCUSSION: Spontaneous cerebrospinal fluid (CSF) rhinorrhea remains a relatively rare occurrence, incidence of 3-4% in all cases of CSF leaks (Beckhardt, 1991). Obese females in their 5-6th decades of life are more likely to experience spontaneous CSF nasal leaks (Sayed MSU, Dunn CJ, Alaani A, 2012). Due to the potential complication of meningitis, spontaneous or traumatic CSF leaks requires a keen eye for detection and prompt treatment.

CONCLUSION: Originally postulated by Roman physician Galen during the first century A.D, CSF leak carries substantial risk for meningitis and death (Decherd, 1999). Identification of compromise to the blood brain barrier should be consider when investigating cases of meningitis. Unilateral rhinorrhea with reported changes in volume leak in relation to positional changes should be further investigated with high resolution CT imaging and appropriate consultation services.

NOT 'JUST A PHLEBITIS': A CASE OF ENDOGENOUS METHICILLIN-RESISTANT STAPHYLOCOCCUS AUREUS ENDOPHTHALMITIS.

Steven Omansky¹; Patricia Dharapak². ¹Mount Sinai Beth Israel Hospital, New York, NY; ²Mount Sinai Beth Israel, New York, NY. (Control ID #3162820)

LEARNING OBJECTIVE #1: To identify the common presentations, risk factors, and treatments for bacterial endophthalmitis.

CASE: A 69 year-old female with uncontrolled diabetes mellitus and hypertension was referred from an affiliate eye clinic for further

management of suspected endophthalmitis. One week before presentation, she was discharged from an outside hospital where she was admitted for suspected transient ischemic attack. Her family reported that she was febrile prior to discharge, and her peripheral IV site was erythematous and mildly purulent. The IV was removed and she left without medical therapy. Five days later, she developed weakness with worsening visual acuity and pain in the left eye, and after two days of symptoms she visited the eye clinic. She now presents with a fever of 101°F, left periorbital edema, marked left eye injection, and chemosis but no remaining phlebitis. Labwork was notable for a WBC count of 15 u/L with neutrophilia. Empiric IV vancomycin and piperacillin-tazobactam were started, and blood cultures later grew methicillin-resistant *Staphylococcus aureus* (MRSA). Urine culture and chest x-ray were unremarkable, and transesophageal echocardiogram showed no vegetations. Two vitrectomies and several intravitreal antibiotic injections lessened her swelling and pain but did not improve her sight. Her vitreous cultures remained sterile. She completed a 14-day course of IV antibiotics and was discharged with close ophthalmology follow-up.

IMPACT/DISCUSSION: We describe a case of endogenous MRSA endophthalmitis, suspected to be secondary to metastatic seeding from a peripheral IV-associated phlebitis. Endophthalmitis, a bacterial or fungal infection within the eye, is a sight-threatening emergency. Most cases are exogenous as a consequence of trauma, eye surgery, or as an extension of keratitis. Endogenous bacterial cases in the US are uncommon but may result from bacterial seeding of the eye by an endocarditis, urinary tract infections, abdominal abscesses, indwelling catheters, injection drug use, or procedures associated with transient bacteremia. Endogenous endophthalmitis is diagnosed when there are consistent ocular findings in the setting of bacteremia or by positive vitreous or aqueous cultures in patients without direct transmission. Although patients may present with signs of sepsis, less than 20% present with fever, and many patients present only with eye pain and decreased vision. Treatment includes systemic and intravitreal antibiotics, usually accompanied by vitrectomy. Clinical outcomes, including sight retention, are affected by the timeliness of appropriate antibiotic therapy and the virulence of the pathogen.

CONCLUSION: Acute endogenous bacterial endophthalmitis is a sight-threatening emergency. Given that such patients may have intermittent bacteremia, serial blood cultures and a careful assessment of nosocomial risk are essential adjuncts to optimal ophthalmologic management of those presenting with ocular symptoms in the absence of recent eye trauma or surgery.

NOT FOR HUMAN CONSUMPTION!

Manojna Konda; Heather Ali; Kinza Ahmed; Susan Beland. University of Arkansas for Medical Sciences, Little Rock, AR. (Control ID #3186169)

LEARNING OBJECTIVE #1: Recognize the abuse potential and adverse effects of phenylbutazone, especially in patients with access to livestock

LEARNING OBJECTIVE #2: Recognize the importance of thorough medication reconciliation

CASE: A 41-year-old previously healthy female presented with 2 weeks duration of nausea, vomiting, generalized weakness. The patient lived on a farm and also reported a tick bite about 1 week prior to the development of her symptoms. Her physical examination was remarkable for dry mucous membranes and tenderness to palpation of RUQ of her abdomen. Laboratory tests revealed pancytopenia with white count of 2.20K/uL with ANC of 1K/uL, HgB 10.1g/dL, platelets of 48k/uL. Her BMP was significant for Na 128 mmol/L, Creatinine 1.7 mg/dL, CO₂: 15 mmol/L. LFTs were elevated with AST 617 IU/L, ALT: 211 IU/L, LD: 1039 IU/L, GGT: 54 IU/L, ALP: 81 and Total Bilirubin 0.5. Lactate, procalcitonin, hepatitis, HIV tests were negative. Coagulation panel was within normal limits. Peripheral smear was negative for schistocytes. Blood cultures were obtained and she was started on intravenous fluids and broad spectrum antibiotics including doxycycline to cover for tick borne diseases. She

was also started on NAC protocol for possible tylenol toxicity. Ultrasound abdomen showed mild splenomegaly and normal examination of the liver. Urine drug screen was negative. Blood cultures and tests for tick borne disease remained negative. The patient later confessed to taking her "horse's bute" i.e. phenylbutazone which was her horse's painkiller for back pain after she sprained her back and was most likely the cause of her presentation. Antibiotics were discontinued. Her blood counts, creatinine and LFTs improved with hydration.

IMPACT/DISCUSSION: Impact: This case illustrates the adverse effects of taking phenylbutazone, including pancytopenia, elevated liver enzymes and kidney injury. It also demonstrates that taking a good history and performing a thorough medication reconciliation can guide the diagnosis. Phenylbutazone, commonly known as "bute", is an NSAID which was originally introduced in the early 1950s as one of the "wonder drugs" to treat rheumatoid arthritis and gout. Eventually in the early 1980s, it was banned from human use due to its severe side effects. However, it continues to be used in veterinary medicine as a pain killer. The most serious adverse effects are related to bone-marrow resulting in pancytopenia and aplastic anemia. Other serious reactions include gastric ulceration with bleeding, hepatitis, renal failure, heart failure, respiratory and metabolic acidosis, coma and death. The mainstay of treatment is aggressive supportive care.

CONCLUSION: Commonly called as "Bute", while it is not currently available for human consumption, it is still available for use in livestock. It is important for clinicians to recognize the side effects and also realize the abuse potential in patients with access to livestock.

NOT JUST FOR KIDS: MECKEL'S DIVERTICULUM CAUSING ACUTE LOWER GASTROINTESTINAL BLEEDING IN AN ADULT

Iris Huang, University of California, San Francisco, San Francisco, CA.
(Control ID #3183679)

LEARNING OBJECTIVE #1: Recognize Meckel's diverticulum as a cause of acute lower gastrointestinal (GI) bleeding in adults

LEARNING OBJECTIVE #2: Recognize early predictors of severity in acute lower GI bleeding

CASE: 33 year-old Asian male with medical history of hemorrhoids presented to urgent care with 8 episodes of bloody diarrhea, diffuse abdominal pain and dizziness for one day. He denied fever, vomiting, rectal pain, medication, alcohol or drug use, travel or sick contacts. Physical exam showed an anxious appearance, diffuse abdominal tenderness and blood on rectal exam. He did not have fever, jaundice or hemorrhoids. Sitting blood pressure (BP) was 130/70 and heart rate (HR) was 100; standing BP 86/64 and HR 140. Initial hemoglobin was 13 g/dL. After referral to the emergency department (ED), he had more bloody diarrhea and hemoglobin decreased to 10 g/dL in 6 hours. In the next 12 hours, he was transferred to the Intensive Care Unit and started on massive transfusion protocol and pressors for hypovolemic shock. Upper endoscopy (EGD), colonoscopy and Interventional Radiology angiogram did not reveal a bleeding source. Retrograde double-balloon enteroscopy revealed a diverticulum at the terminal ileum with ulceration consistent with a Meckel's diverticulum (MD). After surgical resection of the MD, his GI bleeding finally stopped. He was discharged home 1 week later.

IMPACT/DISCUSSION: MD is typically associated with GI bleeding in children. About 25-50% of symptomatic MD cases present under 10 years of age (Park, 2005). Certain clinical features increase the probability of MD in adults: younger age, male sex, lack of risk factors for alternative causes of GI bleeding and no source identified on EGD and colonoscopy. The patient presented to urgent care with several important clinical features: tachycardia, orthostatic hypotension, gross blood on rectal exam and bleeding during the first 4 hours of evaluation. Strate (2003) identified these features along with non-tender abdomen, aspirin use and multiple co-morbidities as early predictors of severity in acute lower GI bleeding.

Multiple features correlated with more severe bleeding. The initial outpatient evaluation of acute GI bleeding assesses hemodynamic stability. His sitting blood pressure of 130/70 appeared misleadingly stable. Measurement of standing vital signs revealed severe orthostatic hypotension (BP 86/64 and HR 140). These high-risk features prompted urgent referral to the ED where severe hypovolemic shock developed within hours.

CONCLUSION: MD is an uncommon cause of acute GI bleeding in adults that should be considered in younger adults who lack risk factors for alternative causes and have normal EGD and colonoscopy. Early predictors of severity in acute lower GI bleeding include tachycardia, orthostatic hypotension, gross blood on rectal exam and bleeding during the first 4 hours of evaluation. Patients with acute GI bleeding may present with normal blood pressure while sitting. Orthostatic blood pressure should also be used to assess hemodynamic stability.

NOT JUST HYPERALGESIA: DIFFUSE PAIN DUE TO MULTIFOCAL OSTEONECROSIS IN A LUPUS PATIENT

Callie Plafkin; Tiffany Lin, University of Wisconsin Hospital and Clinics, Madison, WI. (Control ID #3138587)

LEARNING OBJECTIVE #1: Recognize osteonecrosis as a common cause of bone pain in lupus patients

LEARNING OBJECTIVE #2: Recognize systemic lupus erythematosus and corticosteroid use as risk factors for avascular necrosis

CASE: We present a case of a 22-year-old female patient with a history of systemic lupus erythematosus (SLE), complicated by lupus nephritis, antiphospholipid syndrome, Libman-Sacks endocarditis, multifocal cerebral infarcts, pericardial effusion, arthralgias, cytopenias (leukopenia, thrombocytopenia), hypocomplementemia, and positive serologic markers (double-stranded DNA, anti-Smith, and antinuclear antibodies), on chronic corticosteroids and immunosuppressants, who presented with diffuse bone pain. Her primary team was initially concerned for lupus flare versus hyperalgesia or diffuse pain syndrome. The pain was described as affecting 'all of her bones,' more prominent in the lower extremities, and different in character and location (more diffuse) compared to her prior lupus flares. She noted mild knee swelling, but no other swollen joints. Aside from one oral ulcer, she lacked other symptoms suggestive of lupus flare, including rashes, nasal ulcers, alopecia, or hematuria. Her exam was notable for diffuse tenderness, most prominent over the bilateral shins and calves. She had mild bilateral knee effusions without other evidence of synovitis. Labs showed stable blood counts, normal inflammatory markers, normal complement levels that were higher than her prior baseline, normal anti-double-stranded DNA antibody titer, and normal creatine kinase. A diagnosis of tacrolimus pain syndrome was considered, though deemed unlikely when tacrolimus level returned undetectable. Bilateral knee and ankle radiographs were unremarkable. MRI revealed multifocal osteonecrosis involving the left femoral condyles, left patella, left proximal tibial metaphysis, right distal femur and proximal tibia, and bilateral femoral heads, and avascular necrosis was determined to be the cause of the patient's widespread bone pain.

IMPACT/DISCUSSION: Avascular necrosis (AVN) is a common complication affecting SLE patients. Among the most important risk factors for AVN is corticosteroid (CS) use—both duration and total cumulative dose. Some studies suggest concomitant use of immunosuppressants may amplify this risk. Notably, SLE seems to be an independent risk factor for AVN, as AVN occurs more frequently in patients with lupus than in those receiving comparable CS doses for alternate diagnoses. MRI is the diagnostic test of choice. Multifocal AVN should be considered on the differential in lupus patients presenting with widespread bone pain without clear alternate etiology.

CONCLUSION: This case illustrates the importance of maintaining a broad differential for diffuse pain in a lupus patient, beyond merely lupus flare and hyperalgesia, and to further investigate alternate diagnoses when labs and symptomatology are not consistent with a lupus flare. Avascular necrosis should be considered as an etiology of bone pain in the SLE patient.

NOT THE TYPICAL CAUSE OF AORTIC ANEURYSMS. A RARE CASE OF GIANT CELL ARTERITIS PRESENTING WITH CHEST PAIN

Sally Salman; Karam Khaddour; Dipesh Ludhwani; Rosemina Patel. Rosalind Franklin University of Medicine and Science- Chicago Medical School, McHenry, IL. (Control ID #3185522)

LEARNING OBJECTIVE #1: Recognize giant cell arteritis (GCA) in patients with aortic aneurysms despite the absence of typical GCA symptoms.

LEARNING OBJECTIVE #2: Conduct more studies to assess the efficacy of screening for aortic involvement in patients with giant cell arteritis.

CASE: A 74-year-old male patient with a known history of hypertension and hypothyroidism presented with atypical chest pain for three days. The patient was a nonsmoker and family history was significant for hypertension and type 2 diabetes mellitus. On physical examination, vitals were significant for mild tachycardia, blood pressure 138/75, oxygen saturation 98% on ambient air and afebrile. Physical examination was normal. Serial troponins were negative and electrocardiogram showed no ischemic changes. Further evaluation with chest computed tomography (CT) showed large ascending aortic aneurysm measuring 5.7 cm. After medical optimization, the patient underwent surgical repair of the ascending aortic aneurysm. A specimen of the dilated aorta was sent to pathology which showed multinucleated giant cells and associated positive elastin break in the lamina which was consistent with giant cell arteritis. Oral glucocorticoids therapy was recommended. However, the patient declined medical treatment after understanding risks and benefits. During a two year follow up the patient did not have any indication of disease relapse.

IMPACT/DISCUSSION: Giant cell arteritis (GCA) is a granulomatous inflammatory disease affecting individuals older than 50 years. Clinically, it comprises overlapping presentations including cranial arteritis and extracranial GCA (large-vessel GCA). The presentation of GCA in large-vessel is seen in limb claudication, aortic aneurysm, and aortic dissection. Our patient presented with chest pain and did not present with the typical symptoms of GCA; temporal headache, jaw claudication or ophthalmic symptoms. The aorta may be affected in about a third of patients according to one prospective study assessing large vessel involvement. However, aortic aneurysms are very uncommon and appear in only 6% of patients with large vessel involvement. Retrospective studies have demonstrated a higher prevalence of aortic aneurysm among patients with GCA compared with the general population. Most clinicians recommend steroid treatment as long as the patient is showing disease activity or elevated inflammatory markers. In reviewing the literature, there were no clear guidelines to screen for aortic aneurysms in GCA patients, although studies have shown that aortic aneurysm those patients have increased risk of dissection.

CONCLUSION: Giant cell arteritis is a common cause of vasculitis, however, a rare cause of ascending aortic aneurysm. Giant cell arteritis should be in the differential diagnosis of patients presenting with aortic aneurysms even in the absence of typical GCA symptoms. The need for screening guidelines to look for aortic aneurysms and close follow up should be considered in patients with Giant Cell arteritis.

NOT YOUR TYPICAL HEART ATTACK

Erica Chung; Omar Saeed. Montefiore Medical Center, Bronx, NY. (Control ID #3171747)

LEARNING OBJECTIVE #1: Recognize the clinical features of post-partum spontaneous coronary artery dissection (SCAD)

LEARNING OBJECTIVE #2: Understand the importance of early recognition of SCAD to reduce mortality

CASE: A 39-year-old woman presented with 1 hour of sudden onset chest pain. She had no cardiovascular (CV) risk factors, no family history of

cardiac disease, and denied any drug use. Further history revealed that she had an uncomplicated vaginal delivery 1 month ago. On presentation, she was hemodynamically stable, but troponin T was elevated to 2.39 ng/mL and ECG revealed ST elevations in the inferior leads. She was taken for urgent coronary catheterization, which showed only mild luminal narrowing of the mid first obtuse marginal. However, given a high clinical suspicion for coronary artery dissection, further intracoronary imaging with optical coherence tomography (OCT) was done, revealing a large intramural hematoma with focal intimal disruption and significant obstruction of the true lumen. This confirmed the diagnosis of spontaneous coronary artery dissection (SCAD), leading to an inferior wall myocardial infarction (MI). She was managed medically with aspirin and metoprolol. Her chest pain soon resolved, troponins trended down, and ST segments normalized. She was discharged on medical therapy and remains stable with preserved cardiac function.

IMPACT/DISCUSSION: SCAD is a rare yet potentially fatal cause of chest pain that accounts for 0.2% of cases of acute coronary syndrome. In SCAD, an intimal tear creates an intramural hematoma, leading to compression of the true lumen and resultant MI. SCAD mainly occurs in young women with few, if any, of the traditional CV risk factors, and is associated with the post-partum period. The pathogenesis is not fully understood, but may be related to the progesterone-induced alterations in elastic fiber content that weaken the arterial walls, and the increased cardiac demand of pregnancy and stress of labor that further predispose to dissection. Recent studies have also identified specific genetic loci that may be associated with SCAD. In our case, lack of risk factors in this otherwise healthy woman strongly implicated her recent pregnancy as the main precipitating cause of SCAD. Given this clinical suspicion, OCT, with its high resolution and superior ability to visualize intracoronary pathology, was used to confirm the diagnosis. Failure to recognize and diagnose SCAD can lead to an MI, acute heart failure, cardiogenic shock, and death. In fact, the short-term mortality associated with SCAD is about 50%, and reaches 70% in patients who present with MI. Thus, SCAD presents a unique diagnostic challenge because although uncommon, it can be fatal if missed, and requires accurate history taking and clinical acumen to promptly diagnose and manage these high-risk patients.

CONCLUSION: Acute MIs rarely occur in young patients with no CV risk factors. This case illustrates the need to maintain a high index of suspicion for SCAD in post-partum women presenting with chest pain

NOT YOUR USUAL PALMS-AND-SOLES RASH

Carolina Gonzalez Lopez¹; Lindsay Hammons^{2, 1}. ¹Mount Sinai Beth Israel, New York, NY; ²Mount Sinai Beth Israel, NY, NY. (Control ID #3186029)

LEARNING OBJECTIVE #1: To consider disseminated cutaneous varicella zoster virus in an HIV patient with a rash on his palms and soles.

CASE: A 46 year-old male with a history of HIV presented with lower back/flank pain and rash. Three days before admission, the patient experienced 8/10 sharp pain in right lower back/flank; the pain was also associated with shooting pain to palpation, with subsequent numbness two days later. At this time, the patient also developed a non-pruritic, non-painful, diffuse maculopapular rash over his whole body and bruising over his arms. The patient had not been on HAART for over five months due to insurance issues, and had no known history of chickenpox or varicella zoster virus (VZV) vaccinations. On exam, the patient was afebrile. Other vital signs were as follows: BP 114/72 mmHg, HR 109 bpm, RR 20 bpm and SpO₂ 97% on room air. Physical exam was significant for a warm, edematous confluent rash with overlying pustules on his right back/flank following dermatomes T9 through T11 to mid-back; the area had decreased sensation. Additionally, the patient had a diffuse red maculopapular rash (lesions 1-4mm) over his entire body, including his palms, soles, head and scrotum, with crusting in different stages. Initial labs showed CD4 count 250 with viral load 60,100; CBC

included WBC 6.9k K/ μ L, Hb 14.7g/dL and platelets 13 K/ μ L. Pertinent positive results included VZV IgM 0.96, VZV IgG >4000, EBV IgG >600, CMV IgG >10, AST 57 and ALT 78. Pertinent negative results included cryoglobulin and Coxsackie A/B viral titers. The patient was diagnosed with disseminated cutaneous VZV. He was treated with acyclovir for 14 days, dexamethasone and restarted on HAART with substantial improvement of his rash after one week.

IMPACT/DISCUSSION: Varicella zoster virus causes two clinically distinct diseases: varicella and herpes zoster. Varicella is characterized by vesicular lesions on erythematous bases in different stages of healing; the rash spreads first to the trunk then to the extremities, usually sparing palms, soles and genitals. Herpes zoster results from reactivation of the virus leading to painful, usually unilateral vesicular lesions in a dermatomal distribution. HIV patients are at a greater risk of developing herpes zoster than the general population. Additionally, disseminated cutaneous herpes zoster (VZV) is more common in immunocompromised patients, especially in those with HIV and in transplant recipients. Disseminated cutaneous VZV is characterized by a maculopapular rash with >20 lesions outside the affected dermatome; this rash also usually spares the palms/soles. This is the first reported case in the literature of disseminated cutaneous VZV affecting the palms and soles of an HIV patient.

CONCLUSION: VZV infection is common in immunocompromised patients. Therefore, in addition to more common causes—like syphilis and coxsackievirus—it is important to consider VZV infection in an immunocompromised patient who presents with an atypical rash affecting his/her palms and soles.

NOW WATCH ME WHIPPETS: AN ATYPICAL CAUSE OF PERIPHERAL NEUROPATHY

Jason Ng; Angela Arbach. NYU Langone, New York, NY. (Control ID #3185506)

LEARNING OBJECTIVE #1: Recognize the clinical & laboratory presentation of chronic nitrous oxide abuse.

CASE: 51yo F with history of hypothyroidism and anxiety presented to the ED after being brought in from the street by police. Over the course of the past month, she reported mental slowing and relative weakness, numbness and tingling in her hands and feet, incoordination of fine motor movements and gait abnormalities. ROS was otherwise negative. She denied any visual or auditory hallucinations, SI or HI. Past medical, surgical and family history were unremarkable. She lives in Manhattan with her boyfriend, who was apprehended by authorities under similar circumstances. She takes daily synthroid and Valium and reported distant history of alcohol use 1 month ago. VS WNL. She was alert and oriented to self and location but believed the year was 1920 and exhibited word-finding difficulty. Physical exam revealed grossly normal cranial nerve functions without dysarthria, and normal strength, sensation, and bulk muscle tone. She had a negative Romberg exam but exhibited some impairment of proprioception sense in fingers and toes, particularly with downward movement. She was able to stand up and walk unassisted with a wide-based and unsteady gait. BMP, LFTs, coags, TSH, CPK were normal. CBC was remarkable for a leukopenia to 1.7 (ANC 250), Hgb 12.5 with an MCV of 87.8, platelets 166. Iron studies were suggestive of anemia of chronic disease, with LDH 240 and reticulocyte index was 0.9. Vitamin B12 returned low at 183 ng/L and homocysteine and methylmalonic acid levels were elevated at 191 umol/L and 0.9mmol/L respectively. Utox was positive for benzodiazepines. Many diagnoses were considered including MS, tertiary syphilis, and GBS, but the patient ultimately admitted to abusing up to 8-10 containers of whippets (small presurized containers containing N2O) daily for the past month. Toxicology and neurology were consulted and her physical exam and lab derangements were thought to be secondary to a functional B12

deficiency, for which she was initiated on IM repletion. An MRI brain and spine was ordered but she ultimately left AMA. She intended on cutting back on whippets use and expressed a desire to "clear her head" on her walk home.

IMPACT/DISCUSSION: Nitrous oxide abuse has recently gained popularity as a recreational party drug due to its availability. When inhaled, it causes euphoria, analgesia within seconds. Chronic use leads to toxicity through the oxidation of cobalt ions in vitamin B12, hence causing inactivation. This causes reduced recycling of homocysteine to methionine, thereby preventing methylation of myelin proteins. Patients present with fatigue, weakness, poor balance and paresthesias and MRI imaging may show posterior column hyperintensities on T2W imaging. High-dose intramuscular B12 replacement is recommended, but recovery may ultimately be slow and incomplete.

CONCLUSION: N2O is a rare cause of functional B12 deficiency, pernicious anemia and peripheral neuropathy.

NUTCRACKER PHENOMENON MISDIAGNOSED AS LEFT RENAL VEIN THROMBOSIS

Mohammad Zmaili; Motasem Alkhayyat; Mobin Malik; Deborah Hornacek. Cleveland Clinic Foundation, Cleveland, OH. (Control ID #3176026)

LEARNING OBJECTIVE #1: Recognize and diagnose nutcracker phenomenon

LEARNING OBJECTIVE #2: Recognize the difference between nutcracker phenomenon and nutcracker syndrome

CASE: A 61-year-old African American male with a history of hypertension, hyperlipidemia, and hepatitis C was incidentally found to have left renal vein thrombosis (RVT) on an abdominal ultrasound (US) during routine surveillance for hepatocellular cancer. The abdominal US appeared to demonstrate a left RVT on greyscale imaging and color power angiography with a recognizable Rouleaux flow. The patient remained asymptomatic. He was admitted and started on heparin infusion. Renal venous duplex US was repeated in a seated, instead of a supine, position with no evidence of RVT on color power angiography and power energy settings. However, there was a dynamic external compression of the vein. We concluded that the initial finding was not a true thrombus but rather a flow artifact due to the compression of the left renal vein as it passes between the aorta and the superior mesenteric artery (SMA), a phenomenon referred to as "Nutcracker phenomenon". Anticoagulation was stopped and the patient was discharged.

IMPACT/DISCUSSION: The patient described above had an incidental finding that was initially interpreted as left RVT. Given the rarity of spontaneous isolated RVT in the absence of nephrotic syndrome or renal malignancy, a repeat study was pursued. Interestingly, reimaging in the seated position alleviated the compression on the left renal vein and revealed no venous thrombosis. Rapid weight loss with reduction of retroperitoneal fat is thought to contribute to this phenomenon by decreasing the aortomesenteric angle (the angle between the aorta and SMA). When extrinsic left renal vein compression leads to the emergence of symptoms, the condition is referred to as nutcracker syndrome. Characteristic symptoms include flank or pelvic pain, hematuria, varicocele, and orthostatic proteinuria. Diagnosis is established based on clinical suspicion by imaging studies with demonstration of reduced aortomesenteric angle and increased left renal vein hilar-to-aortomesenteric diameter ratio. Management depends on severity and age of presentation. It ranges from conservative management for mild cases in younger patients, to intravascular or surgical interventions. This patient was asymptomatic with no significant laboratory abnormalities. He was educated on the symptoms of nutcracker syndrome for which he should seek medical attention.

CONCLUSION: Spontaneous isolated RVT is rare unless there is renal malignancy or nephrotic syndrome. The risk increases with inherited

thrombophilias, hypercoagulability, hypovolemia, and trauma. Nutcracker syndrome is an underdiagnosed condition and should be suspected when clinical presentation suggests left renal venous hypertension. The asymptomatic equivalent of the syndrome is referred to as nutcracker phenomenon which can be managed conservatively.

OBSCURE GI BLEED: GETTING THE "GIST" OF A TRICKY DIAGNOSIS

Lydia A. Flier, Beth Israel Deaconess Medical Center, Brookline, MA. (Control ID #3185824)

LEARNING OBJECTIVE #1: Recognize the difference between occult, overt and obscure gastrointestinal bleeding.

LEARNING OBJECTIVE #2: Compare and contrast options for deep small bowel imaging to diagnose a source of bleeding.

CASE: The patient is a 74 year old woman with coronary artery disease status-post drug eluting stent to her left anterior descending coronary artery in 1 month prior to initial presentation, atrial fibrillation on Apixaban, remote breast and ovarian cancer, and CKD, who presented with a hemoglobin of 6.2 and concern for GI bleed. She was initially admitted to an affiliated community hospital with a hemoglobin of 5.6 and eventual melena. Upper endoscopy and colonoscopy showed enteritis, superficial ulceration, mucosal petechiae, left-sided diverticular disease, and scant old blood in the colon. Her Apixaban was held and aspirin 81mg was added to Clopidogrel. The next month, outpatient capsule endoscopy showed antral erythema (suggesting gastritis or GAVE) and diminutive duodenal AVMs. She was admitted weeks later with a Hgb of 6.3; repeat colonoscopy showed old blood in the left colon, red blood in the right colon, and fresh blood in the terminal ileum without a source. Repeat capsule showed bright red blood 40 minutes into small bowel, but no source. Push enteroscopy did not show a source. She then underwent balloon enteroscopy, which showed an ulcerated mass in the proximal ileum. Biopsy of this mass revealed a gastrointestinal stromal tumor. Imaging was negative for metastatic disease. She underwent a subtotal colectomy and was discharged with outpatient oncology follow up.

IMPACT/DISCUSSION: Approximately 5% of gastrointestinal bleeding (GIB) qualifies as obscure, or lacking a clear source after upper endoscopy and colonoscopy. Obscure GI bleeds (OGIB) can be occult (chronic) or overt (acute), but usually the source is located between the papilla and the ileocecal valve; consequently, terminology is shifting to call this kind of GI bleed "suspected small bowel bleeding." The source of up to 50% of OGIB can be found on repeat endoscopy and colonoscopy, but if is not successful, further workup is necessary. This can include capsule endoscopy, push enteroscopy, balloon-assisted enteroscopy (single or double), spiral-assisted enteroscopy, and CT or MR enterography. These modalities have different pros and cons, and hospitals may rely on different modalities based on resources such as advanced radiology capacity, advanced endoscopy, or anesthesiology time. This patient had a GIST as the source of her GI bleed, the treatment of which includes complete surgical resection followed by a course of imatinib.

CONCLUSION: Obscure GI bleeding refers to GI bleeding without a clear source after repeat colonoscopy and endoscopy, and can be overt/acute or occult/chronic. A systematic approach to occult OGIB may be necessary to diagnose the cause, and includes capsule endoscopy, MR/CT enterography, and push, balloon and/or spiral enteroscopy.

OCCAM'S RAZOR OR HICKAM'S DICTUM: MAKING THE DIAGNOSIS IN COMPLEX CARE

Caroline Chen; Kristen Kelley; Arielle Sommer; Pourandokht S. Nourbakhsh, University of California - Los Angeles, Los Angeles, CA. (Control ID #3175641)

LEARNING OBJECTIVE #1: Recognize atypical features of sinusitis.

LEARNING OBJECTIVE #2: Identify physician, patient, and systems factors that contribute to missed diagnoses.

CASE: A 76 year-old female with Crohn's disease, tobacco-related COPD, obesity, hypertension, and diastolic dysfunction presents to her physician with sinus pain. Antibiotics temporarily improve her symptoms but they return with hearing loss, ear pain, and fatigue. She receives several courses of antibiotics for recurrent sinusitis. During this time, she also reports dyspnea. She is encouraged to comply with her inhalers and is given diuretics for diastolic dysfunction. Nine months later, she presents to the hospital with pre-syncope. Chest x-ray shows bilateral infiltrates and CT of the sinuses shows otomastoiditis for which she is given antibiotics. She is also given diuretics for heart failure exacerbation given intermittent hypoxia. Two weeks later, she presents with 1 day of dizziness and blurred vision. On exam she is lethargic with left anisocoria, right nasolabial fold weakness, and 4/5 strength in the left upper and lower extremities. Imaging reveals an infarct of the thalamus and midbrain. Chest x-ray shows a right lower lobe opacity. She receives antibiotics for pneumonia. Further work-up of her acute stroke is unrevealing. She develops fevers and leukocytosis followed by hypoxemia and renal failure. Active urinary sediment leads to rheumatologic evaluation with positive p-ANCA, c-ANCA, and myeloperoxidase antibodies. Kidney biopsy reveals necrotizing vasculitis with giant cells, consistent with granulomatosis with polyangiitis (GPA). The patient receives steroids, plasmapheresis, and rituximab but unfortunately passes away 17 months after her symptoms began. Physicians involved in her care wondered if her diagnosis could have been made sooner.

IMPACT/DISCUSSION: Annually, 1 in 7 US adults is diagnosed with acute sinusitis while the prevalence of GPA is only 3 per 100,000. Per IDSA Clinical Practice Guidelines, patients who fail first and second line therapies for bacterial sinusitis should be evaluated for non-infectious causes including GPA, a granulomatous small-to-medium vessel vasculitis. As 5 to 12% of patients with GPA die within the first year and 6 to 13% develop CNS disease, prompt diagnosis and treatment is essential. In isolation, our patient's problems could be explained: sinusitis in a susceptible host, hearing loss due to sinusitis, dyspnea due to undertreated COPD, hypoxia due to diastolic dysfunction, stroke in an at-risk individual, pneumonia in a patient with aspiration risk, and acute kidney injury due to hypotension from sepsis. Despite Hickam's dictum's tempting explanations, hindsight favors Occam's razor and may have led to earlier diagnosis and treatment for this patient.

CONCLUSION: In complex patients with fragmented care, summarizing the case to look for a unifying diagnosis by Occam's razor may reveal new insights. When patients fail empiric therapy for acute sinusitis, an alternate diagnosis should be considered.

OCCULT TENSION PNEUMOTHORAX; A LIFE SAVED.

Ali Azim; Harshit Dua; Allan Tachauer. Weiss Memorial Hospital, Chicago, IL. (Control ID #3185981)

LEARNING OBJECTIVE #1: Spontaneous tension pneumothorax is a rare entity and needs high clinical suspicion for prompt diagnosis.

LEARNING OBJECTIVE #2: Isolated physical or radiological findings are neither sensitive nor specific.

CASE: 56-year-old quadriplegic female was seen in emergency department(ED) for altered mental status(AMS) and abdominal pain. She had history of multiple sclerosis(17years), recurrent urinary tract infections(UTI), dysphagia status post G-tube. Vital signs showed hypotension(97/63mmHg), tachycardia(101/min), hypothermia(95.3F). Physical exam revealed bilateral equal breath sounds with minimal crackles at right lower lung zone, profound sweating and mild epigastric tenderness. Electrocardiogram(EKG) showed sinus tachycardia. Broad spectrum antibiotics and intravenous fluid(IVF) were started. Urinalysis was suggestive of UTI. Labs showed severe hyponatremia(106mEq/L) and no

leukocytosis. Femoral venous catheter was placed for pressor support. Chest X-ray(CXR) was done as a part of sepsis work-up which surprisingly revealed pneumothorax with no mediastinal shift. Given the small pneumothorax reported on CXR, the hypotension was linked to underlying sepsis. Mean arterial pressure did not improve despite multiple pressors and IVF. Follow-up exam of the chest revealed decreased breath sounds on the right side and increased respiratory distress. Immediate needle thoracostomy was performed followed by chest tube placement with gush of air released from the chest cavity. Patient was weaned off of pressors instantly. During her course, she was briefly intubated for worsening AMS. She was successfully treated with broad spectrum antibiotics for UTI and pneumonia and was discharged in stable condition.

IMPACT/DISCUSSION: Tension pneumothorax(TPT) is a clinical diagnosis. Spontaneous tension pneumothorax is not well recognized in spontaneously breathing patients. In these patients, it's always the valve mechanism that causes the air to accumulate in pleural cavity. The developing pressure with every breath causes kinking of the great vessels, decreasing cardiac output. All classical signs of TPT are not always present. Mediastinal shift cannot differentiate TPT from simple pneumothorax. Pneumothorax is considered under tension if it results in reversal of respiratory or hemodynamic compromise. Sepsis contributing to hypotension in our case delayed the appropriate management of TPT. Multiple studies of ventilated patients showed increased mortality in undiagnosed or delayed diagnosis of TPT.

CONCLUSION: To our knowledge, none of the previously reported cases of spontaneous tension pneumothorax presented with background sepsis. According to the literature, in a retrospective analysis of 176 ED presentations of pneumothorax, 30 patients deteriorated awaiting chest tube placement with no evidence of mediastinal shift on CXR. Therefore, in patients with developing respiratory distress accompanied with hypotension, tachycardia and pneumothorax, immediate needle thoracostomy and chest tube placement is warranted.

OCULAR SYPHILIS: A DIAGNOSTIC CHALLENGE IN AN IMMUNOCOMPETENT PATIENT

Pakhadi H. Buddhadev; Nisreen Mobayed. Medical College of Wisconsin, Milwaukee, WI. (Control ID #3185115)

LEARNING OBJECTIVE #1: - Recognizing, diagnosing, and managing ocular syphilis in immunocompetent patients

LEARNING OBJECTIVE #2: - Distinguishing isolated ocular syphilis from ocular syphilis with concomitant neurosyphilis

CASE: A 75-year-old woman with history significant for stroke presented with 7-months of recurrent uveitis of the right eye. The patient reported right eye photophobia, blurry vision, and throbbing pain refractory to several courses of steroid drops. Social history revealed that patient has not been sexually active for 12 years and has no history of STIs. Exam was only notable for right eye erythema and pain as well as chronic neurological findings secondary to prior stroke. Ophthalmology was consulted and performed optical coherence tomography that revealed cystoid macular edema (CME) in the right eye and normal foveal contour in the left eye. Fluorescein angiography of the right eye confirmed presence of CME without peripheral vasculitis. Slit lamp exam of the right eye demonstrated deep, trace flare with 1+ cells in the anterior chamber, anterior vitreous cells and haze, and 2+ injection with limbal flush. Visual acuity was 20/40 bilaterally. Further work-up to evaluate for sarcoidosis and infectious etiologies were performed. Work-up revealed a positive treponema pallidum antibody as well as a RPR quantification of 1:16. The remainder of the work-up was negative, including TB and HIV. Evaluation for neurosyphilis, including a MRI of the brain and a LP for VDRL CSF screen, was negative. Patient was admitted for treatment of uveitis syphilitic chorioretinitis, initiating a 14-day course of IV penicillin-G.

IMPACT/DISCUSSION: The CDC has reported increasing prevalence of ocular syphilis; however, few publications document rates of ocular syphilis in immunocompetent patients. Despite the paucity of research evidence, clinicians should consider ocular syphilis as a differential for recurrent uveitis, especially when refractory to standard therapy. This case demonstrates the importance of recognizing and appropriately managing syphilis in an immunocompetent patient. Given the risk of significant complications, including blindness, thorough evaluation and a high degree of clinical suspicion is necessary for the prompt diagnosis and treatment of ocular syphilis. Although the diagnostic criteria of ocular syphilis and neurosyphilis are different, there is a large amount of overlap in presentation. Up to 70% of patients with ocular syphilis also demonstrate evidence of neurosyphilis on LP. While ocular syphilis and neurosyphilis are treated with the same regimen, it is necessary to evaluate patients for neurosyphilis to mitigate any further neurological complications.

CONCLUSION: - Ocular syphilis may be the only clinical manifestation of syphilis - Clinicians should have a low threshold for performing serologic analysis in patients with uveitis refractory to corticosteroids - It is necessary to evaluate for neurosyphilis in patients with ocular syphilis

ODD, BLACK LESIONS - A FATAL CASE OF A GRAVE ILLNESS IN CHRONIC KIDNEY DISEASE

Varun Shah¹; Elizabeth Sullivan¹; Steven G. McKee². ¹University of Arkansas for Medical Sciences, Little Rock, AR; ²University of Arkansas, Little Rock, AR. (Control ID #3185168)

LEARNING OBJECTIVE #1: Contrast early versus delayed timing of skin biopsy in patients with end-stage renal disease (ESRD) and necrotic lesions

LEARNING OBJECTIVE #2: Contemplate the frequency of enteric ulcers in patients with this rare disease

CASE: A 58-year-old with ESRD secondary to diabetes mellitus, on peritoneal dialysis for one year, presented with fever and painful skin lesions. The initial ulcer appeared behind her left knee six months prior to presentation. Later, similar lesions appeared on both legs culminating in multiple, tender ulcers covered by hard, affixed eschar. The lesions progressed despite five months of standard wound care, antibiotics, and sodium thiosulfate. She did not receive surgical debridement. On admission, she noted fissuring of the eschars with purulent drainage, anorexia, and difficulty with ambulation. She was ill appearing, had wounds as described, and was hypotensive to 95/30mmHg. White blood cell count was 15K/uL, corrected calcium 9mg/dL, ionized calcium 1.1mmol/L, phosphorus 4.8mg/dL, and parathyroid hormone 78.5pg/mL. Peritoneal dialysate and blood cultures were negative. Skin biopsy of the wound confirmed calciphylaxis. Wound cultures grew multi-drug resistant *Pseudomonas aeruginosa* and *Achromobacter*. She was transitioned to hemodialysis and intravenous sodium thiosulfate. However, she developed severe sepsis and was put on vasopressors nine days after the biopsy resulted. Subsequently, she developed large volume melena from duodenal ulcers that proved recalcitrant to intra-luminal cauterization and image-guided arterial embolization. She died 20 days after diagnosis.

IMPACT/DISCUSSION: We argue for early biopsy in patients with ESRD and suspicious lesions. Gastrointestinal (GI) hemorrhage in patients with calciphylaxis is rarely reported and this may be an underappreciated manifestation. Calciphylaxis confers 50% mortality at one year mainly due to wound infections, and this patient's diagnosis was delayed by six months. Timely diagnosis requires high clinical suspicion and often skin biopsy. Yet prompt recognition is critical since recent evidence suggests early surgical management or hyperbaric oxygen therapy can improve cure rates and survival. Neither treatment was available to our patient due to delay in definitive diagnosis. Calciphylaxis is known to cause cutaneous ulcers but visceral ulcers may be under reported. Literature review uncovered only two other cases of gastrointestinal ulcer and hemorrhage in patients with calciphylaxis, and the sites of these ulcerations were rectal and esophageal, respectively.

CONCLUSION: Early biopsy and diagnosis of calciphylaxis can reduce time to and preserve the feasibility of curative interventions. Further research is warranted to investigate if anti-acid medications or endoscopic therapies can prevent GI hemorrhage in calciphylaxis patients.

ONE AGEP AT A TIME: A PATIENT WITH A NEW RASH

Brianna C. Harder; Nicholas F. Maston; Taylor Zuber; Evan Raff. University of North Carolina, Chapel Hill, NC. (Control ID #3159271)

LEARNING OBJECTIVE #1: Recognize the presentation of Acute Generalized Exanthematous Pustulosis (AGEP)

LEARNING OBJECTIVE #2: Identify common medications associated with AGEP.

CASE: A 58-year-old man presented with two weeks of right lower extremity redness and pain. He was diagnosed with cellulitis and received 1 g intramuscular ceftriaxone followed by a 10-day course of cephalexin. His symptoms did not improve. He received a 10-day course of trimethoprim-sulfamethoxazole and topical mupirocin. Five days later, he developed new pruritic skin lesions and was admitted for further evaluation. His temperature was 37 C, blood pressure was 147/71 mmHg, and pulse was 65 bpm. Skin demonstrated numerous small, non-follicular papules on an erythematous, edematous background involving the lower extremities, groin, trunk, arms, and face. Significant labs include peripheral white blood cell count of 16.6 x 10⁹/L with neutrophilic predominance, eosinophils 0.5 x 10⁹/L, serum creatinine 1.54 mg/dL and CRP 25.7 mg/L. Skin biopsy revealed prominent multi-loculated intraepidermal collections of neutrophils in variably-sized pustules, spongiosis, and lympho-eosinophilic infiltrate, overall consistent with acute generalized exanthematous pustulosis (AGEP). Trimethoprim-sulfamethoxazole was discontinued. He received clindamycin for his cellulitis and antihistamines, and triamcinolone ointment for his AGEP. At follow-up one week later, his rash had resolved.

IMPACT/DISCUSSION: AGEP has been associated with numerous common medications. Anti-infective agents including sulfonamides (such as sulfamethoxazole), aminopenicillins, quinolones, terbinafine, ketoconazole, fluconazole, and chloroquines have been implicated, as well as non-anti-infective medications, including diltiazem. AGEP is characterized by the acute development of erythema, edema, pruritus or burning, followed by the emergence of numerous non-follicular, sterile pustules, often originating on the face or intertriginous areas and subsequently becoming widespread. AGEP may develop two days to three weeks after drug exposure. Systemic symptoms, including elevated transaminases, renal insufficiency, and respiratory distress, can develop. Pustules may sometimes take on a papular appearance, especially when corticosteroid therapy is employed early in the disease course, and the diagnosis may only be readily apparent on skin biopsy as in this case. Discontinuation of the offending medication, supportive care, and topical corticosteroids are the mainstays of treatment. Spontaneous resolution usually occurs within 2 weeks of drug discontinuation, but topical corticosteroids may help accelerate resolution of the rash.

CONCLUSION: The general internist must maintain a high index of suspicion for the development of adverse drug reactions. Recognition of the presentation of AGEP and identification of commonly associated drug classes are critical for prompt discontinuation of the causative drug and resolution of symptoms.

OPHELIA SYNDROME

Samiullah Arshad. Montefiore Medical Center, Wakefield, Bronx, NY. (Control ID #3186399)

LEARNING OBJECTIVE #1: Recognize the paraneoplastic presentation of hodgkin's lymphoma

LEARNING OBJECTIVE #2: Treat limbic encephalitis due to Hodgkin's lymphoma with chemotherapy

CASE: 58 year-old male was admitted for new onset seizures. He had cervical lymphadenopathy (LAD) on exam. Hemoglobin was 8.6 g/dL and Erythrocyte sedimentation rate (ESR) was 120. Computed tomography (CT) chest revealed cervical, thoracic and hilar lymphadenopathy. Patient had another episode of witnessed seizure described as bilateral small amplitude fast frequency tremulous movements of extremities which terminated after patient received lorazepam followed by altered mental status that lasted several days. Further history obtained from the patient's wife revealed that the patient had been having low grade fevers, night sweats and had lost 40 pounds in the past 1 year. Magnetic resonance imaging (MRI) brain without contrast showed subtle asymmetric signal intensity and volume loss involving the left mesial temporal lobe. Electroencephalogram (EEG) revealed positive triphasic waves concerning for encephalopathy, without any epileptiform activity. Lumbar puncture was negative for infection and malignant infiltration. Characteristic Reed Sternberg cells were seen on the cervical lymph node biopsy. Patient was treated with intravenous immunoglobulins (IVIG) for 5 days followed by Adriamycin, bleomycin, vincristine and dacarbazine (ABVD) therapy with patient returning to baseline mental status within 1 week of therapy with no further seizures.

IMPACT/DISCUSSION: Paraneoplastic neurological syndromes (PNSs) are commonly associated with small cell lung cancer, germ cell tumors and breast cancer but rarely associated with Hodgkin's lymphoma. PNSs are caused by immune mechanisms triggered against antigens that are normally present in the nervous system and ectopically expressed by the tumor (onconeural antigens). Paraneoplastic limbic encephalitis (PLE) is a subtype of PNS, characterised by personality changes, irritability, depression, seizures, memory loss and dementia. Generalized or partial complex seizures occur in 50% of the patients. The most frequent MRI abnormalities in PLE are hyperintensity signals on T2-weighted or fluid attenuation inversion recovery (FLAIR) images involving one or both medial temporal lobes. Early recognition of PNS often leads to the discovery and treatment of the underlying tumor. Limbic encephalitis in patients with Hodgkin's lymphoma is associated with mGluR5 antibody. This is well defined in the literature as Ophelia Syndrome. It is named after the character Ophelia in Shakespeare's drama hamlet, and was first described by Dr. Ian Carr whose daughter, at the age of 15, developed progressive loss of memory, depression, hallucinations, and bizarre behaviour. These symptoms aptly describe the character Ophelia's deluded and obsessional behavior towards Hamlet.

CONCLUSION: Ophelia syndrome is a rare but treatable presentation of Hodgkin's lymphoma. Early chemotherapy improves outcomes.

OUT OF SIGHT, OUT OF MIND: DELAYED DIAGNOSIS OF A NECROTIZING SOFT TISSUE INFECTION

Dustin McCurry; Clark A. Veet; Deborah DiNardo. University of Pittsburgh School of Medicine, Pittsburgh, PA. (Control ID #3186337)

LEARNING OBJECTIVE #1: Evaluate the accuracy of the laboratory risk indicator for necrotizing fasciitis (LRINEC) score and review attempts to improve upon its diagnostic value.

LEARNING OBJECTIVE #2: Recognize how posterior probability error and the two forms of availability bias affect type 1 and type 2 diagnostic reasoning and review strategies to counter these cognitive biases.

CASE: A 54-year-old male with past medical history significant for type 2 diabetes and recurrent stage III squamous cell carcinoma of the rectum presented to oncology clinic for repeat infusion of nivolumab. He complained of subjective fevers, foul smelling anal drainage, and increased anorectal pain for the past 2 months, worsened over the past week. There were 2 emergency department (ED) visits for the same complaint over the past 2 months. At each visit, his symptoms were attributed to small abscesses caused by obstructing tumor, and he received antibiotics prior to discharge from the ED. In clinic, he was afebrile, HR 123 BP 103/71 RR 18 99% on room air. Exam showed a necrotic

appearing perirectal mass, with non-purulent discharge. Labs notable for WBC 40,900 Hgb 10.2 sodium 129 BUN 22 creatinine 0.8 and glucose 208. He was diagnosed with a perirectal abscess and triaged to an inpatient oncology service in the evening without further work up and recommendations for surgical oncology evaluation in the morning. Upon arrival, repeat vitals showed T 38.1°C HR 125 BP 90/52 97% on room air. Compared to his previous exam, he was also noted to have a systolic murmur, tense, leathery induration of the L buttock, and exquisite tenderness with movement of the left hip. There was no crepitus. Additional labs were performed: lactate 3.4 CRP 22.030 and ESR 96. Calculation of a LRINEC score raised suspicion for necrotizing soft tissue infection (NSTI), resulting in urgent imaging, NSTI diagnosis, and surgical intervention.

IMPACT/DISCUSSION: We hypothesize that the patient's history of ED visits led to a type 1 reasoning failure: posterior probability error. In posterior probability error, prior diagnoses unduly influence diagnostic reasoning. In NSTI, where early recognition is challenging but crucial, this case illustrates how adjunctive scoring systems, such as LRINEC or revised forms of LRINEC, can be used to counter biases in type 1 reasoning and prompt type 2 thinking. Additionally, given that NSTI is not a common diagnosis in the outpatient oncology setting, we argue that the non-availability formulation of the availability bias, the "out of sight, out of mind" bias, likely contributed to diagnostic delay. While more reflective and methodical thinking has been shown to mitigate the classic formulation of the availability bias, the non-availability bias can persist despite the use of type 2 reasoning, making this case a diagnostic challenge on multiple levels.

CONCLUSION: A high index of suspicion is required for early diagnosis of NSTI. Cognitive biases affect both type 1 and type 2 diagnostic reasoning.

OUT OF THE FRYING PAN AND INTO THE MRI MACHINE: LONG-TERM PERILS OF CANCER TREATMENT

Carlos A. Lopez¹; Joanne L. Candela¹; Nancy A. Kernan¹; Alexandra Heerdt¹; Emily S. Tonorezos². ¹Memorial Sloan Kettering Cancer Center, New York City, NY; ²Memorial Sloan-Kettering Cancer Center, New York City, NY. (Control ID #3186136)

LEARNING OBJECTIVE #1: Recognize that female cancer survivors who receive chest radiation therapy (RT) require early breast cancer screening with MRI in addition to mammography.

CASE: A 29 year-old female with a history of acute lymphocytic leukemia (ALL) treated with total body RT, chemotherapy, and a bone marrow transplant (completed treatment at age 21) presented for a routine follow up visit for management of treatment-related late effects. Because she was 8 years post-RT, she underwent her first breast cancer screening via both mammogram and breast MRI. She was generally well, but she reported breast discomfort during breast imaging and when getting an echocardiogram; she denied any other breast symptoms. She was on a combined estrogen-progesterone patch due to being menopausal after her treatment. Exam was notable for an inverted left nipple (unchanged over 6 years) and left breast tenderness without discrete masses but with a heterogenous quality on palpation. There was no axillary lymphadenopathy and there were no skin changes. History and physical were otherwise noncontributory. Though her mammogram was negative, her MRI revealed a 1.2 cm mass in the left breast and a 0.3 cm mass medial to the dominant mass suspected to be a satellite lesion. She underwent an ultrasound guided biopsy which revealed an infiltrating duct carcinoma that was ER+/PR+/HER2- on pathology. Her sentinel lymph node biopsy was positive for micro-metastatic disease. She opted to undergo bilateral mastectomy prior to starting systemic chemotherapy.

IMPACT/DISCUSSION: There were some potential diagnostic pitfalls that arose during our case that were fortunately avoided. First, a mammogram would have been insufficient to detect her lesion; by obtaining a breast MRI, we were able to identify an early malignant lesion that would have been otherwise missed. Secondly, we avoided prematurely ascribing

breast pain to a non-malignant etiology: though breast pain makes other diagnoses more likely, her risk factors and the presence of a mass on imaging necessitated an expedient tissue diagnosis. Patients who carry high-risk gene mutations and patients who received chest RT for treatment of childhood cancers are particularly vulnerable to developing breast cancer at an early age. Mammography alone tends to underperform in younger patients because of associated higher breast density, so adding an MRI is recommended in these populations. In patients who have received RT, screening is recommended to begin 8 years after RT or at age 25, depending on whichever occurs last. Though MRI-based screening can result in more false-positive lesions on initial screen, earlier diagnosis of breast cancer confers a more favorable treatment course.

CONCLUSION: The importance of appropriate and early breast cancer screening in women exposed to chest RT at a young age cannot be overstated. As general providers see more survivors in practice, it is key that they be aware that MRI is recommended in addition to mammography in this population.

OXACILLIN-INDUCED CUTANEOUS LEUKOCYTOCLASTIC VASCULITIS: A CASE REPORT

Meric Mericliker^{1, 2}; Aya Shnawa³; Dalya AlQaysi^{1, 2}; Andrew Moraco^{1, 2}. ¹St. Elizabeth's Medical Center, Brighton, MA; ²Tufts University School of Medicine, Boston, MA; ³Jordan University of Science and Technology, Ramtha, Jordan. (Control ID #3169457)

LEARNING OBJECTIVE #1: Drug-induced cutaneous lesions such as those seen with oxacillin-induced cutaneous leukocytoclastic vasculitis, can be mistaken for cutaneous manifestations of endocarditis and other causes of leukocytoclastic vasculitis such as HCV-related cryoglobulinemic vasculitis.

LEARNING OBJECTIVE #2: A high index of suspicion is imperative for diagnosing drug-related cutaneous manifestations because choosing an alternative therapy is required for complete resolution of vasculitis and completion of infective endocarditis treatment.

CASE: A 32-year-old female with a history of IV drug use presented with fever and malaise. Her blood cultures grew methicillin-susceptible *Staphylococcus aureus*, and transthoracic echocardiogram showed vegetations on the anterior and posterior leaflets of tricuspid valve. The largest measured 2.7 x 1.4 cm. The patient was started on IV oxacillin and planned for a six weeks course. On day twelve after the initiation of therapy, skin examination revealed bilateral palpable painless purpuric papules on volar aspect of the hands and dorsal aspect of the feet. Over the next 48 hours, lesions extended up to the anterior knee and inner aspect of thighs and became bullous. Lesions were not associated with abdominal pain, arthralgia, or paresthesia. Investigations revealed weakly positive ANA (1:40) and was negative for p-ANCA and c-ANCA, cryoglobulins, RF, anti-ds DNA antibody. Complement C3 was low and C4 was normal. HIV testing was negative. Anti-HCV antibody was positive with a HCV viral load of 4.16×10^5 IU/ml. Aspirate from the bullous lesions did not demonstrate any organisms on Gram staining, and culture did not grow any bacteria. Punch biopsies subsequently revealed perivascular neutrophil infiltration with fibrinoid necrosis of small vessels, consistent with leukocytoclastic vasculitis (LCV). Given the temporal relationship between oxacillin administration and development of skin findings, the diagnosis of oxacillin-associated LCV was suspected. Accordingly, vancomycin was started in lieu of oxacillin, resulting in gradual improvement of the lesions.

IMPACT/DISCUSSION: Cutaneous LCV is a rare condition which frequently presents with palpable purpuric nodules of the lower extremities. Medications have been implicated in 10 to 24% of the cases; sulfa drugs, NSAIDs, and beta-lactams have the most frequent association. Furthermore, cutaneous LCV can also be seen in the setting of infective endocarditis (IE) or HCV infection. In the present case, discontinuation of oxacillin improved the skin lesions suggesting that oxacillin was the likely

culprit. Thus, we herein present the second reported case of oxacillin induced cutaneous LCV in the literature.

CONCLUSION: Present case illustrates a rare case of oxacillin-induced cutaneous LCV, masquerading the skin manifestations associated with HCV and IE. A high index of suspicion is imperative for diagnosing drug-related cutaneous manifestations as discontinuation of the suspected agent is critical for resolution of the vasculitis and cutaneous lesions.

PAIN FROM BUTTOCK TO LEG, BUT IT'S NOT SCIATICA: THE UNMASKING OF EXTRA-NODAL DIFFUSE LARGE B CELL LYMPHOMA IN AN HIV-INFECTED PATIENT

Jordonna Brown; Swati Vishwanathan; Carol A. Luhrs. SUNY Downstate Medical Center, Brooklyn, NY. (Control ID #3165797)

LEARNING OBJECTIVE #1: To recognize unusual manifestations of AIDS-related diffuse large B cell lymphoma (DLBCL) in the post HAART era

LEARNING OBJECTIVE #2: To diagnose uncommon causes of common lower extremity pain presentations, avoiding anchoring bias

CASE: A 46 year old woman with HTN presented with a dull aching pain in her left hip and buttock for a few months that was initially diagnosed as sciatica. The pain worsened progressively over a 2 week period, radiated down her left thigh with associated paresthesia. Her diagnosis then changed to trochanteric bursitis but the pain became intractable while on appropriate treatment for same so she was admitted to hospital for pain control. Her vitals were normal at presentation. Physical examination revealed an obese woman (BMI 42), with exquisite left hip and gluteal region tenderness, decreased range of motion but no visible or palpable masses. Labs show Hb 9, HCT 29, WBC 5.09, PLT 260, BUN 24, Cr .92, CD4 17, viral load 129178. CT pelvis shows two discrete soft tissue lesions within the left buttock measuring 5.8 x 4.5 x 4.8 cm and 3.6 x 3.7 x 4.7 cm. Core biopsy reveals high grade neoplasm, favoring lymphoma, cMYC rearrangements on FISH along with CD20, CD10 and Bcl6 positivity and negative MUM on immunohistochemistry, consistent with DLBCL. The patient was discharged home for continued care in oncology and HIV clinics.

IMPACT/DISCUSSION: The advent of HAART has put a dent in the incidence of AIDS-related illnesses such as NHL including DLBCL. Prior to HAART, the risk of AIDS-related NHL maintained an inverse relationship with CD4 counts, the lower the CD4 count, the higher the risk. Post HAART, AIDS-related NHL is seen at higher CD4 counts but vulnerable populations such as African Americans, are disproportionately affected by HIV and are still being diagnosed for the first time with HIV/AIDS when they present with NHL and as such have markedly decreased CD4 counts akin to those seen prior to HAART. Many hospitals have adopted the "Opt-out" policy for HIV testing where patients are notified and HIV testing gets performed unless the patient declines. This policy has proven useful for diagnosing HIV in individuals who would have otherwise gone undiagnosed as is the case with our patient. DLBCL occurs in two-thirds of AIDS-related NHL cases and usually presents with lymphadenopathy with or without "B" symptoms though immunocompromised individuals tend to present with extra-nodal disease. However, the gluteus muscle is an unusual extra-nodal manifestation of DLBCL. Our patient posed a diagnostic dilemma in that she was morbidly obese which made it difficult to appreciate the gluteal mass on physical exam and her pain characteristics seemed more consistent with sciatica.

CONCLUSION: Despite significant progress in the fight against HIV/AIDS a subset of high risk individuals continue to present with an AIDS-related illness such as DLBCL at the time of diagnosis. Maintaining a broad differential even with common presentations is tantamount in preventing anchoring bias.

PAINFUL NECROTIC SKIN ULCERS IN AN END STAGE RENAL DISEASE PATIENT DIAGNOSED AS WARFARIN INDUCED SKIN NECROSIS (WISN) AND CALCIFIC UREMIC ARTERIOLOPATHY (CUA)

Evan R. Gordon-Wollin¹; Minho Yu^{1, 2}. ¹Loma Linda Medical Center, Rancho Cucamonga, CA; ²Riverside University Health System, Moreno Valley, CA. (Control ID #3181023)

LEARNING OBJECTIVE #1: Identify the features of CUA/calciphylaxis and WISN in order to treat early.

LEARNING OBJECTIVE #2: Recognize the risk factors for CUA and WISN in end stage renal disease (ESRD) patients.

CASE: 49-year-old female with a past medical history of ESRD on hemodialysis who was admitted for worsening necrotic skin wounds for one week. She denied fever or chills. Five months prior, she presented with leg ulcers after being on Warfarin for two months, and a punch biopsy confirmed WISN. Warfarin was discontinued, but eventually her wounds progressed and spread, prompting monthly admissions. She underwent one prior surgical debridement, which showed gangrenous necrosis on pathology. Home medications included aspirin, sevelamer, and simvastatin. Surgical history was significant for two failed renal transplants. Her family history was non-contributory. She had a prior 7.5 pack year smoking history, and she denied alcohol or drug use. Her vital signs were stable, and on exam she had multiple necrotic wounds scattered on her bilateral lower extremities and abdomen that had increased in size, number, and severity. Labs were significant for normal white count, calcium and phosphorus within normal limits, and iPTH elevated at 142.7 pg/mL. Prior hypercoagulable workup showed decreased antithrombin III activity at 78% (ref 88-138%). The patient had a second surgical debridement of her wounds, showing calcium deposits, consistent with CUA. She then underwent twenty hyperbaric oxygen sessions, local wound care, and sodium thiosulfate therapy (STS) 25gm TIW, with significant improvement after two months.

IMPACT/DISCUSSION: Ulcerating wounds among ESRD patients are common given their high prevalence of peripheral arterial disease. Although both conditions are rare, the differential diagnosis should include CUA and WISN when an ulcer is found in an atypical location (i.e. abdomen), does not resolve, the patient is on Warfarin therapy, or has risk factors such as protein C and S or antithrombin III deficiency. Warfarin has been found to increase the odds of CUA up to 10-fold, and ESRD decreases the levels of protein S. While WISN typically occurs within the first ten days of initiating Warfarin, as this case and other case reports have shown, it can present much later. Prompt Warfarin discontinuation and reversal greatly improves outcomes. Multiple biopsies and a high clinical suspicion are often necessary to diagnose CUA. Optimal treatment is largely unknown without large randomized controlled studies. However, as seen in our patient, some retrospective reviews have shown that the use of STS led to a 26% resolution and 47.2% improvement in CUA wounds (Nigwekar et al. CJASN, 2013). Similarly, An et al. (Nephrology, 2015) showed a 58% improvement in wounds with HBO therapy among 34 patients.

CONCLUSION: It is vital for a clinician to be aware of the risk factors and presentations of CUA and WISN in ESRD patients, because each diagnosis carries high morbidity and mortality. Early and appropriate treatment has been shown to improve outcomes.

PAINTING THE BIG M

Navid Berenji; Abdulrahman S. Museedi; Saket Kottewar. UT Health San Antonio, San Antonio, TX. (Control ID #3185876)

LEARNING OBJECTIVE #1: Recognize incidence of Multiple Myeloma in young patients with no genetic predisposition

LEARNING OBJECTIVE #2: Assess occupational risk factors in Multiple Myeloma

CASE: A 39-year-old Hispanic man presented with four weeks of dry cough. The cough was associated with minimal dyspnea on exertion, low grade intermittent fevers, back pain and pleuritic chest pain related to frequent coughing, and recent unintentional weight loss of 20 pounds over 2 months due to anorexia. Patient denied dyspnea at rest, night sweats, fatigue, recent travel or incarceration, or sick contact. Physical exam was unremarkable except for conjunctival pallor. Labs were significant for Hemoglobin 5.9 g/dl, Hematocrit 19.6%, MCV 96.6 fl, MCH 29.1 pg, MCHC 30.1 g/dl, reticulocyte 3.8%, and peripheral smear revealed rouleaux formation. Complete Blood Count with differential, Basic Metabolic panel including serum Calcium and Creatinine, and Urine studies including urine protein were unremarkable on admission. However, patient was found to have a higher total protein to albumin gap of 12.4 g/dl. Further investigations revealed kappa/lambda ratio of 17 and beta-2 microglobulin of 4.9 mg/L. Serum protein electrophoresis and immunofixation did not demonstrate a monoclonal spike. Skeletal survey revealed diffuse lytic lesions in the axial and appendicular skeleton. We proceeded with Bone marrow biopsy, which revealed 78% plasma cell population, and fluorescence in-situ hybridization revealed hyperdiploid clone. Patient was started on chemotherapy for Multiple myeloma.

IMPACT/DISCUSSION: Multiple Myeloma (MM) is a disease of older adults with mean age of 68 years old. MM occurs in all races, but the incidence is variable by ethnicity: higher in African Americans, while lower in Mexicans and Japanese. While some cases appear to be familial, there are studies showing an increased incidence of MM with occupational exposure. This is a case of a young patient with non-measurable free light chain only MM that is very rare in patients younger than 40 years of age. Our patient did not have risk factors for MM given his young age, Mexican heritage, and lack of family history. His painting occupation, however, is a concerning risk factor for occupational exposure leading to MM.

CONCLUSION: Few case reports have suggested a higher incidence of MM in patients with Chlorinated solvent exposure, which is commonly found in paint thinners. This relationship is however not well studied. This case serves to make physicians aware to recognize MM in young patients with appropriate clinical suspicion and laboratory findings, while assessing for occupational risk factors.

PARAGLOTTIC FUNGAL ABSCESS IN A PATIENT WITH UNCONTROLLED DIABETES

Ayah A. Megahed¹; Lenar Latypov¹; Jose Amaya Suarez². ¹Lincoln Medical and Mental Health care Centre, New York, NY; ²Lincoln Medical and Mental Health Centre, New York, NY. (Control ID #3165587)

LEARNING OBJECTIVE #1: To maintain a high clinical index of suspicion for diagnosing paraglottic abscess as a cause of upper airway obstruction, as prompt and urgent treatment is required to prevent potentially lethal outcome

CASE: The patient is a 26 years old female with PMH of DM II, GERD and hyperthyroidism with repeated admissions for DKA with history of multiple intubations. She was admitted due to progressively worsening dyspnea, productive cough, low grade fever, sore throat and hoarseness. Laryngoscopy showing unilateral vocal fold immobility. She was admitted to the medical floor for monitoring of her respiratory status. The patient reported pain in the right side of the neck radiating to the right ear. The pain was not controlled with NSAIDs and the patient was started on opioids. Subsequently, she developed stridor, for which she received prednisone. ENT were consulted. Laryngoscopy was done repeatedly evidencing progressive worsening of vocal cord paralysis, which warranted a CT scan of the neck. CT scan showed right glottic abscess compressing the laryngeal airway. Patient underwent tracheostomy- for worsening stridor- and drainage of the fluid, culture was positive for C. albicans. She was started on IV Fluconazole. Post-operative CT scan revealed multi-loculated mass that required a surgical re-intervention with

Penrose drains, it showed clear purulent discharge. The patient's condition improved, and she was discharged with the tracheostomy, to follow up with ENT as an outpatient.

IMPACT/DISCUSSION: Laryngeal abscess is usually seen in patients with immunosuppression, underlying malignancy, trauma due to airway instrumentation, and external beam radiotherapy. It usually presents as hoarseness, dysphagia, dysphonia, odynophagia, stridor and respiratory distress. The most common isolated organisms are Haemophilus Influenzae, Methicillin-resistant Staphylococcus aureus, Streptococcus Pneumoniae, Meningococci, Haemophilus parainfluenza, Klebsiella pneumoniae, Nocardia species and Candida albicans. Treatment decisions should be dictated by the severity of the obstruction of the patient's airway and the size of the abscess. Laryngeal abscess treatments include airway management, surgical drainage of the abscess and IV antibiotics. Airway obstruction can require the immediate establishment of an airway-either by intubation or acute surgical intervention (e.g. a tracheostomy or cricothyroidotomy). Surgical drainage of the abscess is recommended if indicated.

CONCLUSION: Despite being a rare condition, laryngeal abscess should be considered as a differential diagnosis in the presentation of upper airway obstruction in patients with history of poorly controlled diabetes or other medical condition associated with immunosuppression, and history of airway instrumentation.

PARATHYROID CRISIS IN A PATIENT WITH A PARATHYROID ADENOMA

Nicholas Ojile¹; Georges Elhomsy². ¹University of Kansas Wichita, Wichita, KS; ²Kansas University-Wichita, Wichita, KS. (Control ID #3184259)

LEARNING OBJECTIVE #1: Manage Parathyroid Crisis

LEARNING OBJECTIVE #2: Recognize the underlying causes for significantly elevated parathyroid hormone levels

CASE: A 72 year old female was admitted for hypercalcemia. Family members reported that over the past several days the patient had become more confused, lethargic, and weak; she fell the day of her admission. Initial laboratory evaluation showed serum calcium of 14.7 mg/dl (normal 8.5-10.1 mg/dl) and phosphorus of 2.5 mg/dl (normal 2.5-4.9 mg/dl). A serum intact PTH was 1351 pg/ml (normal 14-85 pg/ml). Her renal function was normal. The patient was volume resuscitated with crystalloid fluids and subsequently treated with intravenous furosemide. She was also given 4mg of zoledronic acid. A Sestamibi scan was suggestive of a parathyroid adenoma, and her serum calcium normalized prior to parathyroidectomy. A right inferior parathyroid gland mass was resected and was consistent with a parathyroid adenoma on pathology. The first fragment measured 4x 2x 1.3 cm and had a mass of 3.175 g; the second fragment measured 3x1.4 x.9 cm with a mass of 1.286 g. Postoperatively, the patient developed hypocalcemia and required calcium supplementation.

IMPACT/DISCUSSION: Parathyroid crisis is a rare complication of primary hyperparathyroidism, occurring in 1.6% to 6% of primary hyperparathyroidism cases. Patients usually present with markedly elevated PTH levels and a calcium level greater than 14 mg/dl with symptoms of hypercalcemia. The laboratory evaluation of parathyroid crisis from an adenoma can be confused with parathyroid malignancy as both can present with markedly elevated PTH levels and should be included in the differential diagnosis. Despite the significantly elevated laboratory values associated with parathyroid carcinoma, parathyroid adenomas are the usual pathology found. These patients are at high risk for multi-organ decompensation due to the severe hypercalcemia including oliguria, coma, cardiac arrhythmias, or even cardiac arrest if the serum calcium level is not decreased prior to surgery with fluid resuscitation and loop diuretics. The use of bisphosphonates prior to parathyroidectomy as in this case is controversial, as parathyroidectomy is the definitive treatment for parathyroid crisis and bisphosphonates could potentially worsen

postoperative hypocalcemia. The use of bisphosphonates in parathyroid crisis in the literature is limited to case studies and small case series, which do not suggest, however, an increased risk of postoperative hypocalcemia.

CONCLUSION: Parathyroidectomy is the definitive treatment for parathyroid crisis, with fluids and diuretics used as a stabilizing measure. Despite significantly elevated parathyroid hormone levels being associated with parathyroid carcinoma, parathyroid adenomas are more common.

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA MASQUERADE AS AN ULCERATIVE COLITIS FLARE

Jared D. Romeo; Joseph M. Rocco. University of Pittsburgh, Pittsburgh, PA. (Control ID #3185548)

LEARNING OBJECTIVE #1: Recognize the limits of ulcerative colitis (UC) assessment

LEARNING OBJECTIVE #2: Highlight an illness script for paroxysmal nocturnal hemoglobinuria (PNH)

CASE: A 29-year-old woman with UC on infliximab presented with 1 week of hematochezia and abdominal pain. One month prior, she had right upper quadrant pain with transaminase elevations. CT scan of the abdomen was notable for a heterogenous liver, but she improved with supportive care. Two weeks later, diplopia prompted MRI of the brain which revealed right sigmoid and transverse sinus thrombosis. Warfarin was started but a hypercoagulable workup was negative. One week later, abdominal pain and hematochezia started. The pain was similar but more diffuse than in prior flares. Labs showed Hgb 10.9 g/dL, platelet 163,000, and bilirubin 1.7 mg/dL. Stool culture, clostridium difficile, and parasite assays were negative. Parenteral steroids for presumed UC flare were initiated. The next day the patient's Hgb and platelets continued to decrease. Bilirubin was now 2.7mg/dL, haptoglobin <30mg/dL, and LDH 940 suggested hemolysis. A colonoscopy revealed new thrombi within the colonic lamina suggestive of ischemic colitis. Her prior abdominal CT was re-evaluated, and hepatic vein thrombosis was evident. Flow cytometry was performed and revealed decreased expression of CD59 consistent with PNH. The patient was started on eculizumab and at the time of discharge had resolved abdominal pain and stable hemoglobin.

IMPACT/DISCUSSION: Diagnosis of UC is challenging as no set diagnostic criteria exist. Endoscopically, UC presents as continuous erythema, edema, ulceration, and/or bleeding, but up to 15% of UC cases are indistinguishable from other causes of colitis. Histopathology showing crypt distortion and hypercellularity are consistent with but not specific for UC. Diagnosis is further complicated by lack of correlation between endoscopic and pathologic findings. Thus, clinical correlation is paramount to diagnosing UC and flares. In our patient, slight differences in her symptomatology and unexplained hemolysis suggested an alternative diagnosis for her pain. PNH is characterized by non-immune hemolysis, pancytopenia, and venous thrombosis. The pathophysiology of PNH is an acquired deficiency of glycolipid GPI which anchors CD59 to the surface of RBCs. CD59 typically prevents complement mediated destruction of RBCs. The presentation of Budd-Chiari with dural sinus thrombosis is often seen in PNH, as in our patient, which prompted flow cytometric analysis. Currently, there is no clear mechanism to explain thrombosis in PNH. First line treatment is with eculizumab, but bone marrow transplant is curative. This case highlights the pitfalls of diagnosing abdominal pain in the setting of UC. Physicians should keep in mind that neither endoscopy nor pathology are specific for UC, and alternative diagnoses must always be considered.

CONCLUSION: There is no gold standard for diagnosing UC. PNH should be considered in patients that have atypical venous thrombosis.

PATIENT-DIRECTED CRYOTHERAPY AS A CAUSE OF PERIPHERAL NEUROPATHY

Victoria G. Gillett¹; David Feldstein²; Linda Baier Manwell³; Brian Lewis⁴; Katie Miller¹. ¹University of Wisconsin, Madison, WI; ²University of

Wisconsin School of Medicine and Public Health, Madison, WI; ³University of Wisconsin-Madison, Madison, WI; ⁴University of Wisconsin, Middleton, WI. (Control ID #3185702)

LEARNING OBJECTIVE #1: Recognize patient-directed cryotherapy as a cause of peripheral nerve damage

LEARNING OBJECTIVE #2: Explain the importance of giving clear instructions for non-pharmaceutical interventions

CASE: A 53-year-old female consulted urgent care for progressive lower extremity pain of 7 weeks duration. The pain localized to her right medial ankle with associated numbness in her medial arch. She ran 15 miles weekly and did daily bicycling and aerobics. She had tenderness to palpation over the medial talus, no ligamentous laxity, an intact Achilles tendon, intact plantarflexion, and no redness, erythema, or warmth. She was diagnosed with overuse injury and told to decrease her high-impact exercises and "ice as she sees fit". Her pain persisted. She consulted a primary care provider who diagnosed her with tarsal tunnel syndrome and recommended further activity reduction. She then self-referred to podiatry where she received custom orthotics. Her pain continued to progress. Over the next 4 months, she was seen by orthopedic surgery, sports medicine, and primary care without a clear diagnosis or pain alleviation. An MRI of her ankles and feet found no acute nerve or soft tissue injury and her labs were normal including ANA, RF, SPEP, fasting glucose, TSH, CK, B12, BMP, and CBC. Due to worsening pain, an EMG was performed. It revealed multiple absent sensory evoked potentials and motor unit loss in intrinsic foot muscles innervated by the tibial and peroneal nerves. At her next visit, 6 months after initial presentation, she reported icing her lower extremities continuously for two or more hours daily since symptoms began. She was told to stop cryotherapy and monitor symptoms. With the cessation of icing, her pain resolved over 12 months and she returned to her normal activities.

IMPACT/DISCUSSION: Cryotherapy after an acute sports injury is standard practice. It is recommended by professional organizations including the National Athletic Trainer's Association and the American Academy of Orthopedic Surgeons, but there is no high-quality evidence for duration or frequency of cryotherapy. The risk of neuropathy from cryotherapy is rare and experimental studies report that risk increases with treatments longer than 20 minutes. Injuries classically affect single nerves. The most commonly affected nerve is the peroneal, resulting in activity-limiting foot drop. Cryotherapy causing a chronic neuropathy or a peripheral polyneuropathy is less frequently documented. Based on this case, it is now my standard practice to provide written, detailed instructions for safe home cryotherapy to any patient with soft tissue injury.

CONCLUSION: 1. Include patient-directed cryotherapy in your differential diagnosis of peripheral neuropathy especially for physically active patients with normal labs and imaging 2. Make it standard practice to query ways in which patients manage symptoms at home 3. Instruct patients how to safely use all prescribed therapies including nonpharmacologic techniques

PECTORAL PAIN, A PALPABLE MASS, AND A POOR PROGNOSIS: CHONDROSARCOMA AS AN ATYPICAL CAUSE OF CHEST PAIN

Lydia A. Flier; Sydni M. Cole. Beth Israel Deaconess Medical Center, Brookline, MA. (Control ID #3185781)

LEARNING OBJECTIVE #1: Recognize features of high-risk chest wall masses in the primary care setting.

LEARNING OBJECTIVE #2: Diagnose chest wall tumors with the appropriate imaging modality.

CASE: A 72 year old male Jehovah's witness with anxiety, an unspecified learning disability, and remote prostate cancer, presents to his PCP with four weeks of sharp mid-chest pain, increasing in intensity and "incapacitating." Initial evaluation, including ECG, is reassuring, and there was no

change in management. He re-presents two months later with episodes of chest pain lasting several minutes, having noticed a new 2 cm, nontender, left-sided mass adjacent to the sternum. Chest x-ray and ultrasound at this time are unrevealing. A subsequent CT chest reveals a 9 cm sternal lesion, and biopsy shows a grade 2 chondrosarcoma of the sternum, which is resected by thoracic surgery. One month post-operatively, he re-presents with a new 2 cm chest wall mass thought to be a postoperative hematoma, which is imaged and drained. Two weeks later, he re-presents with enlarging left chest wall mass and persistent drainage and is admitted to the thoracic surgery service. MRI shows a 21 cm mass with lung nodules concerning for metastases, with ongoing chondrosarcoma on pathology. He is transferred to oncology, where he is initiated on ifosfamide chemotherapy. His course is complicated by ongoing bleeding from the surgical site and tumor, as well as agitation and clumsiness thought to be toxicity from ifosfamide. His clinical status does not improve, and he ultimately transitions to palliative-focused care. He passes away 5 months after his initial presentation for chest wall pain.

IMPACT/DISCUSSION: The differential for non-cardiac chest pain is broad, including both musculoskeletal and visceral etiologies. Musculoskeletal chest pain is thought of as either isolated musculoskeletal (e.g. costochondritis), rheumatologic (e.g. spondyloarthritis), or systemic (e.g. neoplastic). Most non-cardiac chest pain is not neoplastic in origin, thus chest wall tumors are rarely considered in this differential. However, chest wall pain is the most common symptom of both benign and malignant chest wall tumors — a diagnosis likely to be missed if a careful examination is not performed. Generally, chest wall imaging should not be pursued for chest pain without a palpable mass. If a mass is palpated on exam, imaging should be done, with CT chest the imaging modality of choice. 50-80% of chest wall tumors are malignant; older age and male gender are predictors of malignancy. Chondrosarcomas are the most common malignant chest wall tumors, are not chemosensitive, and require excision with 4 cm margins. 5-year survival post-resection of chondrosarcomas is 92%, but survival is much lower after local recurrence.

CONCLUSION: Painful palpable chest wall masses, particularly in older men, are highly suspicious for malignancy. CT imaging is the modality of choice to evaluate for chest wall tumors. Survival post-resection of chondrosarcoma is greatly reduced after local recurrence.

PENETRATING CHEST INJURY LEADING TO METHICILLIN-RESISTANT STAPHYLOCOCCUS AUREUS (MRSA) BACTEREMIA AND MYCOTIC ABDOMINAL AORTIC ANEURYSM IN IMMUNOCOMPROMISED PATIENT

Sunjay Modi; Dilshan Dhillon; Paul Nona; Daniel S. Moore. Henry Ford Hospital, Detroit, MI. (Control ID #3170815)

LEARNING OBJECTIVE #1: Recognize that mycotic aneurysm is a term used to describe any localized dilation of an artery due to destruction of the vessel wall by infection. This aneurysm can result from the infection or a preexisting aneurysm that becomes infected.

LEARNING OBJECTIVE #2: Recognize that trauma, endocarditis and impaired immunity are common risk factors for infected aneurysms.

CASE: A 52-year-old male with a PMHx of chronic lower back pain s/p laminectomy, presented with a 4 day history of right-sided flank pain, subjective fevers and chills. Additional symptoms included dysuria along with episodic suprapubic pain. Vitals were significant for episodic fever. Physical examination was significant for superficial skin abscesses. He did admit to a recent history of incarceration and reported that he was stabbed in the right upper chest which resulted in a pneumothorax. There was a high index of suspicion for pyelonephritis. UA showed findings consistent with UTI. Initial urine cultures and blood cultures came back positive for MRSA. Due to evidence of persistent bacteremia, IV daptomycin and ceftazidime was initiated. CT chest showed findings consistent with septic emboli in the lungs. Echocardiogram was obtained and

subsequent transesophageal echocardiogram which were negative for vegetations. MRI was negative for spinal abscess. HIV-1 quantitative and total CD4+ T cell count were obtained and revealed values 102,587 and 11, respectively. At this time, the patient began complaining of acute abdominal pain and painful pulsatile abdominal mass was appreciated on physical exam. CT abdomen revealed a 3.1x2.8x3.5 cm saccular mycotic aneurysm projecting off the right side of the abdominal aorta. The patient was treated with 6 weeks of daptomycin and placed on dapsone and azithromycin prophylaxis following completion of daptomycin. The patient underwent surgical repair of the aneurysm with a rifampin-soaked Dacron graft and right nephrectomy for an infarcted right kidney.

IMPACT/DISCUSSION: This case highlights that penetrating chest injury in a immunocompromised host led to a MRSA bacteremia causing a mycotic aneurysm. The most commonly involved organisms in mycotic aneurysms include *S. aureus*, *Streptococci* and *Salmonella*. In our case, the patient's risk factors for an infected aneurysm were the stab wound which was a likely inoculation site for MRSA and impaired immunity (HIV+). Clinical findings are a painful, pulsatile mass in the abdomen. CT angiography is the diagnostic test of choice. Empiric antibiotics should include MRSA and gram negative coverage, while definitive treatment is surgical excision of the aneurysm and extensive debridement of infected tissues.

CONCLUSION: - Trauma such as penetrating chest wall injury, endocarditis, and immunocompromised hosts are common risk factors for infected aneurysms - Clinical presentation can include a painful, pulsatile mass - The diagnosis of an infected aneurysm is based upon imaging of the aneurysm and infection is confirmed with blood cultures and/or cultures from aneurysm wall.

PERICARDIAL EFFUSION AS AN INITIAL PRESENTATION OF MYXEDEMA COMA

Dana Awad; Omar Kousa; Abdallah Qasim; Mohsin Mirza; Emily P. Walker. Creighton University, Omaha, NE. (Control ID #3186260)

LEARNING OBJECTIVE #1: Recognize and treat the early manifestation of Myxedema coma that can affect multiple organ systems and cause cardiovascular collapse.

LEARNING OBJECTIVE #2: Recognize the common cardiovascular changes in Myxedema coma that include cardiomegaly, bradycardia, decreased ventricular contractility, low voltage ECG and rarely, pericardial effusion that can progress to Tamponade.

CASE: A 63-year old white female presented to the ED with worsening dyspnea and cough over the previous two weeks. She has a history of hypothyroidism status post thyroid radio-ablation for Grave's disease greater than 20 years prior. She was poorly compliant with thyroid replacement therapy. On physical examination, she was lethargic and in respiratory distress with low O₂ saturation. Examination of the head revealed facial plethora and enlarged tongue. She had diminished heart sounds and decreased air entry bilaterally on chest auscultation. A chest x-ray showed enlarged cardiac silhouette and ECG demonstrated low voltage QRS complexes. Echocardiogram was significant for ejection fraction of 50-55% with circumferential pericardial effusion. She was promptly admitted for stabilization and further work up. On the night following admission, she became more lethargic and unresponsive to stimulus. Temperature was 35 C, she developed bradycardia, hypoxia and hypercarbia. Repeat chest x-ray was consistent with acute respiratory distress syndrome (ARDS). She was intubated and remained sedated on a ventilator with vasopressor support and broad-spectrum antibiotic coverage. Initial thyroid function tests resulted with severe hypothyroidism and the diagnosis of myxedema coma was made. She was started on IV levothyroxine daily. Morning serum cortisol on that same day ruled out adrenal insufficiency. On the second day, her heart rate and temperature gradually started to improve. Four days later she became hemodynamically stable and vasopressors were stopped. Thyroxine replacement was continued throughout her hospital stay. She gradually regained

consciousness, and was successfully extubated on day 10 of hospitalization. She was then switched to oral thyroxine, and discharged to acute rehabilitation a few days later with a plan to follow up shortly with endocrinology.
